WARNINGS: CAUTION SHOULD BE EXERCISED WHEN ANTICOAGULANTS ARE GIVEN IN CONJUNCTION WITH ATROMID- (CLOFIBRATE). THE DOSAGE OF THE ANTICOAGULANT SHOULD BE REDUCED USUALLY BY ONE-HALF (DEPENDING ON TH INDIVIDUAL CASE) TO MAINTAIN THE PROTHROMBIN TIME AT THE DESIRED LEVEL TO PREVENT BLEEDING COMPLICATIONS FREQUENT PROTHROMBIN DETERMINATIONS ARE ADVISABLE UNTIL IT HAS BEEN DEFINITELY DETERMINED THAT THE PRC THROMBIN LEVEL HAS BEEN STABILIZED.

Hyperlipidemia

of Atromid-S®

Brand of clofibrate

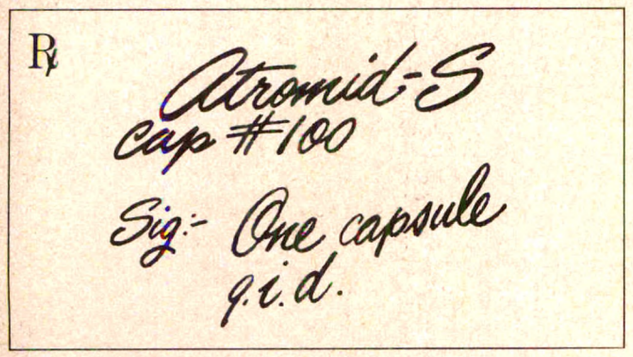
the most widely prescribed lipid-lowering agent–
significantly reduces
elevated levels of cholesterol and/or triglycerides,
not just cholesterol alone

Hyperlipidemia/**Atromid-S®** (clofibrate) **Ayerst®**

AN IMPORTANT NOTE: It has not been established whether the drug-induced lowering of serum cholesterol or lipid levels has a detrimental, beneficial, or no effect on the morbidity or mortality due to atherosclerosis or coronary heart disease. Several years will be required before current investigations will yield an answer to this question.

See last page of advertisement for prescribing information.

Atromid-S® (clofibrate)
helps reduce elevated cholesterol and/or triglyceride levels — not just cholesterol alone



BRIEF SUMMARY

(For full prescribing information, see package circular.)

ATROMID-S® (clofibrate)

Antilipidemic agent for reduction of elevated serum lipids

INDICATIONS: ATROMID-S is indicated as adjunctive therapy to diet and other measures for the reduction of elevated serum cholesterol (especially the beta lipoprotein fraction) and/or triglycerides. Clofibrate appears to have a greater depressant effect on the very low density lipoproteins (S_f 20-400) rich in triglycerides than the low density lipoproteins (S_f 0-20) rich in cholesterol.

ATROMID-S is also indicated for treatment of patients with xanthoma tuberosum associated with hyperlipidemia. The skin lesions frequently regress with clofibrate.

It has not been established whether the drug-induced lowering of serum cholesterol or lipid levels has a detrimental, beneficial, or no effect on the morbidity or mortality due to atherosclerosis or coronary heart disease. Several years will be required before current investigations will yield an answer to this question.

CONTRAINDICATIONS: Clofibrate is contraindicated in pregnant women. While teratogenic studies have not demonstrated any effect attributable to clofibrate, it is known that serum of the rabbit fetus accumulates a higher concentration of clofibrate than that found in maternal serum, and it is possible that the fetus may not have developed the enzyme system required for the excretion of clofibrate.

It is contraindicated in lactating women since it is not known if clofibrate is secreted in the milk.

It is contraindicated in patients with clinically significant hepatic or renal dysfunction.

It is contraindicated in patients with primary biliary cirrhosis since it may raise the already elevated cholesterol in these cases.

WARNINGS: CAUTION SHOULD BE EXERCISED WHEN ANTICOAGULANTS ARE GIVEN IN CONJUNCTION WITH ATROMID-S. THE DOSAGE OF THE ANTICOAGULANT SHOULD BE REDUCED USUALLY BY ONE-HALF (DEPENDING ON THE INDIVIDUAL CASE) TO MAINTAIN THE PROTHROMBIN TIME AT THE DESIRED LEVEL TO PREVENT BLEEDING COMPLICATIONS. FREQUENT PROTHROMBIN DETERMINATIONS ARE ADVISABLE UNTIL IT HAS BEEN DEFINITELY DETERMINED THAT THE PROTHROMBIN LEVEL HAS BEEN STABILIZED.

Strict birth control procedures must be exercised by women of childbearing potential. In patients who plan to become pregnant, clofibrate should be withdrawn several months before conception. Because of the possibility of pregnancy occurring despite birth control precautions in patients taking clofibrate, the possible benefits of the drug to the patient must be weighed against possible hazards to the fetus.

PRECAUTIONS: Before instituting therapy with clofibrate, attempts should be made to control serum lipids with appropriate dietary regimens, weight loss in obese patients, control of diabetes mellitus, etc.

Because of the long term administration of a drug of this nature, adequate base line studies should be performed to determine that the patient has significantly elevated serum lipid levels. Frequent determinations of serum lipids should be obtained during the first few months of ATROMID-S administration, and periodic determinations thereafter. The drug should be withdrawn after three months if response is inadequate. However, in the case of xanthoma tuberosum, the drug should be employed for longer periods (even up to one year) provided that there is a reduction in the size and/or number of the xanthomata.

Subsequent serum lipid determinations should be done to detect a paradoxical rise in serum cholesterol or triglyceride levels. Clofibrate will not alter the seasonal variations of serum cholesterol peak elevations in midwinter and late summer and decreases in fall and spring. If the drug is discontinued, the patient should be placed on an appropriate hypolipidemic diet, and his serum lipids should be monitored until stabilized, as a rise in these values to or above the original base line may occur.

During clofibrate therapy, frequent serum transaminase determinations and other liver function tests should be performed since the drug may produce abnormalities in these parameters. Hepatic biopsies are usually within normal limits. These effects are usually reversible when the drug is discontinued. If the hepatic function tests steadily rise or show excessive abnormalities, the drug should be withdrawn. Therefore use with caution in those patients with a past history of jaundice or hepatic disease.

Clofibrate may produce "flu like" symptoms (muscular aching, soreness, cramping). The physician should differentiate this from actual viral and/or bacterial disease.

Use with caution in patients with peptic ulcer since reactivation has been reported. Whether this is drug-related is unknown.

The physician should monitor the patient with complete blood counts since peripheral anemia and, more frequently, leukopenia have been reported in patients who have been taking clofibrate. Whether these are drug-related is unknown.

Various cardiac arrhythmias have been reported with the use of clofibrate.

Several investigators have observed in their studies that clofibrate may produce a decrease in cholesterol linoleate but an increase in palmitoleate and oleate, the latter being considered atherogenic in experimental animals. The significance of this finding is unknown at this time.

ADVERSE REACTIONS: Of the pertinent reactions, the most common is nausea. Less frequently encountered gastrointestinal reactions are vomiting, loose stools, dyspepsia, flatulence, and abdominal distress. Reactions reported less often than gastrointestinal ones are headache, dizziness, and fatigue; muscle cramping, aching, and weakness; skin rash, urticaria, and pruritus. There have been occasional cases of dry, brittle hair and of alopecia.

The following reported adverse reactions are listed alphabetically by systems:

Cardiovascular
- Cardiac arrhythmias
- Both swelling and phlebitis at site of xanthomas

Dermatologic
- Skin rash
- Alopecia
- Allergic reaction including urticaria
- Dry skin and dry brittle hair
- Pruritus

Gastrointestinal
- Nausea
- Diarrhea
- Gastrointestinal upset (bloating, flatulence, abdominal distress)
- Vomiting
- Stomatitis and gastritis

Genitourinary
- Impotence and decreased libido
- Findings consistent with renal dysfunction as evidenced by dysuria, hematuria, proteinuria, decreased urine output. One patient's renal biopsy suggested "allergic reaction."

Hematologic
- Leukopenia
- Potentiation of anticoagulant effect
- Anemia
- Eosinophilia

Musculoskeletal
- Myalgia (muscle cramping, aching, weakness)
- "Flu like" symptoms
- Arthralgia

Neurologic
- Fatigue, weakness, drowsiness
- Dizziness
- Headache

Miscellaneous
- Weight gain
- Polyphagia

Laboratory Findings
- Abnormal liver function tests as evidenced by increased transaminase (SGOT and SGPT), BSP retention, and increased thymol turbidity
- Proteinuria
- Increased creatine phosphokinase

Reported adverse reactions whose direct relationship with the drug has not been established: increased angina, peptic ulcer, gastrointestinal hemorrhage, rheumatoid arthritis, tremors, increased perspiration, systemic lupus erythematosus, blurred vision.

DOSAGE AND ADMINISTRATION: Adult Dose: The recommended dosage for adults is one capsule (500 mg.) four times daily.

In Children: Insufficient studies have been done in children to show safety and efficacy.

DRUG INTERACTIONS: Caution should be exercised when anticoagulants are given in conjunction with ATROMID-S (clofibrate). The dosage of the anticoagulant should be reduced usually by one-half (depending on the individual case) to maintain the prothrombin time at the desired level to prevent bleeding complications. Frequent prothrombin determinations are advisable until it has been definitely determined that the prothrombin level has been stabilized.

MANAGEMENT OF OVERDOSAGE: While there has been no reported case of overdosage, should it occur, symptomatic supportive measures should be taken.

HOW SUPPLIED: ATROMID-S—No. 243—Each capsule contains 500 mg. clofibrate, in bottles of 100.

Beat after beat...day after day

CARDIOQUIN tablets

(quinidine polygalacturonate)

To convert...to MAINTAIN normal sinus rhythm

After conversion of cardiac arrhythmias—whether with CARDIOQUIN Tablets or some other current method—only low b.i.d. or t.i.d. dosage of this unique polygalacturonate salt of quinidine is required in most cases to maintain normal sinus rhythm.

Well-tolerated, CARDIOQUIN Tablets are particularly suited for maintenance therapy, since the polygalacturonic acid serves as a buffering moiety. It protects the mucosa of the stomach and permits dependable absorption of the quinidine.*

*Aviado, D. M., *Krantz and Carr's Pharmacologic Principles of Medical Practice*, ed. 8, Baltimore, Williams and Wilkins Co., 1972, p. 456.

BRIEF SUMMARY—INDICATIONS: CARDIOQUIN Tablets (quinidine polygalacturonate) are indicated in the treatment of: premature atrial and ventricular contractions; paroxysmal atrial tachycardia; paroxysmal AV junctional rhythm; atrial flutter; paroxysmal atrial fibrillation; established atrial fibrillation when therapy is appropriate; paroxysmal ventricular tachycardia when not associated with complete heartblock; maintenance therapy after electrical conversion of atrial fibrillation and/or flutter. CONTRAINDICATIONS: Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine. WARNING: In the treatment of atrial flutter reversion to sinus rhythm may be preceded by a progressive reduction in the degree of AV block to a 1:1 ratio and resulting extremely rapid ventricular rate. COMPOSITION: Each CARDIOQUIN Tablet (quinidine polygalacturonate 275 mg.) is equivalent in quinidine content to 3 grains quinidine sulfate. DOSAGE AND ADMINISTRATION: Dosage must be adjusted to individual needs, both for conversion and maintenance. An initial dose of 1 to 3 tablets may be used to terminate arrhythmias, and may be repeated in 3-4 hours. If normal sinus rhythm is not restored after 3 or 4 equal doses, the dose may be increased by ½ to 1 tablet (137.5 to 275 mg.) and administered three to four times before any further dosage increase. For maintenance, one tablet may be used two to three times a day; generally one tablet morning and night will be adequate. SUPPLIED: Uncoated, scored tablets in bottles of 50.

CONTENTS

CLINICAL STUDIES

327 **Atropine-Induced Cardioacceleration and Myocardial Blood Flow in Subjects With and Without Coronary Artery Disease**

SUZANNE B. KNOEBEL, PAUL L. McHENRY, JOHN F. PHILLIPS and STEVEN WIDLANSKY

After intravenous administration of atropine sulfate (1 mg) heart rate and myocardial blood flow increased 52 and 48 percent, respectively, in 10 patients without coronary occlusive disease, 37 and 44 percent, respectively, in 14 patients with single vessel disease or partial occlusion of two vessels, and 30 and 15 percent, respectively, in 11 patients with two or three vessel disease. The latter group of 11 patients had a smaller increase in nutrient myocardial blood flow in response to atropine-induced cardioacceleration than patients with no or lesser degrees of coronary artery disease.

333 **Electrophysiologic Effects of Atropine on Atrioventricular Conduction Studied by His Bundle Electrogram**

MASOOD AKHTAR, ANTHONY N. DAMATO, ANTHONY R. CARACTA, WILLIAM P. BATSFORD, MARK E. JOSEPHSON and SUN H. LAU

Administration of atropine, 0.5 mg intravenously, produced an average increase of 20 percent in the sinus rate, enhanced atrioventricular (A–V) nodal conduction and shortened the functional and effective refractory periods of the A–V node without any direct effect on His-Purkinje conduction time or refractoriness. By shortening the functional refractory period of the A–V node, atropine shortened H_1–H_2 intervals on the His bundle electrograms.

344 **Effects of Digoxin on Atrioventricular Conduction Patterns in Man**

ANDREW C. PRZYBYLA, KARLEN L. PAULAY, EMANUEL STEIN and ANTHONY N. DAMATO

Bundle of His studies in 17 patients given digoxin demonstrated that an early atrial premature impulse was either blocked in the A–V node or reached the distal intraventricular conduction system so late that block or conduction delay below the His bundle observed in the control state was reduced or no longer occurred. These effects are attributed to the action of digoxin in slowing A–V nodal conduction of a premature impulse. Aberrant ventricular conduction in atrial fibrillation may thus be abolished.

351 **Diagnostic Value of Clinical History, Exercise Testing and Atrial Pacing in Patients with Chest Pain**

JAN PIESSENS, WALTER VAN MIEGHEM, HUGO KESTLELOOT and HILAIRE DE GEEST

In this study of 70 patients with a history of chest pain warranting coronary angiography, a clinical history of angina pectoris was a very sensitive (90 percent) but less specific (80 percent) predictor of severe coronary artery disease. Ischemic S–T segment depression of 1 mm or more was the most accurate electrocardiographic predictor. Atrial pacing was slightly more sensitive in provoking ischemic S–T segment depressions than the graded exercise test but showed less specificity and did not contribute significantly to diagnosis when a graded exercise test was performed.

CONTENTS

357 Pulmonary Arterial Diastolic Pressure in Acute Myocardial Infarction

MICHAEL ROTMAN, JAMES T. T. CHEN, RONALD P. SENINGEN, JOHN HAWLEY, GALEN S. WAGNER, ROBERT M. DAVIDSON and MARCEL R. GILBERT

Pulmonary arterial diastolic pressure measurements provided a reliable estimate of left ventricular filling pressure and the degree of myocardial failure (third sound gallop or rales) in 91 patients with acute myocardial infarction. Radiographic evidence of increasing pulmonary congestion correlated significantly with the level of pulmonary arterial diastolic pressure.

363 Early Sequential Changes in Left Ventricular Dimensions and Filling Pressure in Patients After Myocardial Infarction

McKAMY SMITH, ROBERT A. RATSHIN, FRANK E. HARRELL, Jr., RICHARD O. RUSSELL, Jr. and CHARLES E. RACKLEY

In 14 patients studied within 8 days after acute myocardial infarction echocardiographic end-diastolic volume correlated with end-systolic volume and echocardiographic stroke volume but not with pulmonary arterial end-diastolic pressure. Large changes in the latter with no change in left ventricular end-diastolic dimension imply acute changes in left ventricular compliance. Early sequential changes in filling pressure, echocardiographic dimensions and left ventricular compliance correlated closely with the clinical course of the patients, suggesting the value of these data in the management of patients with hemodynamic instability after acute myocardial infarction.

370 Left Ventricular A Wave Amplitude in Patients After Myocardial Infarction

McKAMY SMITH, RICHARD O. RUSSELL, Jr., ROGER E. MORASKI, BOLLING J. FEILD and CHARLES E. RACKLEY

Increased left ventricular A wave amplitudes in 42 patients studied within 1 year after acute myocardial infarction indicated a decrease in both left ventricular diastolic compliance and systolic function. The inverse relation between left ventricular A wave amplitude and ejection fraction in this study suggests that augmentation of left ventricular end-diastolic fiber length by atrial systole may improve the performance of ventricles with decreased systolic function.

378 Dynamic Characterization of Premature Ventricular Beats and Ventricular Tachycardias

LESLIE M. EBER, BAROUH V. BERKOVITS, JACK M. MATLOFF, RICHARD GORLIN, with the technical assistance of JOHN M. COOKE

Premature ventricular beats and ventricular tachycardias produced in man during left ventriculography and in dogs by epicardial stimulation produced two similar patterns of ventricular contractions. Apically stimulated left ventricular beats produced an "hour glass" type of contraction pattern; basilar stimulation produced an inverse "teardrop" pattern. The former were hemodynamically more effective, thus indicating the importance of a normal sequence of ventricular contraction.

EXPERIMENTAL STUDIES

384 Surface Recording of Electrical Activity from the Region of the Bundle of His

NANCY C. FLOWERS, R. CHRIS HAND, PATRICIA C. ORANDER, CAREY B. MILLER, MARY O. WALDEN and LEO G. HORAN

Surface recordings of electrical activity during the P–R interval in 16 dogs are interpreted as having originated from the bundle of His in 7 dogs, from the region of the bundle branches in 6 and from both sites in 3. These results suggest that examination of the amplified surface P–R segment should become an important addition to the noninvasive techniques of cardiac evaluation.

390 Microelectrode Study of Wenckebach Periodicity in Canine Purkinje Fibers

JAMES R. WENNEMARK and JACK P. BANDURA

Experimentally produced Wenckebach periodicity appeared to be related to two factors: (1) a progressive decrease in the efficiency of the transmitted electrotonic potential arising from an increased maximal repolarization voltage of the transmembrane potential, and (2) a decreased diastolic interval that, in the presence of enhanced phase 4 diastolic depolarization, caused the voltage level from which the electrotonic potential originates to become further removed from the stimulation threshold with successive impulses of the cycle.

METHODS

399 Detection of Ventricular Arrhythmias in Real-Time with a Portable Analog Computer

DAVID S. CANNOM and DONALD C. HARRISON

This preliminary study of a portable analog computer to detect arrhythmias in 26 patients in a controlled in-hospital setting demonstrates the potential value of this device. Appropriate electrode placement is essential. Use of this detector may permit large-scale monitoring of patients with a high risk of sudden death, provided potential problems of long-term electrode placement, patient acceptance and tolerance of the concept of continuous monitoring and mechanisms for telephone transmissions to a coronary care unit or central hospital facility are solved.

PEDIATRIC CARDIOLOGY

403 Ventricular Septal Defect with Increased Pulmonary Vascular Resistance. Late Results of Surgical Closure

BEAT FRIEDLI, B. S. LANGFORD KIDD, WILLIAM T. MUSTARD and JOHN D. KEITH

Eighteen of 57 children died at or immediately after surgical closure of ventricular septal defect in the presence of increased pulmonary vascular resistance; seven late deaths occurred 1 to 7 years after operation. These overall results of surgery for ventricular septal defect and high pulmonary vascular resistance are unfavorable and call for surgical closure before age 2 years or pulmonary arterial banding in infancy before the development of significant pulmonary vascular obstructive changes.

410 Effect of Red Cell Volume Reduction on Pulmonary Blood Flow in Polycythemia of Cyanotic Congenital Heart Disease

AMNON ROSENTHAL and DONALD C. FYLER

Acute red cell volume reduction in patients with D-transposition of the great arteries and no significant pulmonary stenosis was associated with decreased pulmonary vascular resistance and increased pulmonary blood flow and mixing between the systemic and pulmonary circulations; in patients with severe pulmonary stenosis or atresia and a ventricular septal defect, it was associated with decreased pulmonary blood flow and left to right shunt and an increase in right to left shunt. These changes are attributed to a reduction in blood viscosity produced by lowering of hematocrit concentration.

REPORTS ON THERAPY

415 Bypass Graft Surgery Versus Medical Therapy of Angina Pectoris

WILBERT S. ARONOW and EDWARD A. STEMMER

This carefully matched study of 20 patients with angina who underwent coronary artery bypass graft surgery and 20 similar subjects treated medically provides no good evidence that such surgery favorably alters the natural history of stable angina pectoris due to coronary artery disease by reducing mortality or preventing myocardial infarction. The operation may improve the quality of life and should be considered if medical therapy fails to relieve disabling angina.

SYMPOSIUM ON THE EFFECTS OF SURGICAL TREATMENT ON THE NATURAL HISTORY OF ACQUIRED HEART DISEASE. PART I. CORONARY ARTERY DISEASE

421 Introduction

JOHN ROSS, Jr.

423 Natural History of Angina Pectoris

T. JOSEPH REEVES, ALBERT OBERMAN, WILLIAM B. JONES and L. THOMAS SHEFFIELD

Combined data on patients with angina pectoris from several laboratories indicate an annual mortality rate of 2 percent when one coronary artery is significantly stenosed, 7 percent when two coronary arteries are stenosed and 11 percent when all three arteries are stenosed. These rates are increased when cardiac enlargement or congestive heart failure is also present. Such data on the natural history of angina pectoris are crucial in making a decision in surgical versus medical management of this condition.

431 Outlook for Patients After Coronary Artery Revascularization

VINCENT L. GOTT

Data from many centers indicate that about 85 percent of patients surviving the coronary artery bypass operation have relief of their angina and 60 percent have no further chest pain. Myocardial contractility for segments with a patent graft can be improved. The operative mortality rate for patients with stable angina, less than 6 percent in most centers, is related to the quality of ventricular function. The mortality rate in patients with unstable angina is considerably higher. Bypass surgery may favorably influence the annual survival rate in subjects with stable angina, but there are not enough data to say whether it can extend the life of patients with unstable angina.

DIAGNOSTIC SHELF

438 Echocardiographic Features of Primary Pulmonary Hypertension

DANIEL J. GOODMAN, DONALD C. HARRISON and RICHARD L. POPP

Echocardiograms in nine patients with primary pulmonary hypertension all showed a reduced diastolic slope of the anterior mitral valve leaflet motion simulating mitral stenosis but with normal motion of the posterior valve. The normal motion of this structure excludes the diagnosis of mitral stenosis as a cause for the pulmonary hypertension.

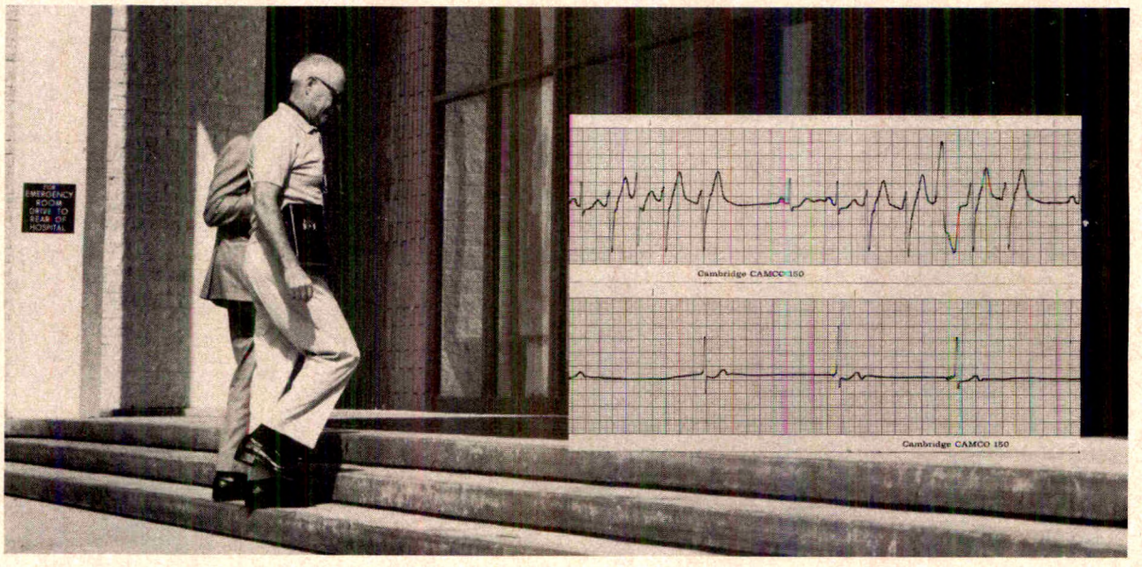
Holter DCG Monitoring Case History No. 20



A dynamic electrocardiogram was obtained on this 69-year old male patient, because of symptoms of severe dizziness and lightheadedness. The initial 1½ hours of the DCG demonstrated frequent 3-to-5 beat salvos of paroxysmal ventricular tachycardia and multifocal ventricular extrasystoles, which were frequently paired (see first strip); in addition, ventricular bigeminy and trigeminy were demonstrated. During the third hour of the recording (see second strip), a wandering pacemaker with an intermittent slow junctional rhythm (as low as 28 beats/minute) occurred.

While still wearing the Holter monitor, the patient was admitted to the hospital with symptoms of dizziness. The DCG permitted documentation of this patient's tachyarrhythmias and bradyarrhythmias, and appropriate therapy was then instituted.

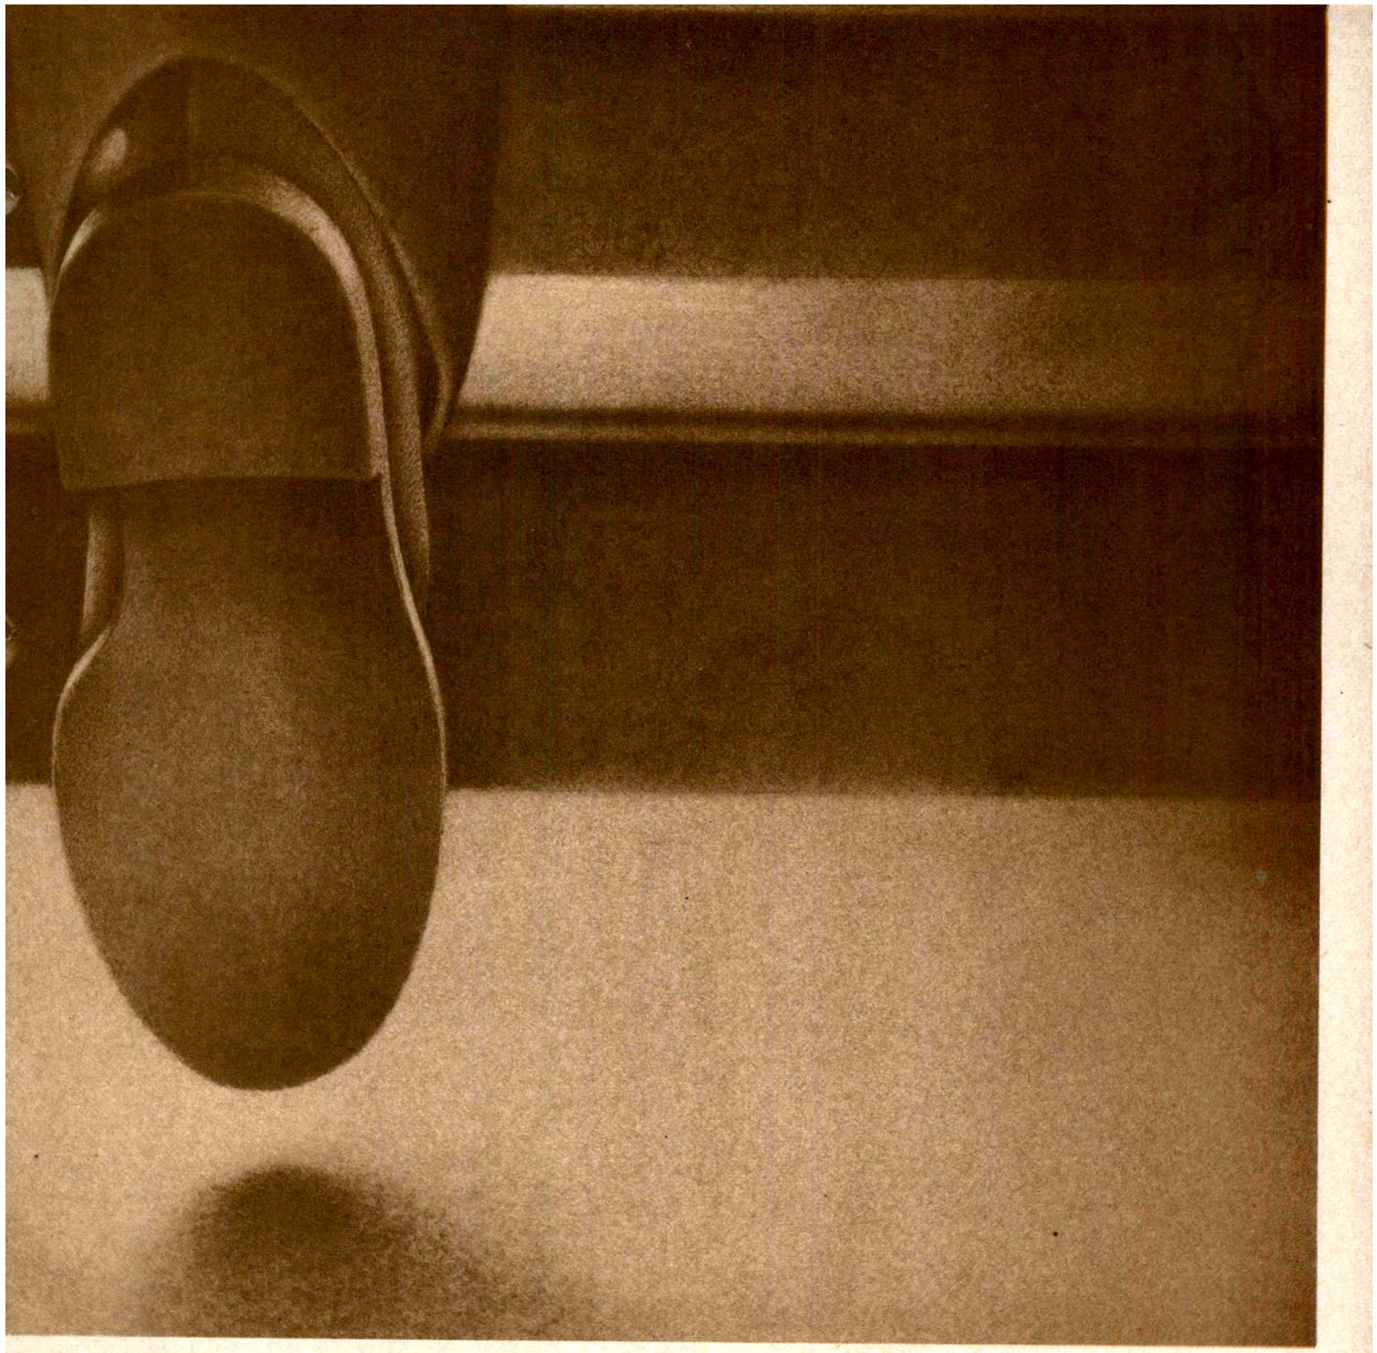
Onset of action:
within 15-30 minutes

And when indicated:
Sorbitrate® (isosorbide dinitrate) 5 mg. oral tablets

*Oral dosage forms of this drug have been evaluated as possibly effective. See Brief Summary.



SUMMARY OF PRESCRIBING INFORMATION

Indications: Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indication as follows:

"Possibly" effective: For the treatment of angina pectoris.

Final classification of the less-than-effective indications require further investigation.

Contraindications: A history of sensitivity to the drug.

Warnings: Data supporting the use of nitrates during the early days of the acute phase of myocardial infarction are insufficient to establish safety.

Precautions: Should be used with caution in patients who have glaucoma. Tolerance and cross tolerance to other nitrates may occur.

Adverse Reactions: Headache which may be severe and persistent. Lowering the dose and using analgesics will help control the headaches which usually diminish or disappear as therapy is continued.

Adverse reactions seen occasionally: Cutaneous vasodilation with flushing; transient dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension; individual marked sensitivity to the hypotensive effects of nitrates wherein severe responses can occur even with the usual therapeutic dose (alcohol may enhance this effect); drug rash and/or exfoliative dermatitis.

This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine and other agents.

Dosage and Administration: Oral tablets.

Individual Dose: Smallest effective dose should be employed. Five to 10 mg. is the range commonly used although doses of up to 30 mg. have frequently been employed.

Dosage Schedule: Smallest effective dose necessary for the prevention and treatment of pain of an anginal attack. Oral SORBITRATE may be taken 3 to 4 times daily. Although the onset and duration of effect of coronary nitrates may vary, following are the generally reported ranges of these values for SORBITRATE:

Onset of Effect: Oral: 15 to 30 minutes.

Duration of Effect: Oral: Estimated to be 4 to 6 hours.

It is recommended that the oral dosage be taken on an empty stomach.

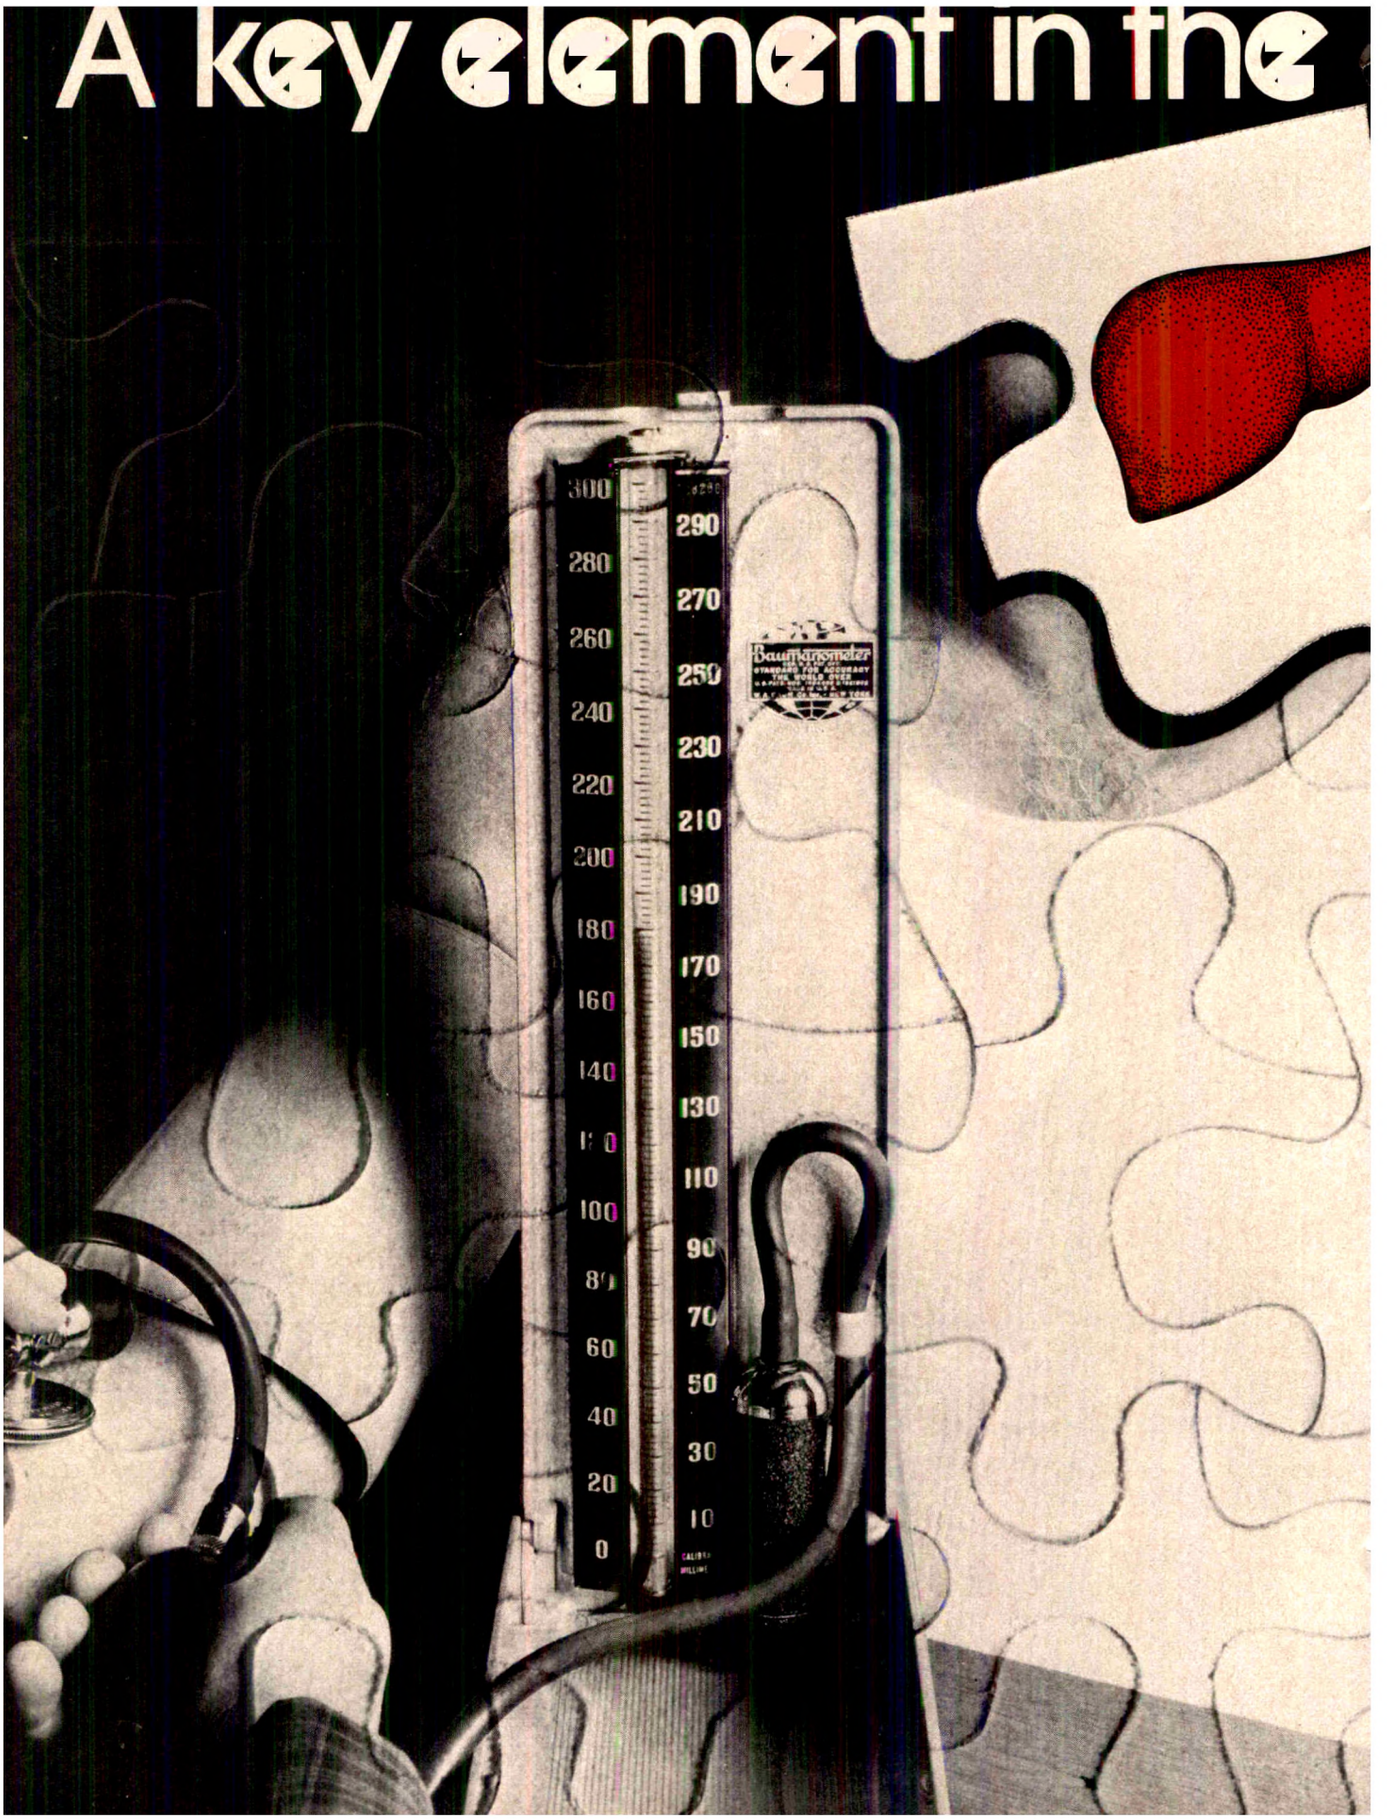
WILMINGTON, DEL. 19899 | PASADENA, CALIF. 91109

A key element in the



hypertension puzzle

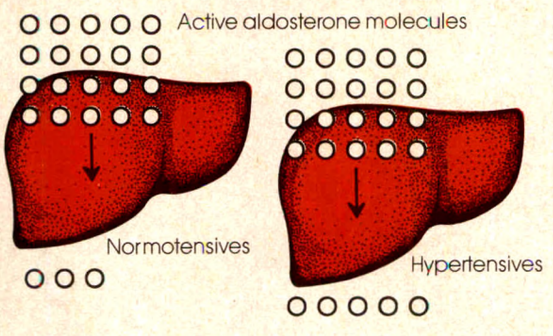
The liver metabolizes significantly less aldosterone in hypertensives than in normotensives.[1,2]

A significantly decreased hepatic MCR (metabolic clearance rate) of aldosterone, without significantly decreased SR (secretion rate), was demonstrated in approximately 90 percent of a group of 56 patients with benign essential hypertension.[1]

Thus "Failure of the aldosterone SR to fully adapt to the decrease in MCR may be responsible for a relative state of hyperaldosteronism in many patients with BEH [benign essential hypertension], even when the secretion and excretion rates are within normal range.

"It is conceivable that it is the mineralocorticoid [aldosterone] excess that is leading to an increase of sodium content in the arteriolar wall and the hypertensive process itself, in many patients with BEH."[2]

Metabolic clearance of aldosterone in hypertensives and in normotensives*



*Schematic representation

To help control the aldosterone factor in essential hypertension

Aldactazide®

(spironolactone 25 mg./hydrochlorothiazide 25 mg.)

- Spironolactone blocks the pressor effect of aldosterone at the arteriole,[3-5] and exerts natriuretic action in the distal renal tubule.
- Hydrochlorothiazide exerts additive antihypertensive effect through its action at a different renal site.
- Aldactazide helps maintain potassium balance—without the need for potassium supplements—because the potassium-sparing action of spironolactone offsets the potassium-losing effect of hydrochlorothiazide.

See following page for brief summary.

To help control the aldosterone factor in essential hypertension

Aldactazide®

(spironolactone 25 mg./hydrochlorothiazide 25 mg.)

Indications—Hypertension; edema or ascites of congestive heart failure, cirrhosis of the liver and the nephrotic syndrome; idiopathic edema. Some patients with malignant effusion may benefit from Aldactazide therapy.

Contraindications—Acute renal insufficiency, rapidly progressing impairment of the renal function. Anuria; sensitivity to thiazides or other sulfonamide-derived drugs. Probably contraindicated in acute or severe hepatic failure.

Warnings—Fixed-dose combination drugs are not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual patient. If the fixed combination represents the dosage so determined, its use may be more convenient in patient management. The treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

Potassium supplementation is recommended only in exceptional instances, but may be considered when a glucocorticoid is also given. Utilize normal dietary sources of potassium if possible when potassium supplementation is necessary. If enteric-coated potassium is used be alert to the possible development of hemorrhagic, stenotic, ulcerated or perforated small-bowel lesions; deaths have occurred. The possibility of exacerbation or activation of systemic lupus erythematosus by sulfonamide derivatives, including thiazides, has been reported.

Administer thiazides with caution to pregnant or lactating patients. Adverse reactions which may occur in the adult (hyperbilirubinemia, thrombocytopenia, altered carbohydrate metabolism, etc.) may possibly occur in the newborn, since thiazides cross the placental barrier and may also appear in breast milk.

Precautions—Consider the possibility of fluid and electrolyte imbalance. Serum and urine electrolyte determinations are particularly important in patients with excessive vomiting or in those receiving fluids parenterally. Medications such as digitalis may also influence serum electrolytes. Warning signs of possible fluid and electrolyte imbalance are: dryness of the mouth, thirst, weakness, lethargy, drowsiness, restlessness, muscle pains, cramps or fatigue, hypotension, oliguria, tachycardia, gastrointestinal symptoms. Hypokalemia may develop with brisk diuresis in severe cirrhosis or during the concomitant use of glucocorticoids or ACTH. Inadequate oral electrolyte intake contributes to hypokalemia. Hypokalemia may cause signs of digitalis intoxication with previously tolerated doses of digitalis.

Give Aldactazide cautiously to patients with severe liver disease since thiazides can precipitate hepatic coma; discontinue if mental confusion increases. Consider also other factors that may precipitate hepatic coma, including blood in the gastrointestinal tract or preexistent potassium depletion. Reversible elevation of NPN and BUN may occur in some patients receiving Aldactazide. The most common electrolyte disturbance is dilutional hyponatremia which requires appropriate corrective measures. A true low-salt syndrome is rare; discontinue Aldactazide and administer sodium for this condition.

Although rare, the most potentially serious electrolyte disturbance is hyperkalemia; if this occurs discontinue Aldactazide and restrict potassium intake. Rarely, fatality due to hyperkalemia has been reported. Hyperkalemia is more likely to occur in severely ill patients with relatively small urine output or in patients receiving supplemental potassium; determine serum electrolytes frequently in such patients. Consider the possibility of hyperuricemia or a decrease in tolerance to glucose.

Patients with severely resistant edema may have an increased diuretic response following the addition of a potent glucocorticoid, such as 15 to 20 mg. of prednisone daily, to Aldactazide therapy. Supplemental potassium will usually be necessary in such patients and the usual precautions with glucocorticoids are necessary. Use caution if regional or general anesthesia is necessary since Aldactazide reduces vascular responsiveness to norepinephrine in such patients. Thiazides may increase responsiveness to tubocurarine. The antihypertensive effects of hydrochlorothiazide may be enhanced in patients who have undergone sympathectomy.

Pathologic changes in the parathyroid glands, with hypercalcemia and hypophosphatemia, have been observed in a few patients on prolonged thiazide therapy.

Thiazides may increase serum PBI levels without signs of thyroid disturbance.

Adverse Reactions reported with *spironolactone* use: Drowsiness and lethargy, mental confusion, diarrhea and other gastrointestinal symptoms, mild androgenic manifestations (including hirsutism, menstrual irregularity, deepening of the voice), gynecomastia, inability to achieve or to maintain erection, headache, maculopapular or erythematous cutaneous eruptions, urticaria, drug fever, ataxia.

Adverse reactions reported with *thiazide* use: purpura, thrombocytopenia, leukopenia, agranulocytosis, gastrointestinal disorders (anorexia, nausea, vomiting, diarrhea, abdominal cramps), rash, pruritus, paresthesia, acute pancreatitis, jaundice, dizziness, vertigo, headache, xanthopsia, photosensitivity, urticaria, necrotizing angiitis, aplastic anemia, orthostatic hypotension, muscle spasm, weakness, restlessness. Reduce dosage or withdraw drug whenever adverse reactions are moderate or severe.

Dosage and Administration—Dosage should be determined by individual titration. *For essential hypertension* the daily *adult* dosage is two to four tablets in divided doses; continue treatment for two weeks or longer. Adjust the dosage according to the response of the patient. Reduce the dosage of other antihypertensive agents, particularly ganglionic blocking agents, by 50 percent since Aldactazide potentiates the action of such drugs. *For edema, ascites or effusion in adults* the average dosage is one tablet 4 times daily; dosage may range from 1 to 8 tablets daily in divided doses. The daily dosage of Aldactazide *in children* should provide 0.75 to 1.5 mg. of Aldactone® (spironolactone) per pound of body weight.

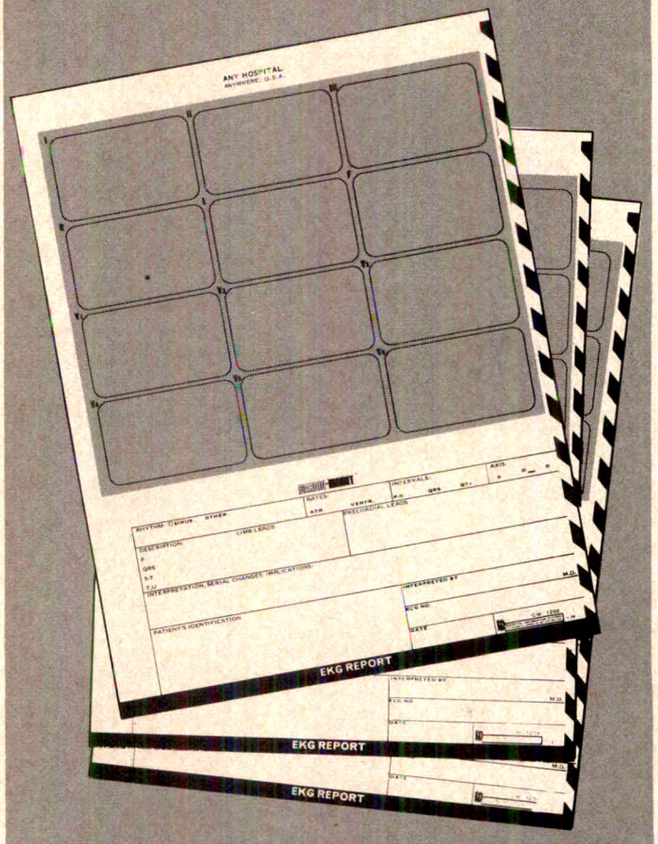
CARDIO-MOUNT™

A NEW WAY TO HELP YOU SEE WHAT MAKES IT TICK.



Cardio-Mount™ is a new EKG mount with some new twists, the result of our 15 years experience in laboratory report mounting systems. Cardio-Mount offers many little differences that add up to a **big** difference in mount quality. For example, permanent and aggressive adhesive make the Cardio-Mount ready and easy to use. Its single-sheet thickness reduces bulk, enhancing the Cardio-Mount's professional appearance. Compatible with most current systems, Cardio-Mount comes in five standard styles. And if one of them isn't right for you, we'll design one that is.

Years from now, when you need to look at a patient's record, the traces you made on *Kodak Linagraph* 1930 Paper will still be sharp. They will be clear, easy to read—bold black-on-white traces that help to make your comparisons meaningful.

With normal storage, you'll continue to have sharp, useful records available. This kind of quality is a must for the results of time-consuming, delicate cardiac catheterization. Equally important: Processing today's records requires as little as 90 seconds with the *Kodak* RP *X-Omat* Processor, already being used for x-ray film in your affiliated hospital. There's no need to change chemicals or readjust the machine in any way. If there's no processor available, you can tray-process the paper. *Linagraph* 1930 Paper also gives you the kind of dimensional stability that provides an undistorted time base. And it's a paper that stays flat, won't wrinkle, and doesn't mar under normal handling. They all add up to more reasons why *Linagraph* 1930 Paper puts time on your side.

Want more facts?

By now she should

Rheumatic fever prevention and the noncompliant patient.

Patients on oral penicillin for prevention of recurrent rheumatic fever usually don't ignore their daily dosage regimen deliberately. But since patients are only human, doses *are* missed occasionally—through simple lapse of memory, lack of time or insufficient drug on hand.

Prolonged penicillin blood levels to obviate need for daily dosage.

A single injection of benzathine penicillin G (1.2 million units) once a month provides continuous prophylaxis in most patients. Which is why it's recommended as the method of choice* to prevent streptococcal infection and possible recurrence of rheumatic fever.

A method of choice in treatment of strep pharyngitis, too.*

In therapy of mild to moderate Group A streptococcal pharyngitis without bacteremia, just one injection of 600,000 to 900,000 units usually maintains penicillin serum concentrations in children for the 10 days necessary to eradicate the infecting organisms.† In adults, 1.2 million units are required.

*Rheumatic Fever Committee of the Council on Rheumatic Fever and Congenital Heart Disease of the American Heart Association.

have taken all of them.

Indications: In treatment of infections due to penicillin G-sensitive microorganisms susceptible to the low and very prolonged serum levels common to this dosage form. Therapy should be guided by bacteriological studies (including sensitivity tests) and clinical response.

The following infections usually respond to adequate dosage of IM benzathine penicillin G.

Streptococcal infections (Group A—without bacteremia). Mild to moderate upper respiratory infections (e.g., pharyngitis).

Venereal infections —Syphilis, yaws, bejel, and pinta.

Medical Conditions in which Benzathine Penicillin G Therapy is indicated as Prophylaxis:

Rheumatic fever and/or chorea —Prophylaxis with benzathine penicillin G has proven effective in preventing recurrence of these conditions. It has also been used as followup prophylactic therapy for rheumatic heart disease and acute glomerulonephritis.

FOR DEEP INTRAMUSCULAR INJECTION ONLY.

Contraindications: Previous hypersensitivity reaction to any penicillin.

Warnings: Serious and occasionally fatal hypersensitivity (anaphylactoid) reactions have been reported. Anaphylaxis is more frequent following parenteral therapy but has occurred with oral penicillins. These reactions are more apt to occur in individuals with history of sensitivity to multiple allergens. Severe hypersensitivity reactions with cephalosporins have been well documented in patients with history of penicillin hypersensitivity. Before penicillin therapy, carefully inquire into previous hypersensitivity to penicillins, cephalosporins and other allergens. If allergic reaction occurs, discontinue drug and treat with usual agents, e.g., pressor amines, antihistamines and corticosteroids.

Precautions: Use cautiously in individuals with histories of significant allergies and/or asthma

Carefully avoid intravenous or intraarterial use or injection into or near major peripheral nerves or blood vessels, since such injection may produce neurovascular damage.

†In streptococcal infections, therapy must be sufficient to eliminate the organism, otherwise the sequelae of streptococcal disease may occur. Take cultures following completion of treatment to determine whether streptococci have been eradicated.

Prolonged use of antibiotics may promote overgrowth of non-susceptible organisms including fungi. Take appropriate measures if superinfection occurs.

Adverse Reactions: Hypersensitivity reactions reported are skin eruptions (maculopapular to exfoliative dermatitis), urticaria and other serum sickness reactions, laryngeal edema and anaphylaxis. Fever and eosinophilia may frequently be only reaction observed. Hemolytic anemia, leucopenia, thrombocytopenia, neuropathy and nephropathy are infrequent and usually associated with high parenteral doses.

As with other antisyphilitics, Jarisch-Herxheimer reaction has been reported.

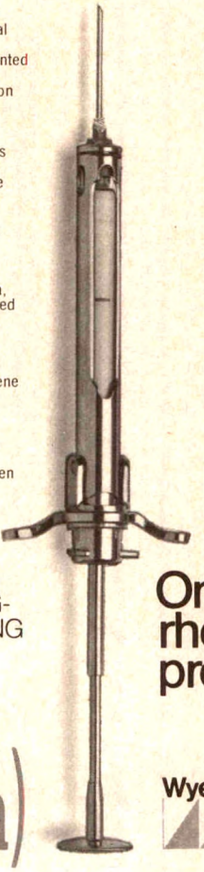
Composition: (units benzathine penicillin G as active ingredient): 300,000 units per cc.—10-cc. multi-dose vial. Each cc. also contains sodium citrate buffer, approximately 6 mg. lecithin, 3 mg. povidone, 1 mg. carboxymethylcellulose, 0.5 mg. sorbitan monopalmitate, 0.5 mg. polyoxyethylene sorbitan monopalmitate, 1.2 mg. methylparaben and 0.14 mg. propylparaben.

600,000 units in 1-cc. TUBEX® (sterile cartridge-needle unit) Wyeth, packages of 10.

1,200,000 units in 2-cc. TUBEX, packages of 10, and in 2-cc. single-dose disposable syringe.

2,400,000 units in 4-cc. single-dose disposable syringe.

Each TUBEX or disposable syringe also contains sodium citrate buffer and, as w/v, approximately 0.5% lecithin, 0.4% carboxymethylcellulose, 0.4% povidone, 0.09% methylparaben and 0.01% propylparaben.



INJECTION

BICILLIN® LONG-ACTING

(sterile benzathine penicillin G suspension)

Once-a-month rheumatic fever prophylaxis.

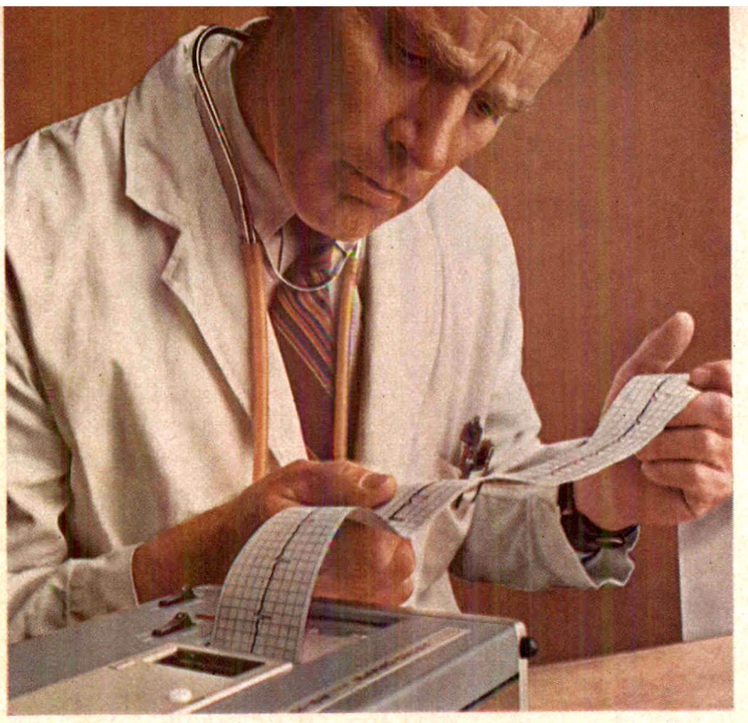
A27

When cardiac complaints occur in the absence of organic findings, underlying anxiety may be one factor



The influence of anxiety on heart function

Excessive anxiety is one of a combination of factors that may trigger a series of maladaptive functional reactions which can generate further anxiety. Often involved in this vicious circle are some cardiac arrhythmias, paroxysmal supraventricular tachycardia and premature systoles. When these symptoms resemble those associated with actual organic disease, the overanxious patient needs reassurance that they have no

---

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Relief of anxiety and tension occurring alone or accompanying various disease states.

Contraindications: Patients with known hypersensitivity to the drug.

Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. As with all CNS-acting drugs, caution patients against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Though physical and psychological dependence have rarely been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage; withdrawal symptoms (including convulsions), following discontinuation of the drug and similar to those seen with barbiturates, have been reported. Use of any drug in pregnancy, lactation, or in women of childbearing age requires that its potential benefits be weighed against its possible hazards.

Precautions: In the elderly and debilitated, and in children over six, limit to smallest effective dosage (initially 10 mg or less per day) to preclude ataxia or oversedation, increasing gradually as needed and tolerated. Not recommended in children under six. Though generally not recommended, if combination therapy with other psychotropics seems indicated, carefully consider individual pharmacologic effects, particularly in use of potentiating drugs such as MAO inhibitors and phenothiazines. Observe usual precautions

organic basis and that reduction of excessive anxiety and emotional overreaction would be medically beneficial.

The benefits of antianxiety therapy

Antianxiety medication, when used to complement counseling and reassurance, should be both effective and comparatively free from undesirable side effects. More than 13 years of extensive clinical experience has demonstrated that Librium (chlordiazepoxide HCl) fulfills these requirements with a high degree of consistency. Because of its wide margin of safety, Librium may generally be administered for extended periods, at the physician's discretion, without diminution of effect or need for increase in dosage. (See summary of prescribing information.) If cardiovascular drugs are necessary, Librium is used concomitantly whenever anxiety is a clinically significant factor. (See Precautions.) Librium should be discontinued when anxiety has been reduced to appropriate levels.

For relief of excessive anxiety adjunctive

Librium® 10 mg

(chlordiazepoxide HCl)

1 or 2 capsules t.i.d./q.i.d.

ROCHE

Roche Laboratories
Division of Hoffmann-La Roche Inc.
Nutley, N.J. 07110

---

in presence of impaired renal or hepatic function. Paradoxical reactions (*e.g.*, excitement, stimulation and acute rage) have been reported in psychiatric patients and hyperactive aggressive children. Employ usual precautions in treatment of anxiety states with evidence of impending depression; suicidal tendencies may be present and protective measures necessary. Variable effects on blood coagulation have been reported very rarely in patients receiving the drug and oral anticoagulants; causal relationship has not been established clinically.

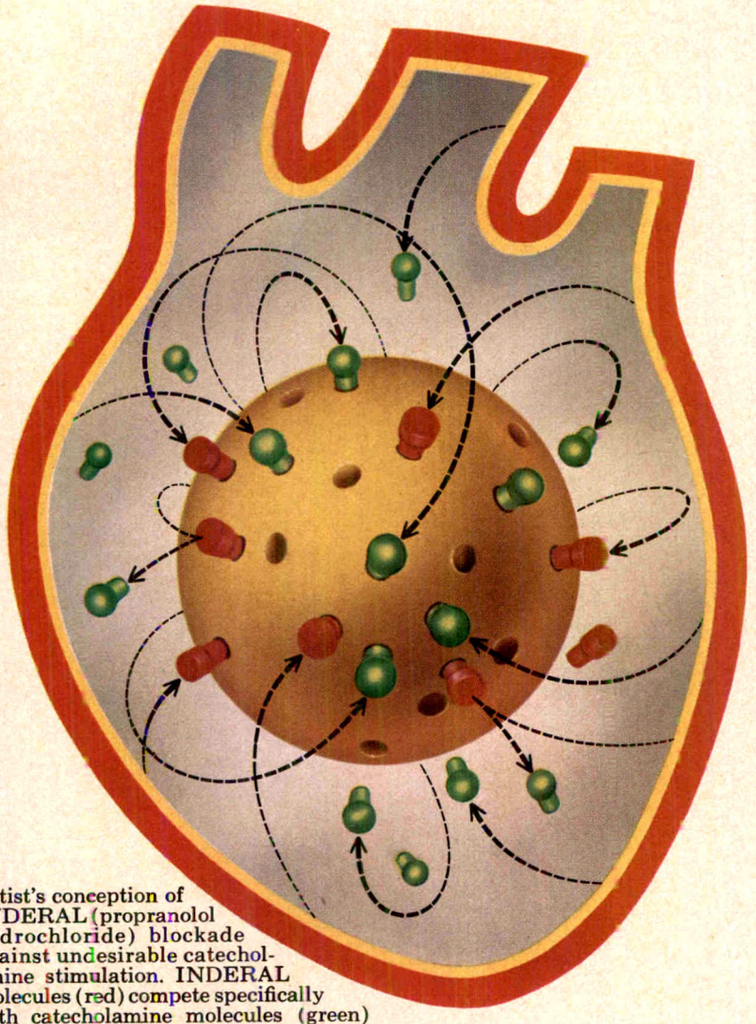
Adverse Reactions: Drowsiness, ataxia and confusion may occur, especially in the elderly and debilitated. These are reversible in most instances by proper dosage adjustment, but are also occasionally observed at the lower dosage ranges. In a few instances syncope has been reported. Also encountered are isolated instances of skin eruptions, edema, minor menstrual irregularities, nausea and constipation, extrapyramidal symptoms, increased and decreased libido—all infrequent and generally controlled with dosage reduction; changes in EEG patterns (low-voltage fast activity) may appear during and after treatment; blood dyscrasias (including agranulocytosis), jaundice and hepatic dysfunction have been reported occasionally, making periodic blood counts and liver function tests advisable during protracted therapy.

Supplied: Librium® Capsules containing 5 mg, 10 mg or 25 mg chlordiazepoxide HCl. Libritabs® Tablets containing 5 mg, 10 mg or 25 mg chlordiazepoxide.

When the heart is under catecholamine siege

INDERAL® Brand of propranolol hydrochloride

The beta-adrenergic blocking agent for many cardiac arrhythmias



Artist's conception of INDERAL (propranolol hydrochloride) blockade against undesirable catecholamine stimulation. INDERAL molecules (red) compete specifically with catecholamine molecules (green) for available beta-receptor sites in cardiac tissue. With fewer catecholamine molecules gaining access to these sites, beta-adrenergic stimulation is reduced proportionately.

As the first beta-adrenergic blocking agent in clinical cardiologic use, INDERAL (propranolol hydrochloride) helps prevent or control catecholamine-induced supraventricular cardiac arrhythmias by means of a unique mechanism of action.

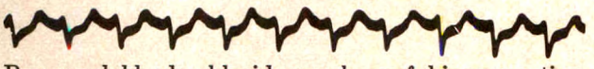
Excitatory adrenergic activity from sympathetic nerve endings and the adrenal medulla is mediated in myocardial and pacemaker tissue via beta receptors. Through blockade of undesirable catecholamine stimulation at these sites, INDERAL decreases impulse formation and conduction, and thus the rate and force of myocardial contraction. The clinical benefit is generally a reduction of supraventricular rate, a slowing of ventricular response, and restoration to sinus rhythm in many cases. In responsive patients, a subsequent maintenance regimen of 10 to 30 mg. INDERAL three or four times daily can prevent recurrence or reduce the frequency and severity of paroxysmal attacks.

With its unique site of action, INDERAL does not interfere with the therapeutic actions of nonadrenergic cardiotonic agents. Thus INDERAL can be used in combination—or alone—to control arrhythmias when other drugs have failed to produce a satisfactory response.

INDERAL is especially effective in the management of catecholamine-induced supraventricular arrhythmias. The response of ventricular arrhythmias is generally less predictable. INDERAL has proved to be of particular value in the control of digitalis-induced arrhythmias.

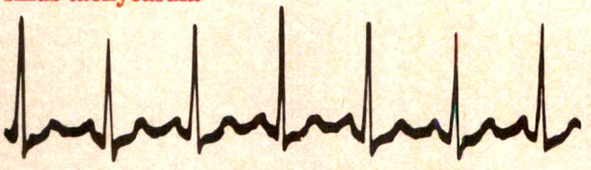
Proved effective over 6 years' clinical use

paroxysmal atrial tachycardia[1-8]



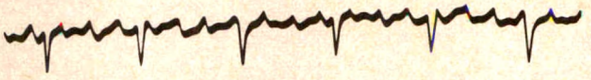
Propranolol hydrochloride may be useful in preventing recurrent attacks of paroxysmal atrial tachycardia "including attacks which may be a part of the Wolff-Parkinson-White syndrome."[1]

sinus tachycardia[9]



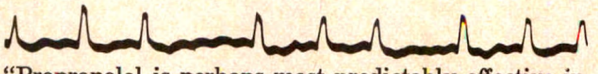
Sonnenblick "would use propranolol hydrochloride in treating a rapid sinus tachycardia which is poorly tolerated by the circulation—if the tachycardia were not due to some underlying process such as occult blood loss."[9]

atrial flutter[4-6,8-11]



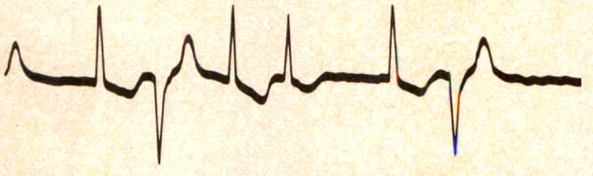
"In the presence of atrial flutter, ventricular rate is often difficult to control, and, as with an atrial fibrillation, propranolol hydrochloride should be added when the flutter is not being controlled by digitalis, especially in the presence of mitral valve disease."[9]

atrial fibrillation[1,3-10]



"Propranolol is perhaps most predictably effective in the treatment of patients with atrial fibrillation. It reduces the ventricular rate by prolonging the functional refractory period of the atrioventricular node. This occurs whether or not the patient is receiving digitalis."[3]

arrhythmias of digitalis intoxication[1,3-6,8-10]



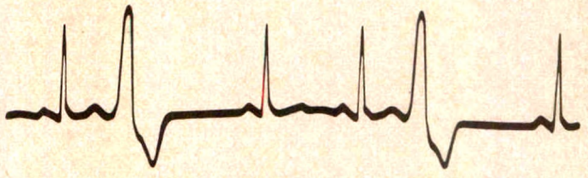
"Propranolol has been especially useful in treating patients with arrhythmias in the presence of established or suspected digitalis toxicity. All too common is the clinical situation in which we know the patient has had digitalis, but do not know whether he is toxic to digitalis. Propranolol may be a very useful drug in this situation."[1]

According to Wehrmacher, propranolol hydrochloride "is probably the treatment of choice for digitalis-induced tachyarrhythmias."[10]

ventricular tachycardias (when a matter of minutes in controlling the arrhythmia may mean life or death and when cardioversion technics are not available)[3,4,7,9,10,12]

"There appears to be a special place for the use of propranolol in patients with prolonged cardiac arrest associated with resistant, recurrent ventricular fibrillation. Propranolol has been shown to have an anti-fibrillatory effect, and we [the clinicians] believe it should be used when standard resuscitation methods and drugs have not produced a satisfactory cardiac rhythm."[12]

arrhythmias associated with anesthesia in selected cases[3,10,12-15]



In the treatment of cardiac disturbances occurring during and/or following halothane anesthesia for cardiovascular operations, 141 episodes in 115 patients "responded consistently to 1 to 2 mg. of propranolol intravenously without serious side effects. The onset of the drug's action was apparent within one to three minutes after its injection."[13]

Also recommended in the management of hypertrophic subaortic stenosis...[5,10,16]

Oral administration has produced symptomatic improvement in a large majority of patients, some treated for several days, and others for as long as several months.[10]

...and pheochromocytoma[3,6,8,10,17,18]

"When surgical removal [of the tumor in pheochromocytoma] is impossible, administration of both α- and β-adrenergic blocking drugs is essential for long-term control."[10]

Administered with awareness of the Contraindications, Warnings, Precautions, and Adverse Reactions, INDERAL (propranolol hydrochloride) provides a valuable tool in controlling a wide variety of cardiac arrhythmias, including cases that have proved refractory to previous therapy with other drugs.

With judicious use of INDERAL in suitably selected patients, symptomatic improvement is most frequently obtained; restoration to sinus rhythm is often possible.

BETA-BLOCKADE / **INDERAL**® (propranolol hydrochloride)

Ayerst®

(See last page of advertisement for prescribing information.)

BRIEF SUMMARY
(For full prescribing information, see package circular.)

INDERAL®
(propranolol hydrochloride)

A beta-adrenergic blocking agent

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

INDICATIONS

Cardiac Arrhythmias
1) Supraventricular arrhythmias
a) Paroxysmal atrial tachycardias, particularly those arrhythmias induced by catecholamines or digitalis or associated with the Wolff-Parkinson-White syndrome. (See W-P-W under WARNINGS.)
b) Persistent sinus tachycardia which is non-compensatory and impairs the well-being of the patient.
c) Tachycardias and arrhythmias due to thyrotoxicosis when causing distress or increased hazard and when immediate effect is necessary as adjunctive, short term (2-4 weeks) therapy.
May be used with, but not in place of, specific therapy. (See Thyrotoxicosis under WARNINGS.)
d) Persistent atrial extrasystoles which impair the well-being of the patient and do not respond to conventional measures.
e) Atrial flutter and fibrillation when ventricular rate cannot be controlled by digitalis alone, or when digitalis is contraindicated.
2) Ventricular tachycardias
Ventricular arrhythmias do not respond to propranolol as predictably as do the supraventricular arrhythmias.
a) Ventricular tachycardias
With the exception of those induced by catecholamines or digitalis, INDERAL is not the drug of first choice. In critical situations when cardioversion technics or other drugs are not indicated or are not effective, INDERAL may be considered. If, after consideration of the risks involved, INDERAL is used, it should be given intravenously in low dosage and very slowly. (See DOSAGE AND ADMINISTRATION.) *Care in the administration of* INDERAL *with constant electrocardiographic monitoring is essential as the failing heart requires some sympathetic drive for maintenance of myocardial tone.*
b) Persistent premature ventricular extrasystoles which do not respond to conventional measures and impair the well-being of the patient.
3) Tachyarrhythmias of digitalis intoxication
If digitalis-induced tachyarrhythmias persist following discontinuance of digitalis and correction of electrolyte abnormalities, they are usually reversible with *oral* INDERAL. Severe bradycardia may occur. (See OVERDOSAGE OR EXAGGERATED RESPONSE.)
Intravenous propranolol hydrochloride is reserved for life-threatening arrhythmias. Temporary maintenance with oral therapy may be indicated. (See DOSAGE AND ADMINISTRATION.)
4) Resistant tachyarrhythmias due to excessive catecholamine action during anesthesia
Tachyarrhythmias due to excessive catecholamine action during anesthesia may sometimes arise because of release of endogenous catecholamines or administration of catecholamines. When usual measures fail in such arrhythmias, INDERAL may be given intravenously to abolish them. All general inhalation anesthetics produce some degree of myocardial depression. Therefore, when INDERAL is used to treat arrhythmias during anesthesia, it should be used with extreme caution and constant ECG and central venous pressure monitoring. (See WARNINGS.)
Hypertrophic Subaortic Stenosis
INDERAL is useful in the management of hypertrophic subaortic stenosis, especially for treatment of exertional or other stress-induced angina, palpitations, and syncope. INDERAL also improves exercise performance. The effectiveness of INDERAL in this disease appears to be due to a reduction of the elevated outflow pressure gradient which is exacerbated by beta receptor stimulation. Clinical improvement may be temporary.
Pheochromocytoma
After primary treatment with an alpha-adrenergic blocking agent has been instituted, INDERAL may be useful as *adjunctive* therapy if the control of tachycardia becomes necessary before or during surgery.
It is hazardous to use INDERAL unless alpha-adrenergic blocking drugs are already in use, since this would predispose to serious blood pressure elevation. Blocking only the peripheral dilator (beta) action of epinephrine leaves its constrictor (alpha) action unopposed.
In the event of hemorrhage or shock, there is a disadvantage in having both beta and alpha blockade since the combination prevents the increase in heart rate and peripheral vasoconstriction needed to maintain blood pressure.
With inoperable or metastatic pheochromocytoma, INDERAL may be useful as an adjunct to the management of symptoms due to excessive beta receptor stimulation.

CONTRAINDICATIONS

INDERAL is contraindicated in: 1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS

CARDIAC FAILURE: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and inhibition with beta-blockade always carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. INDERAL acts selectively without abolishing the inotropic action of digitalis on the heart muscle (*i.e.* that of supporting the strength of myocardial contractions). However, the inotropic action of digitalis may be reduced by INDERAL's opposite inotropic effect. The effect of INDERAL and digitalis are additive in depressing AV conduction.
IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, continued depression of the myocardium over a period of time can, in some cases, lead to cardiac failure. In rare instances, this has been observed during INDERAL therapy. Therefore, at the first sign or symptom of impending cardiac failure, patients should be fully digitalized, and the response observed closely: (a) if cardiac failure continues, INDERAL therapy must be immediately withdrawn; (b) if tachyarrhythmia is being controlled, patients should be maintained on combined dosage and the patient closely followed until threat of cardiac failure is over.
IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term use have not been adequately appraised. Special consideration should be given to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of continuing hyperthyroidism or complications and give a false impression of improvement. Propranolol does not distort thyroid function tests.
IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg. propranolol.
IN PATIENTS DURING ANESTHESIA with agents that require catecholamine release for maintenance of adequate cardiac function, beta blockade will impair the desired inotropic effect. Therefore, INDERAL (propranolol hydrochloride) should be titrated carefully when administered for arrhythmias occurring during anesthesia.
IN PATIENTS UNDERGOING MAJOR SURGERY, beta blockade impairs the ability of the heart to respond to reflex stimuli. For this reason, with the exception of pheochromocytoma, INDERAL should be withdrawn 48 hours prior to surgery, at which time all chemical and physiologic effects are gone according to available evidence. However, in case of emergency surgery, since INDERAL is a competitive inhibitor of beta receptor agonists, its effects can be reversed by administration of such agents, *e.g.* isoproterenol or levarterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported.
IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.* CHRONIC BRONCHITIS, EMPHYSEMA), INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.
DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Because of its beta-adrenergic blocking activity, INDERAL may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia. Especially important with labile diabetics.
USE IN PREGNANCY: The safe use of INDERAL in human pregnancy has not been established. Use of any drug in pregnancy or women of childbearing potential requires that the possible risk to mother and/or fetus be weighed against the expected therapeutic benefit.

PRECAUTIONS

Patients receiving catecholamine depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine blocking action of this drug may then produce an excessive reduction of the resting sympathetic nervous activity. Occasionally, the pharmacologic activity of INDERAL may produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.
In chronically treated patients, dosage should be gradually reduced over a two week period when it is anticipated that the administration of INDERAL will be discontinued. There have been a few reports of myocardial infarction occurring within 2-3 days of propranolol hydrochloride discontinuation in angina pectoris patients, but an association has not yet been established.
As with any new drug given over prolonged periods, laboratory parameters should be observed at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function.

ADVERSE REACTIONS

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura
Central Nervous System: lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics
Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation
Allergic: pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress
Respiratory: bronchospasm
Hematologic: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura
Miscellaneous: reversible alopecia
Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase

DOSAGE AND ADMINISTRATION

The oral route of administration is preferred.
ORAL
ARRHYTHMIAS—10-30 mg. three or four times daily, before meals and at bedtime.
HYPERTROPHIC SUBAORTIC STENOSIS—20-40 mg. three or four times daily, before meals and at bedtime.
PHEOCHROMOCYTOMA—*Preoperatively*—60 mg. daily in divided doses for three days prior to surgery, concomitantly with an alpha-adrenergic blocking agent.—*Management of inoperable tumor*—30 mg. daily in divided doses.
PEDIATRIC DOSAGE
At this time the data on the use of the drug in this age group are too limited to permit adequate directions for use.
INTRAVENOUS
Intravenous administration is reserved for life-threatening arrhythmias or those occurring under anesthesia. The usual dose is from 1 to 3 mg. administered under careful monitoring, *e.g.* electrocardiographic, central venous pressure. The rate of administration should not exceed 1 mg. (1 cc.) per minute to diminish the possibility of lowering blood pressure and causing cardiac standstill. Sufficient time should be allowed for the drug to reach the site of action even when a slow circulation is present. If necessary, a second dose may be given after two minutes. Thereafter, additional drug should not be given in less than four hours. Additional INDERAL should not be given when the desired alteration in rate and/or rhythm is achieved.
Transference to oral therapy should be made as soon as possible.

OVERDOSAGE OR EXAGGERATED RESPONSE

IN THE EVENT OF OVERDOSAGE OR EXAGGERATED RESPONSE, THE FOLLOWING MEASURES SHOULD BE EMPLOYED:
BRADYCARDIA—ADMINISTER ATROPINE (0.25 to 1.0 mg.): IF THERE IS NO RESPONSE TO VAGAL BLOCKADE, ADMINISTER ISOPROTERENOL CAUTIOUSLY
CARDIAC FAILURE—DIGITALIZATION AND DIURETICS
HYPOTENSION—VASOPRESSORS, *e.g.* LEVARTERENOL OR EPINEPHRINE (THERE IS EVIDENCE THAT EPINEPHRINE IS THE DRUG OF CHOICE.)
BRONCHOSPASM—ADMINISTER ISOPROTERENOL AND AMINOPHYLLINE

HOW SUPPLIED

INDERAL (propranolol hydrochloride)

TABLETS—No. 461—Each tablet contains 10 mg. of propranolol hydrochloride, in bottles of 100 and 1,000.
No. 464—Each tablet contains 40 mg. of propranolol hydrochloride, in bottles of 100 and 1,000.
INJECTABLE—No. 3265—Each cc. contains 1 mg. of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as: 1 cc. ampuls in boxes of 10.

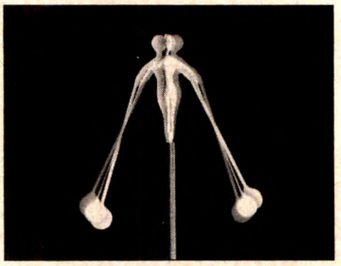
NIT DOSE CONVENIENCE—Tablets individually foil-wrapped

LORVESS offers what you and the patient like

Dorsey
ABORATORIES
vision of Sandoz-Wander, Inc.



KLORVESS®
Effervescent Tablets

Description: Each dry effervescent tablet contains 20 mEq. each of potassium and chloride supplied by potassium chloride 1.125 g., potassium bicarbonate 0.5 g., l-lysine hydrochloride 0.913 g. Solution of the tablet in water provides the potassium and chloride available for oral ingestion as potassium chloride, potassium bicarbonate, potassium citrate, and l-lysine hydrochloride.

Indications: For prevention or correction of potassium depletion and hypokalemic alkalosis. Especially useful when thiazide diuretics or corticosteroids cause excessive excretory potassium losses.

Contraindications: Severe renal impairment with oliguria or azotemia, untreated Addison's disease, adynamia episodica hereditaria, acute dehydration, heat cramps, and hyperkalemia from any cause.

Precautions: In response to a rise in the concentration of body potassium, renal excretion of the ion is increased. With normal kidney function, it is difficult, therefore, to produce potassium intoxication by oral administration. However, potassium supplements must be administered with caution, since the amount of the deficiency or daily dosage is not accurately known. Frequent checks of the clinical status of the patient, and periodic ECG and/or serum potassium levels should be made. High serum concentrations of potassium ion may cause death through cardiac depression, arrhythmias or arrest. This drug should be used with caution in the presence of cardiac disease. Potassium supplements should be given cautiously to digitalized patients. To minimize the possibility of gastrointestinal irritation associated with the oral ingestion of concentrated potassium salt preparations, patients should be carefully directed to dissolve each tablet completely in the stated amount of water.

Adverse Reactions: Vomiting, diarrhea, nausea and abdominal discomfort may occur with the use of potassium salts. The symptoms and signs of potassium intoxication include paresthesias of the extremities, flaccid paralysis, listlessness, mental confusion, weakness and heaviness of the legs, fall in blood pressure, cardiac arrhythmias and heart block. Hyperkalemia may exhibit the following electrocardiographic abnormalities: disappearance of the P wave, widening and slurring of QRS complex, changes of the S-T segment, and tall, peaked T waves.

Dosage and Administration: Adults: 1 tablet (20 mEq. each of potassium and chloride) completely dissolved in 3 to 4 ounces of cold water 2 to 4 times daily depending upon the requirements of the patient. The approximate minimum adult daily requirement of potassium is 40 mEq. Deviations from this recommendation may be indicated, since no average total daily dose can be defined but must be governed by close observation for clinical effects.
NOTE: Klorvess should be taken with meals.

Overdosage: Potassium intoxication may result from overdosage of potassium or from therapeutic dosage in conditions stated under "Contraindications." Hyperkalemia, when detected, must be treated immediately because lethal levels can be reached in a few hours.

How Supplied: Klorvess Tablets (white, round) in boxes of 60 (2 Rx units of 30, NDC 43-100-87). Each tablet is individually foil wrapped.

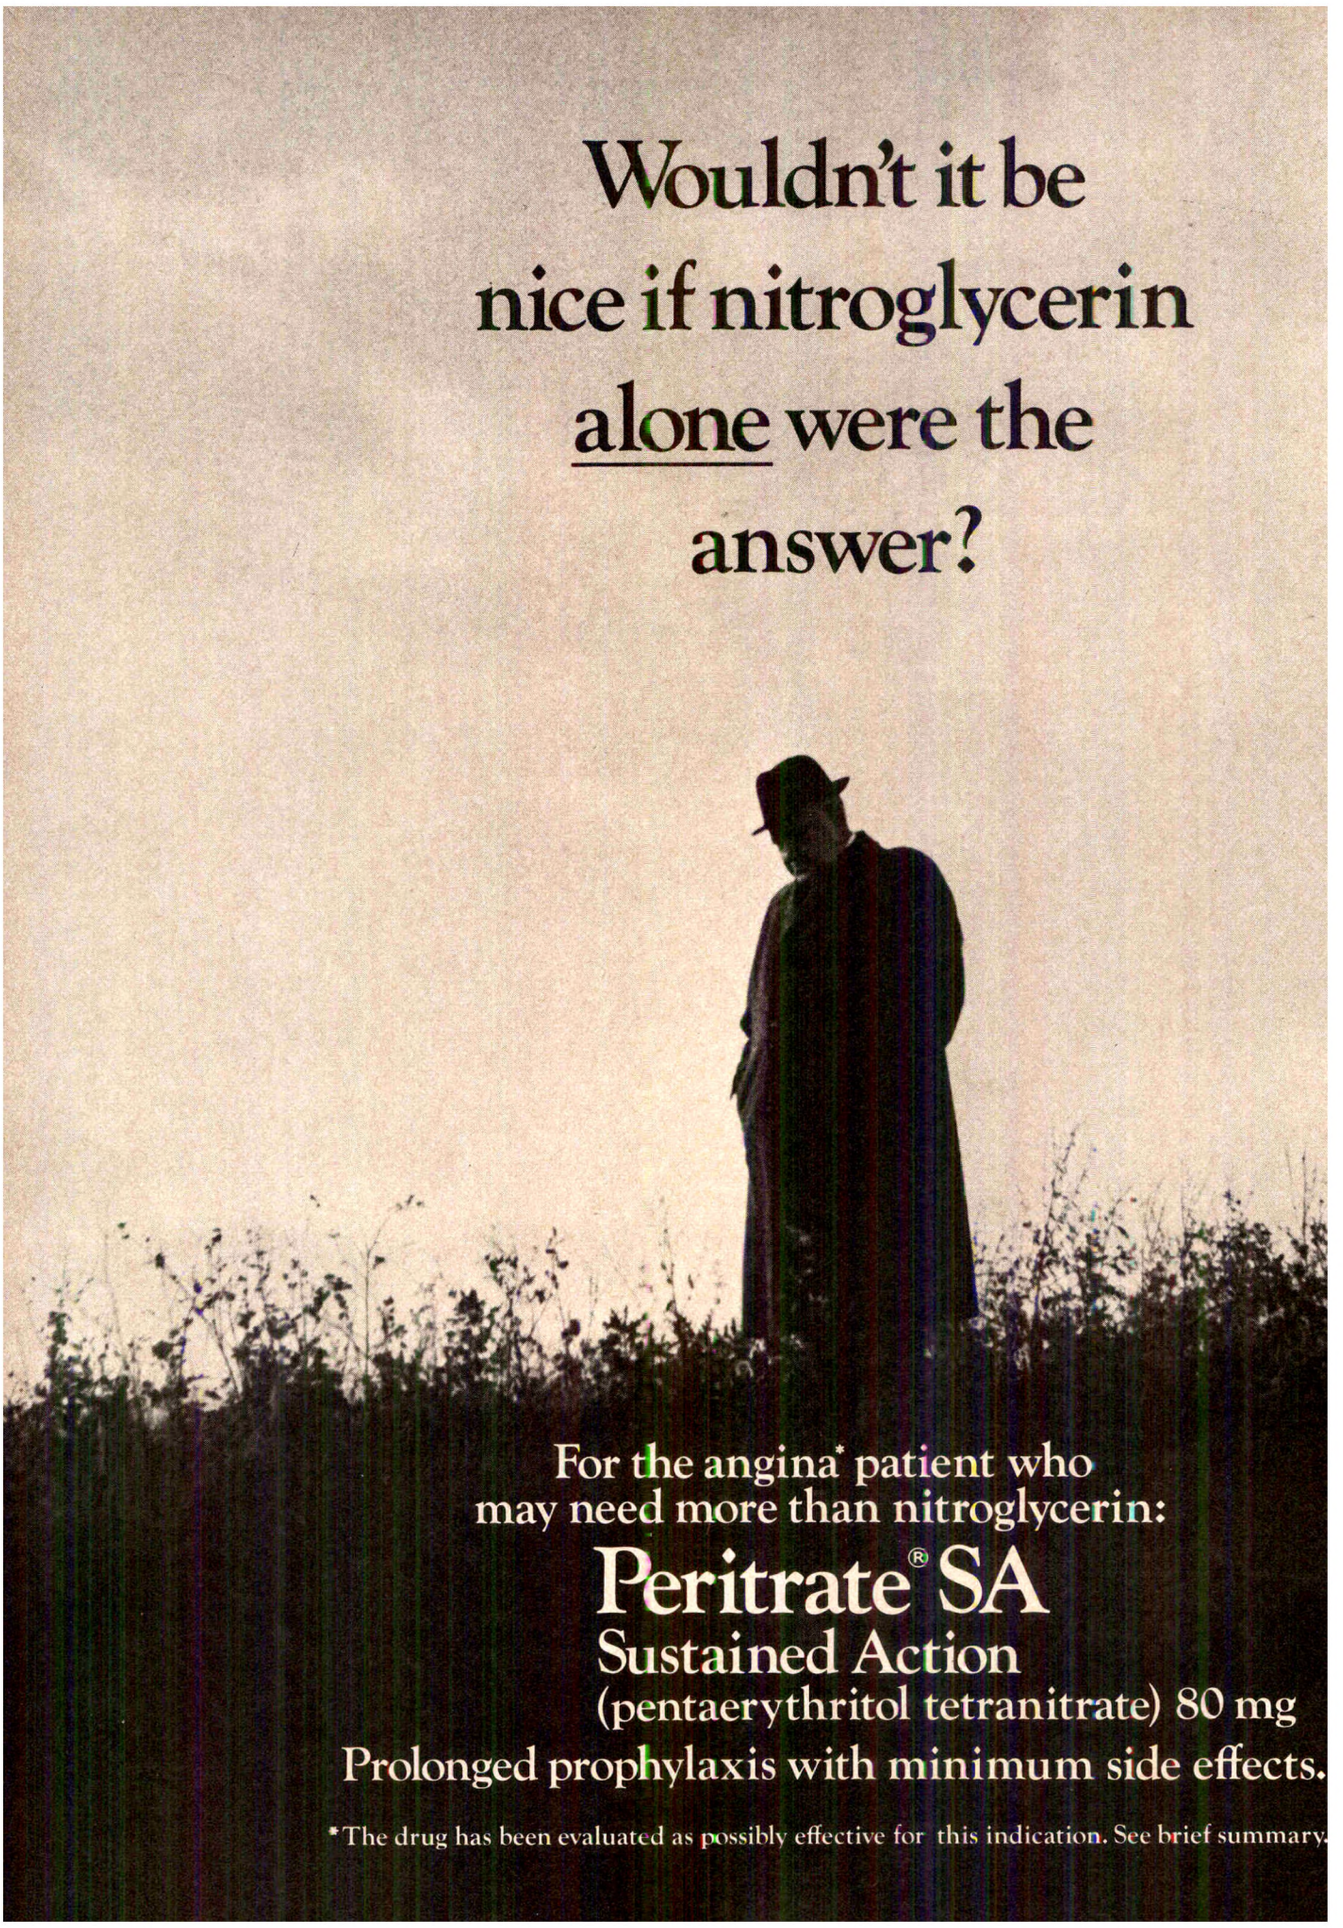
ABC

Wouldn't it be nice if nitroglycerin alone were the answer?



For the angina* patient who may need more than nitroglycerin:

Peritrate® SA

Sustained Action

(pentaerythritol tetranitrate) 80 mg

Prolonged prophylaxis with minimum side effects.

*The drug has been evaluated as possibly effective for this indication. See brief summary.

Peritrate® SA

Sustained Action
(pentaerythritol tetranitrate) 80 mg

CAUTION: Federal law prohibits dispensing without prescription.

Each tablet of Peritrate SA Sustained Action contains: pentaerythritol tetranitrate 80 mg (20 mg in immediate release layer and 60 mg in sustained release base). Peritrate® (pentaerythritol tetranitrate) is a nitric acid ester of a tetrahydric alcohol (pentaerythritol).

Indications: Based on a review of this drug by the National Academy of Sciences–National Research Council and/or other information, FDA has classified the indications as follows:

"Possibly" effective: Peritrate (pentaerythritol tetranitrate), is indicated for the relief of angina pectoris (pain associated with coronary artery disease). It is not intended to abort the acute anginal episode but it is widely regarded as useful in the prophylactic treatment of angina pectoris.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg is contraindicated in patients who have a history of sensitivity to the drug.

Warning: Data supporting the use of Peritrate (pentaerythritol tetranitrate) during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents.

Precautions: Should be used with caution in patients who have glaucoma. Tolerance to this drug, and cross-tolerance to other nitrites and nitrates may occur.

Adverse Reactions: Side effects reported to date have been predominantly related to rash (which requires discontinuation of medication) and headache and gastrointestinal distress, which are usually mild and transient with continuation of medication. In some cases severe persistent headaches may occur.

In addition, the following adverse reactions to nitrates such as pentaerythritol tetranitrate have been reported in the literature:

(a) Cutaneous vasodilatation with flushing.
(b) Transient episodes of dizziness and weakness, as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop.
(c) An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur, even with the usual therapeutic doses. Alcohol may enhance this effect.

Dosage: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg (b.i.d. on an empty stomach), 1 tablet immediately on arising and 1 tablet 12 hours later.

Supplied: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg, double layer, biconvex, dark green/light green tablets in bottles of 100 and 1000.

Additional Dosage Forms: Peritrate 20 mg–light green, scored tablets; Peritrate 10 mg–light green, unscored tablets. Bottles of 100 and 1000. Full information is available on request.

Nitro-Bid® (nitroglycerin) therapy assists in the "total management" of your patient.

Nitro-Bid capsules reduce sublingual nitroglycerin requirements as they reduce the number of angina attacks . . . increase exercise tolerance.

The Third Step in Angina.*

After the classic "2-Step" Test aids in a diagnosis of angina, sustained-release Nitro-Bid® (nitroglycerin) is a logical third step. Here's why.

In angina secondary to arteriosclerotic heart disease, sustained-release Nitro-Bid Plateau CAPS® provide a metered sequence of medication during the night to protect against nocturnal angina attack.

In titrating dosage, availability of different strengths "...is quite an asset..."[1]

Nitro-Bid 2.5 and Nitro-Bid 6.5 capsules afford two dosage strengths for convenience in increasing or decreasing dose to accommodate patient symptoms.

NITRO-BID® 2.5
(nitroglycerin 2.5 mg) Plateau CAPS®

NITRO-BID® 6.5
(nitroglycerin 6.5 mg) Plateau CAPS®

INDICATIONS

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

*"Possibly" effective:
For the management, prophylaxis or treatment of anginal attacks.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Recent myocardial infarction, severe anemia, glaucoma, increased intracranial pressure, idiosyncrasy.
Precautions: For ORAL, not sublingual, use. If blurring of vision or dryness of mouth occurs, discontinue drug. Tolerance may develop on long-term usage.
Adverse Reactions: Occasional transient headaches. Overdose may cause flushing, headaches, tachycardia, dizziness.
Dosage: One capsule two or three times daily at 8 to 12 hour intervals.
Reference: 1. Master, AM: The management of angina pectoris. *Modern Medicine* **38**:92-100 (Feb 23) 1970.

Make Life Easier For You And Your Pacer Patients

Now, with the advent of the ESB Medcor Pacer-Check* system, it is possible for your office to conduct regular, accurate recordings of heart pacer patient's ECG and pacer rates by telephone.

Both you and your patients benefit. Now, with no more than a phone call, you can have information which permits elective decisions on replacement rather than emergency or prophylactic replacements. (By using a regular patient checking program, maximum pacer life can be realized.) Your patient and you have flexibility and safety at the same time.

This two-component system operates simply, requiring minimal training to both your personnel and patients.

The Medic Unit, at left, is the central component and is usually located in the hospital or clinic. It receives ECG and pacer rate input via unaltered telephones from the Patient Unit which is usually located in the patient's home. ECG data, produced on a standard paper chart, indicates the relationship between the QRS complex and pacer artifact to ascertain pacer capture. Pacer rate is shown continuously by illuminated numbers on the front panel. This is the first system available to physicians that records ECG and simultaneously displays pacer rate.

The Patient Unit is lightweight and battery powered. It is capable of transmitting from any telephone to your office. Transmissions have been successfully made from such great distances as Tokyo to New York. To operate, the patient places the telephone headset in the receiving cradle and then slips the two expandable bracelets over his forearms. Transmission begins immediately.

The Pacer-Check* system, approved for reimbursement by Medicare, has proven itself a useful and self-supporting method of maintaining a desirable pacer program.

If the unique qualities of the Pacer-Check* system interest you, contact ESB Medcor, Inc., Dept. 373, 5920 Rodman St., Hollywood, Florida 33023. Toll free call: (800) 327-9780, Ext. 373.

ESB Medcor™

HEMODYNAMICS OF ANGINA PECTORIS* — PATIENTS RESTING AND EXERCISING, BEFORE AND AFTER ISORDIL® SUBLINGUAL
(isosorbide dinitrate)

BEFORE MEDICATION		AFTER 5 mg. ISORDIL SUBLINGUAL (isosorbide dinitrate)
	PULMONARY ARTERY (MEAN PRESSURE)		TOTAL PULMONARY RESISTANCE		CARDIAC INDEX		BRACHIAL ARTERY (MEAN PRESSURE)		TOTAL SYSTEMIC RESISTANCE	
IN ANGINA PECTORIS*

- to abort or terminate acute anginal attacks
- to reduce the frequency and severity of anginal episodes often caused by unavoidable everyday stress

ISORDIL® SUBLINGUAL
(ISOSORBIDE DINITRATE)

SUBLINGUAL TABLETS: 2.5 mg. and 5 mg.

***Indications:** Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indication as follows:
"Probably" effective: When taken by the sublingual route, Isordil Sublingual is indicated for the treatment of acute anginal attacks and for prophylaxis in situations likely to provoke such attacks.
Final classification of the less-than-effective indications requires further investigation.

Contraindication: Idiosyncrasy to this drug.

Warnings: Data supporting the use of nitrites during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

Precautions: Tolerance to this drug and cross-tolerance to other nitrites and nitrates may occur.

Adverse Reactions: Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents. An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

Consult direction circular before prescribing.

May we send you reprints, detailed information and/or professional samples?

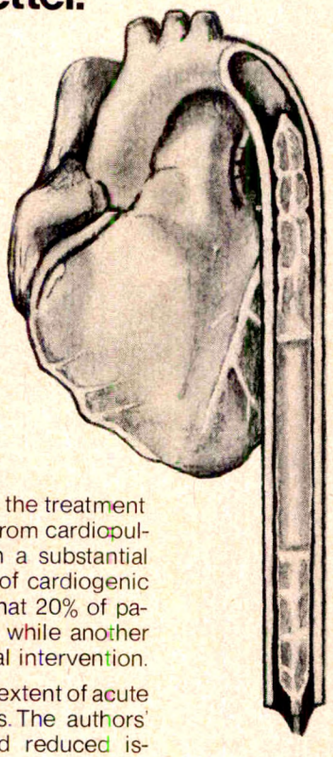
DEDICATED TO IMPROVING THE QUALITY OF LIFE, THROUGH MEDICINE

Adapted from: Kasparian H, Najmi M, Likoff W: Laboratory Evaluation of Coronary Artery Disease. Scientific Exhibit, AMA Convention, Chicago, Ill, June 1966.

"a life-saving measure in a substantial minority of patients"[1]

The Avco Intra-Aortic Balloon Pump* ...and the Sooner, the Better.

The rationale of intra-aortic balloon pump (IABP) therapy in low-cardiac output conditions is widely accepted. By lowering pressure in the proximal aorta at the beginning of systole, myocardial work load is lessened. Also, by augmenting pressure during early diastole, pumping improves coronary perfusion and can open dormant collaterals. Thus a better balance between myocardial oxygen demand and consumption is obtained.



Documented effectiveness

The IABP's effectiveness is clinically proven in the treatment of cardiogenic shock and in weaning patients from cardiopulmonary bypass. It is a "lifesaving measure in a substantial minority of patients who would otherwise die of cardiogenic shock."[1] Braunwald and Maroko[2] estimate that 20% of patients who would otherwise die can be saved, while another 20% can be stabilized for diagnosis and surgical intervention.

IABP "significantly reduced the magnitude and extent of acute myocardial ischemic injury"[3] in animal studies. The authors' preliminary clinical results also demonstrated reduced ischemia as well as hemodynamic improvement.

Time a critical factor

Hemodynamic criteria to determine if a patient who seems to be going into cardiogenic shock is responding to treatment have been developed by Leinbach.[4] These criteria are a major contribution to the effective application of IABP treatment since *early use* of the system greatly increases the chances of success. Buckley and associates[5] used the IABP in 27 heart-surgery patients who went into shock upon termination of cardiopulmonary bypass. Eighteen survived; 13 are long term survivors. Best results occurred with initiation of IABP therapy early in the postoperative period.

*Developed by Avco Corporation and manufactured for Roche Medical Electronics Division.

The IABP versus drugs

Dunkman and others[6] have concluded that "catecholamines may actually increase ventricular dysfunction and necrosis" whereas the IABP's enhancement of coronary perfusion and reduction of oxygen-consuming work in the left ventricle can save patients if applied before about 40% of the left ventricle is irretrievably damaged. Moreover, IABP permits safe use of drugs if needed.

AVCO, the most experienced system

The internal counterpulsation system most widely used clinically is the Avco IABP. There are some very practical reasons for this dominance.

Patented 3-chamber balloon design prevents end occlusion.

QRS triggered synchronization with normal and abnormal rhythms.

Automatic reset for changes in interval or loss of R wave.

Safety engineering with fail-safe venting, self-initiated trouble identification, and emergency compressor with independent power supply.

Nationwide on-site service.

Vitatron Medical upgrade pacemaker reliability

Vitatron Medical now have upgraded the reliability of their pacemakers by application of a new HgO-Zn battery. This battery was specially designed for pacemakers and has a higher energy density and a better dependability.

Battery failure rate is no more than 0.05%/1000h. This new development, together with the battery switch reduces current consumption during transportation and storage to an absolute minimum, increasing pacemaker longevity by 50%.

The small dimensions, light weight, ideal shape and easy electrode connection make the new generation of Vitatron Medical pacemakers extremely easy to implant and assure a minimum of post-operative complications.

The unique intracardial electrode type MIP 2000 with means for fixation to the heartwall allows accurate placement of transvenous electrodes in more difficult cases.

Pacemaker follow-up reliability is achieved by Vitatron Medical's completely analysable pacing system consisting of the VCA pacemaker and the fully automized type MPA 1 digital pacemaker analyzer.

bureau IPS rotterdam

NEW FROM AYERST

the "healthy" hypertensive

It may be years before he experiences a single symptom of hypertension. But left untreated, even mild to moderate elevations of blood pressure may quietly strip years from an otherwise healthy and active life. Early control with DIUCARDIN may help forestall damage to healthy target organs.

DIUCARDIN provides approximately the same diuretic potency as hydrochlorothiazide at maximal therapeutic dosage. With DIUCARDIN, the onset of diuresis is gradual and may be maintained for twelve hours or more with a single dose.[1,2] The antihypertensive effect of DIUCARDIN is usually maintained in long term use. For many patients on DIUCARDIN, a convenient once-a-day dosage may suffice.

Based on efficacy *and* economy, DIUCARDIN provides a good beginning for many hypertensive patients. New DIUCARDIN 50 mg. Tablets. For mild to moderate hypertension and adjunctive therapy for many types of edema.

Ayerst®

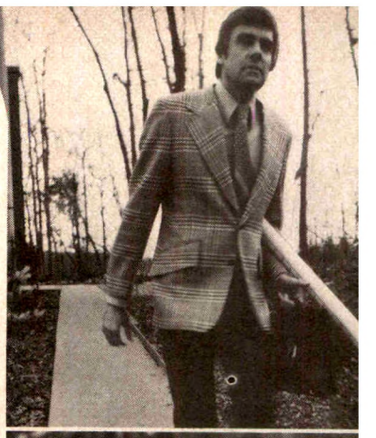
controlled early on

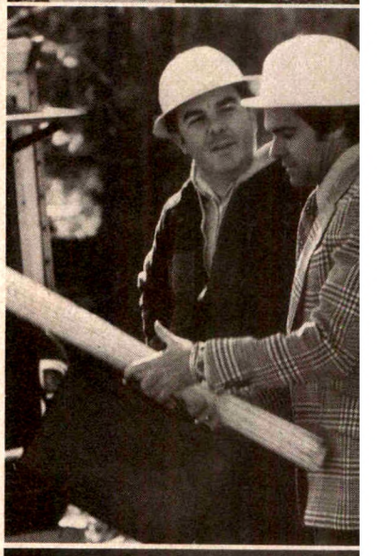
Diucardin® TABLETS

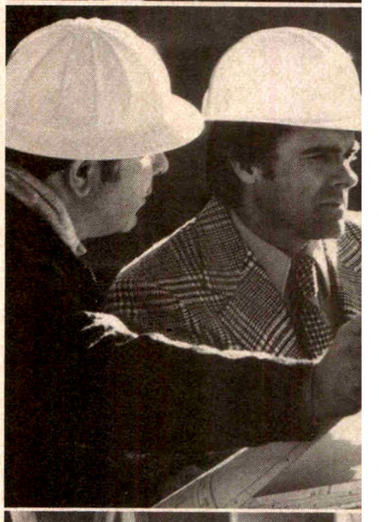
(hydroflumethiazide)

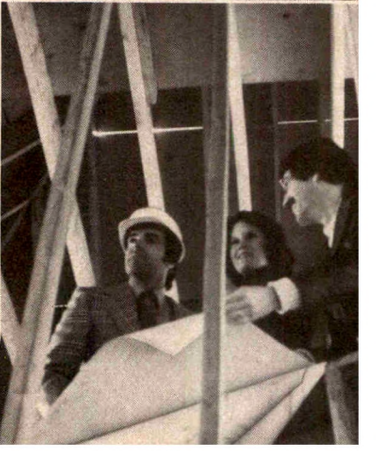
diuretic/antihypertensive

(See prescribing information on next page.)









NEW FROM AYERST

For the "healthy" hypertensive, early control with

Diucardin® TABLETS (hydroflumethiazide)

diuretic/antihypertensive

BRIEF SUMMARY

(For full prescribing information, see package circular.)

ACTIONS: The primary action of the thiazide diuretics is to produce diuresis by increasing the renal excretion of sodium and chloride. They inhibit the mechanism for tubular reabsorption of sodium and chloride by direct action on the distal segment. At maximal therapeutic dosage all thiazides are approximately equal in their diuretic potency.

The mechanism(s) of the antihypertensive action of the thiazides has not been elucidated.

INDICATIONS: **Hypertension:** DIUCARDIN alone may provide adequate control in mild or moderate hypertension. In severe hypertension or in cases of mild or moderate hypertension which do not respond adequately, DIUCARDIN may be used in conjunction with other antihypertensive agents.

DIUCARDIN alone or in conjunction with other antihypertensive agents is indicated for control of hypertension in pregnancy. (See WARNINGS)

Edema: DIUCARDIN is indicated as adjunctive therapy in edema associated with congestive heart failure, hepatic cirrhosis, and corticosteroid and estrogen therapy.

DIUCARDIN is indicated in severe edema during pregnancy. (See WARNINGS)

DIUCARDIN is indicated in the treatment of edema due to various forms of renal dysfunction, *e.g.* nephrotic syndrome, acute glomerulonephritis, and chronic renal failure.

CONTRAINDICATIONS: Anuria, oliguria. Hypersensitivity to DIUCARDIN or other sulfonamide derivatives.

The routine use of diuretics in an otherwise healthy pregnant woman with or without mild edema is contraindicated and possibly hazardous.

WARNINGS: Use with caution in severe renal disease since thiazides may precipitate azotemia. Effects due to accumulation of the drug may occur in patients with impaired renal function.

Use with caution in patients with impaired hepatic function or progressive liver disease since minor changes of fluid and electrolyte balance may precipitate hepatic coma.

Use with caution when hydroflumethiazide is administered in conjunction with other antihypertensive agents. Lowering of dosage of these agents is usually indicated. Thiazides potentiate ganglionic or peripheral adrenergic blocking drugs.

Sensitivity reactions may occur in patients with a history of allergy or bronchial asthma.

The possibility of exacerbation or activation of systemic lupus erythematosus has been reported.

Usage in Pregnancy and During Lactation: Thiazides cross the placental barrier and also appear in breast milk. Consequently, they may cause fetal or neonatal hyperbilirubinemia, thrombocytopenia, altered carbohydrate metabolism and other adverse reactions. Therefore, the potential benefits of thiazide administration in women of childbearing age must be weighed against the possible hazards to the fetus or child.

PRECAUTIONS: Tests should be made at appropriate intervals to detect possible electrolyte imbalance, *i.e.* hypokalemia, hyponatremia, and hypochloremic alkalosis. All patients taking thiazides should be observed for signs and symptoms of electrolyte or fluid imbalance, namely dryness of mouth, thirst, weakness, lethargy, drowsiness, restlessness, muscle pains or cramps, muscular fatigue, hypotension, oliguria, tachycardia, and gastrointestinal disturbances such as nausea and vomiting. Serum and urine electrolyte determinations are particularly important if the patient is vomiting excessively or receiving parenteral fluids.

If hypokalemia should develop, dietary potassium supplementation or the use of dilute potassium solutions should be tried. Small bowel lesions have been reported following the administration of enteric coated, concentrated preparations of potassium salts.

Dilutional hyponatremia may occur in edematous patients during hot weather. Water restriction rather than administration of salt is appropriate except in rare cases when hyponatremia is life-threatening. In actual salt depletion, appropriate replacement should be given.

Hypochloremia is generally mild and usually does not require specific treatment except under extraordinary circumstances, as in renal or liver disease.

The possibility of development of electrolyte or fluid imbalance is increased by brisk diuresis, severe liver disease, or concomitant administration of medications such as digitalis, ACTH, and corticosteroids.

Adequate oral intake of electrolytes should be maintained to minimize the possibility of electrolyte imbalance.

If a progressive increase in serum nitrogen occurs, a careful appraisal of the patient's condition should be made to determine whether diuretic therapy should be continued.

Because of the possibility of hypokalemia developing, patients taking digitalis should be followed carefully since a decrease in body potassium may necessitate lowering digitalis dosage.

Plasma uric acid levels may be increased and could, in susceptible patients, precipitate an attack of gout.

Thiazides alter carbohydrate metabolism. Patients who have diabetes mellitus or are suspected of being prediabetic should be followed closely since hyperglycemia and glycosuria may occur. Dosage adjustment of antidiabetic agents is frequently indicated.

Thiazides may decrease serum PBI without signs of thyroid disturbance.

Thiazides act to decrease the response of the peripheral arterial system to catecholamines and to enhance the effects of curare and its derivatives. Caution should be exercised in administering general anesthesia or curare derivatives to patients taking thiazides.

The antihypertensive effect of thiazides may be enhanced following sympathectomy.

ADVERSE REACTIONS: **Gastrointestinal:** anorexia, gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, acute pancreatitis. **Central Nervous System:** dizziness, vertigo, headache, paresthesias, xanthopsia, restlessness.

Hematologic: leukopenia, thrombocytopenia, agranulocytosis, aplastic anemia.

Allergic: purpura, photosensitivity, rash, urticaria, necrotizing angiitis, exfoliative dermatitis, glomerulonephritis, intrahepatic cholestatic hepatitis.

Cardiovascular: orthostatic hypotension (may be aggravated by alcohol, barbiturates, or narcotics).

Musculoskeletal: muscle cramps, weakness.

Clinical Laboratory Test Findings: electrolyte imbalance, elevation of serum nitrogen, elevation of plasma uric acid, hyperglycemia and glycosuria, decreased serum PBI levels.

DOSAGE AND ADMINISTRATION: **Usual adult dosage:** 50-100 mg. per day.

The dosage regimen should be individualized to obtain the maximum effect at the lowest dosage level. Dosage regimens using 25 mg. DIUCARDIN (hydroflumethiazide) may be adequate in some cases. Dosage should not exceed 200 mg. per day.

HOW SUPPLIED: DIUCARDIN — No. 702 — Each scored tablet contains 50 mg. hydroflumethiazide, in bottles of 100 and 1,000.

Bright new talk show.

We've just come out with a series of patient monitoring modules that are completely new. From their brighter digital displays to their broader capabilities, they talk to you loud and clear.

First the digital displays.

Characters are more than a ½ inch high, and they form solid lines of light which are easily readable across a room or down a corridor.

They flash HI, LO and OFF (in response to high and low alarms and leads off) and, of course, numerical values.

All alarm set points can be read directly on the digital display, improving the accuracy of the setting.

Displays can be darkened at night so as not to disturb a patient. In the event of an alarm, they automatically re-appear.

Now for capability.

Our HR-3 Digital Heart Rate Module is physically independent of the ECG amplifier and can be placed at bedside, central station, or both. It monitors heart rate and eliminates artifacts. It even ignores pacemaker spikes when used with B-D Electrodyne's new ECG amplifier.

Our PR-18 Digital Pressure Module processes and provides two displays to show systolic and diastolic or mean pressures simultaneously. It also has adjustable high and low settings for each pressure. All in one module.

So now you have a lot more reasons for looking into a B-D Electrodyne monitoring system. And if you're using one of ours right now, these new B-D Electrodyne digital modules will fit right in. Remember: one thing you *don't* buy from B-D Electrodyne is obsolescence. Why not send for details? B-D ELECTRODYNE, Division of Becton, Dickinson and Company, Sharon, Massachusetts 02067 (617) 828-9080.

Contraindications: There are no absolute contraindications to digitalis. However, in ventricular paroxysmal tachycardia or ventricular fibrillation, it should be used *only* in refractory cases not induced by digitalis intoxication and if heart failure has developed.

Precautions: If the patient has been given digoxin during the previous week or any other less rapidly excreted drug of the digitalis group during the previous two weeks, the dose of Lanoxin brand Digoxin must be reduced accordingly. Because of impaired renal function and excretion in elderly patients, they frequently require lower than recommended doses.

Potassium loss in patients sensitizes the heart to digitalis intoxication even with recommended doses. The diuretic agents as well as electrolyte manipulations by the physician are major causes of potassium depletion in cardiac patients. Under these conditions, it may be necessary to reduce the usual dosages of Lanoxin brand Digoxin during digitalization and maintenance.

Digoxin is usually ineffective in cases of cardiac failure due to mechanical causes which are independent of myocardial diseases, e.g., cardiac tamponade, or to disorders not primarily of cardiac origin, as severe anemia. Despite a variable or poor response to digoxin in the presence of active rheumatic carditis, the development of cardiac failure is an indication for its use.

Effects of Overdosage and Treatment: The symptoms of overdosage with digoxin are quite similar to those occurring with other digitalis preparations. The most common toxic manifestations are anorexia, nausea, vomiting and various cardiac arrhythmias, including ventricular extrasystoles and paroxysmal supraventricular tachycardia or fibrillation with A-V block. In general, the gastrointestinal manifestations of toxicity with digoxin precede the cardiac arrhythmias occurring from overdosage. Furthermore, because of the rapid dissipation of digoxin, manifestations of toxicity are of short duration, usually lasting from a few hours to one or two days.

If necessary, potassium chloride may be administered as an intravenous infusion containing (adult dosage) 40 milliequivalents in 500 cc. of 5% dextrose in water, given over the course of 1 hour and repeated, if required, until a total of 120 milliequivalents have been given (1 mEq. KCl = 74.5 mg.). Electrocardiographic monitoring should be conducted and the infusion halted immediately upon the appearance of peaking of the T-waves. For children, the intravenous infusion dosage of potassium chloride would be 5 to 10 milliequivalents in 100 cc. of 5% dextrose in water given over the course of 1 hour, repeated if required, to a total of 15 to 30 milliequivalents. For more serious intoxication with abnormal cardiac rhythms, potassium chloride may be given orally in divided doses totalling 4 to 6 grams per day (adults) or 1 to 2 grams (children) provided renal failure is not present.

LANOXIN® digoxin TABLETS. **0.125 mg.** (yellow) in bottles of 100 and 1,000. **0.25 mg.** (white) scored, in bottles of 100, 500, 1,000 and 5,000; also Unit Dose Pack, strips of 10 tablets, 10 boxes of 100 tablets (1,000). **0.5 mg.** (green) scored, in bottles of 100 and 1,000.

CLINICAL STUDIES

Atropine-Induced Cardioacceleration and Myocardial Blood Flow in Subjects With and Without Coronary Artery Disease

SUZANNE B. KNOEBEL, MD, FACC
PAUL L. McHENRY, MD, FACC
JOHN F. PHILLIPS, MD, FACC
STEVEN WIDLANSKY, MD*

Indianapolis, Indiana

Thirty-five patients being studied by coronary cineangiography for diagnosis or evaluation of coronary atherosclerotic occlusive disease had myocardial blood flow determinations at rest and after intravenous administration of atropine sulfate, 1.0 mg. Myocardial blood flow was determined by a coincidence counting system and a single bolus injection of ^{84}rubidium chloride.

In 10 patients without coronary occlusive disease, heart rate increased by 52 percent and myocardial blood flow by 48 percent ($P < 0.001$, $r = 0.888$). In 14 patients with single vessel disease or partial occlusion of two vessels, myocardial blood flow increased by 44 percent and heart rate by 37 percent ($P < 0.05$, $r = 0.553$). In 11 patients with two or three vessel occlusive disease, heart rate increased by 30 percent whereas myocardial blood flow increased by only 15 percent ($r = -0.172$).

We conclude that patients with two and three vessel involvement by atherosclerotic occlusive disease are unable to increase nutrient myocardial blood flow in response to atropine-induced cardioacceleration to the same degree as patients without coronary disease or with less extensive disease. The observation may be of therapeutic importance because of the potential that administration of atropine may have for inducing myocardial ischemia in such patients.

From the Krannert Institute of Cardiology, Marion County General Hospital, and the Department of Medicine, Indiana University School of Medicine, Indianapolis, Ind. This study was supported in part by the Herman C. Krannert Fund, and U. S. Public Health Service Grants HL-6308, HL-5363 and HL-5749. Manuscript accepted July 25, 1973.

Atropine has been considered useful in the management of bradycardia and ventricular ectopic activity in acute myocardial ischemia[1] and in the prehospitalization phase of coronary insufficiency as a possible antiarrhythmic agent.[2] However, atropine may produce deleterious effects in the presence of myocardial infarction by increasing the degree of myocardial ischemia probably by way of an increase in myocardial oxygen need secondary to increased heart rate.[3,4] And, serious ventricular arrhythmias appearing after the administration of atropine to patients with acute myocardial infarction have been reported,[4–6] perhaps reflecting increasing ischemia.

Clinically, the adverse effects of atropine-induced tachycardia on exercise tolerance in patients with coronary artery disease have been recognized for many years.[7] However, little information is available on the effects of atropine itself on myocardial blood flow. The drug has been primarily used in animal studies as a parasympatholytic agent and as an adjunctive agent in pacing studies in man.

This study compares the effect of atropine-induced cardioacceleration on nutrient myocardial blood flow, as measured by a coincidence counting system and single bolus injection of ^{84}rubidium chloride in patients with and without coronary occlusive disease of various degrees of severity.

Methods

Thirty-five consecutive patients undergoing selective coronary cinearteriographic studies for diagnosis or evaluation of coronary arteriosclerotic occlusive disease had myocardial blood flow determinations at rest and 3 minutes after intravenous administration of 1.0 mg of atropine sulfate. All studies were performed just before the arteriographic study, in the morning, with the patients in a fasting state, without sedation, and in the supine position.

A catheter was passed through the basilic vein and positioned in the high right atrium. A short polyethylene catheter (approximately 18 gauge) was introduced percutaneously into the right femoral artery. Blood pressure, measured by means of the indwelling catheter in the femoral artery connected to a Statham P23D strain gauge transducer, was recorded on a Sanborn recorder (model 150). The mean arterial pressure was obtained by electrical integration and the mean systolic arterial pressure by planimetric integration. Pressure-time per minute expressed in millimeters of mercury per second per minute was obtained as the product of systolic mean arterial pressure, heart rate and systolic ejection period. Systolic ejection period in seconds was measured from the pressure records as the time interval between the onset of the femoral arterial pulse and the dicrotic notch and was expressed as the average figure of at least six beats taken at the extremes of respiratory fluctuation. Heart rate was measured from a simultaneously recorded electrocardiogram. The cardiac output was determined using ^{84}rubidium chloride as the indicator.[8]

Myocardial blood flow (MBF) in milliliters per minute per total heart was calculated using the formula:

$$MBF = q(t)/\int_0^\infty A_0(t)dt$$

where q(t) is the myocardial uptake of ^{84}rubidium chloride as measured by the coincidence counting system and $\int_0^\infty A_0(t)dt$ represents the concentration of the isotope in arterial blood during the first circulation, determined by extrapolation after recirculation begins. The theoretical basis of this formulation and experimental verification have been reported in detail.[8–12]

Control measurements were made during sinus rhythm. Then 1.0 mg of atropine sulfate was administered intravenously and repeat measurements were made 3 minutes later. If angina pectoris occurred, the measurements were repeated during the anginal episode.

Coronary cineangiography was performed after completion of the myocardial blood flow and hemodynamic determinations. Multiple oblique views were obtained using renographic contrast medium. Injections were made before and after sublingual administration of nitrites. Recording was performed with 35 mm Kodak Double-X film developed in Ethol-90. A Phillips 6-inch image intensifier was utilized with a 100 mm lens at 64 frames/sec. Only patients with cineangiograms of good quality in multiple projections of all three major coronary vessels were included in this study.

Classification of the coronary arterial lesions was performed as follows: Each of the three major coronary vessels (right, left anterior descending and circumflex) was given a rating of 100; a value of 200 was assigned to the left main coronary artery. The number of vessels involved was then determined (from one to three) and the percent of vessel remaining patent was estimated in increments of 25 percent. In the case of branch stenosis, the degree of occlusion was estimated according to the technique of Rowe et al.[13] For example, if the left anterior descending coronary artery bifurcated, giving off a branch about 50 percent of the size of the parent artery, and if this branch were 50 percent occluded, the estimated occlusion of the branch vessel would be equivalent to 25 percent occlusion of the left anterior descending coronary artery. A final index was then based on the estimated percent of lumen of all three vessels remaining open (a value of 300 equaling no occlusive disease). The cinearteriograms were interpreted independently by three investigators without availability of the physiologic data. Data were analyzed as the significance of the difference between the means of paired data.

Results

Patients without coronary artery disease: In the 10 patients without coronary artery disease, intravenous administration of 1.0 mg of atropine sulfate resulted in a 52 percent increase in heart rate ($P < 0.001$) and a 48 percent increase in myocardial blood flow ($P < 0.001$) (Table IA). There was a significant correlation ($P < 0.001$) between the change in heart rate and myocardial blood flow ($r = 0.888$). Significant changes also occurred in pressure-time per minute ($P < 0.001$), cardiac output ($P < 0.01$) and diastolic pressure ($P < 0.01$). The arterial mean blood pressure increased insignificantly. None of these patients had systemic hypertension or clinically detectable heart disease of any type.

Patients with coronary occlusive disease: In the 25 patients with various degrees of coronary occlusion, heart rate increased by 34 percent ($P < 0.001$) and myocardial blood flow by 31 percent. The relation between the change in heart rate and myocardial blood flow had a correlation coefficient of $r = 0.496$ ($P < 0.025$). Cardiac output increased significantly ($P < 0.001$) as did pressure-time per minute and arterial mean and diastolic pressures ($P < 0.001$).

The patients with coronary artery disease were then classified in two groups, Group 1 comprising 14 patients with a coronary artery index of 150 or greater, and Group 2, 11 patients with a coronary artery index of less than 150. This classification was undertaken to determine the effect of increasing severity of obstructive disease on myocardial blood flow reserve in response to atropine.

Patients in Group 1 manifested a 37 percent increase in heart rate and a 44 percent increase in myocardial blood flow; both changes were significant (P

*Angina.

Arterial mean = arterial mean pressure (mm Hg); CAI = coronary artery index (see text for derivation); CO = cardiac output (liters min); diastolic = mean arterial diastolic pressure (mm Hg); MBF = myocardial blood flow (ml/min per total heart); NS = not signif cant; *P* indicates probability value for change after administration of atropine. PTM = pressure-time (mm Hg/sec per min); SD = standard deviation.

<0.001). The correlation between the change in heart rate and myocardial blood flow was significant at the $P < 0.05$ ($r = 0.553$) level. As in the entire group of patients with coronary occlusive disease, cardiac output, arterial mean and diastolic pressures increased significantly ($P < 0.001$) as well as pressure-time per minute ($P < 0.002$).

In patients in Group 2 (Table IC), those with two and three vessel coronary disease, heart rate increased by 30 percent ($P < 0.001$) and myocardial blood flow by 15 percent ($P < 0.025$). There was a negative correlation ($r = -0.172$) between these two variables. Cardiac output, pressure work, arterial mean and diastolic pressures all increased significantly ($P < 0.001$).

Discussion

Very few clinical studies were available with which to compare our data on the hemodynamic effects of atropine-induced changes in heart rate. Gorlin et al.[14] reported a linear increase in heart rate and coronary blood flow, as measured by the nitrous oxide technique, in six patients, three with valvular heart disease. In their study, a 38 percent increase in heart rate resulted in a 38 percent increase in coronary blood flow and a 33 percent increase in myocardial oxygen consumption. The cardiac output data from their study and those reported here are probably not comparable because of differences in patient group, the unknown sedation factor, calculation in cardiac index versus cardiac output, and so forth. The increase in mean arterial and diastolic pressures was not significant in the study of Gorlin et al., whereas it was in our study. This discrepancy may also be due to differences in number and type of patients, the sedation factor or other differences between the experimental situation in the two studies. McMichael and Sharpey-Schafer[15] reported an increase in cardiac output in 8 of 10 subjects given 1 mg of atropine intravenously. Changes in systemic blood pressure were not reported.

As quoted by Ross,[7] Wayne and LaPlace concluded from exercise stress testing concomitant with administration of atropine that, "the diminution in the number of efforts (trips up the steps) and the increase in the duration of pain under atropine . . . can be attributed . . . to the more rapid action of the heart, which increases its energy expenditure without a concomitant increase in coronary flow . . . ." The data presented here which demonstrate a decreased rate of increase in myocardial blood flow with atropine in patients with two and three vessel coronary artery disease, as a group, as compared with patients with single vessel disease or no occlusive disease are in accord with the above clinical observation. To make that conclusion it must be assumed, however, that linearity between heart rate and flow normally maintains for each increment in rate,[16] all other factors controlling myocardial oxygen consumption remaining equal.

Comparison of normal patients and those with two or three vessel disease: If one assumes that the normal subjects and those with a coronary artery index of less than 150 (Group 2) had had the same increase in heart rate (52 percent), simple linearity comparisons would show that patients in Group 2 would have had a 26 percent increase in blood flow rather than the 48 percent increase demonstrated by the normal subjects. Conversely, if the normal subjects had had an increase in heart rate of only 30 percent, as did patients in Group 2, blood flow in the normal group would have increased by only 28 percent. The difference between the 15 percent increase in blood flow manifested by patients in Group 2 and the 28 percent projected increase in the normal subjects at the same heart rate is significant ($P < 0.02$) from binomial calculation. However, if at a smaller increase in heart rate, myocardial oxygen demand did not increase proportionally, then the response of our patients with two and three vessel disease may not be abnormal since heart rate in this group increased less than in patients without coronary disease.

The problem as it relates to myocardial oxygen consumption and heart rate cannot be answered here since myocardial oxygen consumption was not measured in our patients. Such measurements require a steady state as well as coronary sinus catheterization, and neither condition was included in our experimental design. In addition, there is controversy concerning the accuracy of coronary sinus oxygen determinations in the presence of the heterogeneity of blood flow that occurs in coronary artery disease. Linearity between incremental cardioacceleration produced by right atrial pacing and coronary sinus blood flow values has been demonstrated and shown to exist in patients with coronary disease,[17] but atropine and right atrial pacing may be different interventions. That they are indeed different may be inferred from the fact that, with atropine, the increase in pressure-time per minute did not correlate with the increase in myocardial blood flow in our normal patients to the same degree that occurs with right atrial pacing.[18] With right atrial pacing, the correlation between heart rate and myocardial blood flow increase is highly significant.[18] Perhaps atropine alters another determinant of myocardial oxygen consumption, such as ventricular volume or atrial or ventricular contractility,[19–22] or perhaps a disproportionate increase in flow reflects a direct effect of the drug on coronary vascular resistance.[23–25] In addition, the level of mean arterial pressure in our patients with coronary disease was not as high as in the normal patients. This reduced arterial pressure influences pressure work and may alter blood flow characteristics.

We are not able to explain why patients with coronary artery disease had a smaller increase in heart rate at identical doses of atropine than normal patients. The ages of the patients were comparable, and medications such as digitalis or propranolol were not being taken by either group during or shortly before the study. One recent experimental study[26] showed a

relation between ischemia in the sinus node and sinus rate. Another explanation might be that the patients with coronary disease had less vagal tone, perhaps for psychological reasons, than the patients without disease. The depressed rate response in the patients with coronary disease may have been "protective" in a sense since only one patient experienced angina during the procedure. Clinically, however, we have observed the development of angina after prophylactic administration of atropine before coronary cineangiography.

Limitations of method: Validation of the coincidence counting technique for quantitatively measuring myocardial blood flow in man has been and continues to be a difficult problem. The assumption that the myocardial extraction ratio for rubidium is the same as the extraction ratio for the total body, upon which the application of Sapirstein's formulation[27] rests, has been tested to only a limited degree.[12,28] And even if concomitant myocardial and total body extraction ratios could be accurately measured with every intervention, it is not clear that the problem would be solved. With the known heterogeneity of blood flow in coronary artery disease,[29,30] the extraction ratio for the heart in any particular patient undoubtedly represents a composite of extraction ratios.[29] Thus, a change in overall extraction ratio could theoretically occur because of a redistribution of flow and might not necessarily reflect a change in total myocardial nutrient blood flow. For these reasons, plus the problem of nonlinear isotope exchange at various flow rates,[31] we do not claim quantitation for the technique. The data have been analyzed as the difference in group response, abnormal versus normal. It might be preferable to consider the measurement as a "coronary flow equivalent," a term introduced by Bing and associates[32] in relation to the coincidence counting technique.

Clinical implications: With these limitations in mind, we believe our data suggest that atropine-induced cardioacceleration could potentially result in an increased myocardial oxygen demand in excess of the ability to increase nutrient myocardial blood flow in patients with coronary artery occlusive disease. This consideration may be important in balancing the possible benefits of cardioacceleration with atropine against the potential of the drug for increasing myocardial ischemia. It must be noted, however, that our patients had a relatively normal heart rate at rest, and no conclusions can be drawn concerning atropine-induced cardioacceleration from bradycardia to normal heart rate ranges.

The electrophysiologic effects of atropine were studied with His bundle recordings in 14 patients. Administration of atropine, 0.5 mg intravenously, produced a moderate degree of sinus acceleration in all patients (average increase 20 percent over control rate). Atrioventricular (A–V) nodal conduction was enhanced during both sinus rhythm and at various paced atrial rates after administration of atropine. The paced atrial rates at which the A–V nodal Wenckebach phenomenon occurred were significantly higher after administration of the drug than before. Similar effects on retrograde conduction were observed during ventricular pacing. Atropine shortened both the functional and effective refractory periods of the A–V node but appeared to have no direct effect on either His-Purkinje conduction time or refractoriness. However, aberrant ventricular conduction and block within the His-Purkinje system increased during premature atrial stimulation after atropine administration. This was the result of shortening of the functional refractory period of the A–V node by atropine, which produced significantly shorter H_1–H_2 intervals. The effect of atropine on the electrophysiologic properties of the A–V conducting system was important in interpreting the conversion of a type I gap in A–V conduction to a type II gap.

Atropine sulfate, commonly considered a safe drug, is frequently used in general medical practice. Its effects on the electrophysiologic properties of the sinus[1–5] and atrioventricular (A–V) nodes[1,2,6] have been extensively studied. Most clinical studies have used standard electrocardiographic recordings to assess the effects of atropine on total A–V conduction. Relatively few have considered the possible effects of atropine on the His-Purkinje system.

In this investigation we used His bundle electrograms to study the effects of atropine on the electrophysiologic properties of the A–V node and His-Purkinje system in 14 patients. A–V nodal and His-Purkinje conduction times were compared at various paced atrial rates before and after administration of the drug. The functional and effective refractory periods of the A–V node and His-Purkinje system were also studied with use of the atrial extrastimulus method.[7,8]

Materials and Methods

All 14 patients were studied in the nonsedated, postabsorptive state after informed consent had been obtained. Under local anesthesia a quadripolar catheter was introduced percutaneously into an antecubital vein and fluoroscopically positioned against the lateral wall of the right atrium. The distal two electrodes were used to pace the atrium, and the proximal electrodes to record high right atrial activity. A tripolar electrode catheter was percutaneously introduced into the femoral vein and positioned in the tricuspid

IHD = ischemic heart disease; NHD = no heart disease.

valve area to record electrical activity of the His bundle as previously described.[9] For ventricular pacing a bipolar catheter was inserted into another arm vein and positioned at the apex of the right ventricle.

Atrial pacing was accomplished by using a programmed digital stimulator that delivered rectangular impulses of 1.5 msec duration at approximately twice diastolic threshold. Ventricular pacing was accomplished in a similar way using the lowest milliamperage that permitted reliable capture. Refractory period studies were performed with the atrial extrastimulus method.[7,8]

Three to four standard electrocardiographic leads (I, II, III, V_1) were simultaneously recorded.

All tracings were displayed on a multichannel oscilloscope and recorded on magnetic tape. The recordings were subsequently reproduced at a paper speed of 150 mm/sec. Intracardiac electrograms were recorded at a filter frequency setting of 40 to 500 Hz. Care was taken to insure the grounding of all equipment.

After control values were obtained, 0.5 mg of atropine sulfate was administered intravenously and studies were repeated 5 to 10 minutes after injection. The A–H interval, used as an approximation of A–V nodal conduction time, was measured from the onset of the low right atrial electrogram to the beginning of the His deflection (normal values for our laboratory 60 to 140 msec). The H–V interval represented His-Purkinje conduction time and was measured from the onset of the His bundle deflection to the beginning of ventricular depolarization (normal values for our laboratory 30 to 55 msec). During ventricular pacing with retrograde conduction the interval from the stimulus artifact to the beginning of the low right atrial electrogram was taken as a measure of ventriculoatrial conduction time.

Definitions for relative, functional and effective refractory periods of the various components of the A–V conduction system have been previously published.[10]

Results

Table I provides the essential clinical data on the 14 patients in this study. All patients had sinus rhythm and normal P–R intervals; none was taking medication. Patients with the so-called sick sinus syndrome were excluded from the study.

Sinus cycle: Administration of atropine, 0.5 mg, resulted in an acceleration of the sinus rate in all patients (Table I). The average increase was 15 beats/min (a 20 percent decrease in sinus cycle length).

A–V Conduction Studies

Antegrade conduction: Administration of atropine resulted in significant enhancement of A–V nodal conduction in all 13 patients studied,* as shown by shortening of the A–H interval during sinus rhythm (Table I) and at various paced atrial rates. For example, at a paced atrial rate of 100 beats/min the mean A–H interval measured 113.3 msec (standard error of the mean 9.9 msec) during the control period and 80.0 ± 4.2 msec after administration of atropine ($P < 0.001$). Similarly, in six patients with a paced atrial rate of 150/min the mean decrease in the A–H interval was 33 ± 16 msec after administration of atropine ($P < 0.005$). In seven patients faster rates of atrial stimulation resulted in A–V nodal conduction of the Wenckebach type during the control period. The average atrial rate at the onset of the antegrade A–V nodal Wenckebach phenomenon was 133 beats/min before administration of atropine. After atropine, five of the seven patients demonstrated 1:1 A–V conduction up to an atrial rate of 160 beats/min. Two patients who had an earlier onset of the A–V nodal Wenckebach phenomenon (at atrial rates of 110 and 120 beats/min, respectively) during the control period also demonstrated the phenomenon after atropine administration, but at a much faster atrial rate (150 beats/min in each case). Atropine produced no changes in the H–V interval during antegrade conduction studies.

Retrograde conduction: Retrograde conduction studies were performed in three patients (Cases 6, 11 and 13). At any given paced ventricular rate, retrograde conduction time was less after administration of atropine. The ventricular rate at which the retro-

* Individual patient data on atrioventricular conduction and refractory periods before and after administration of atropine are available on request.

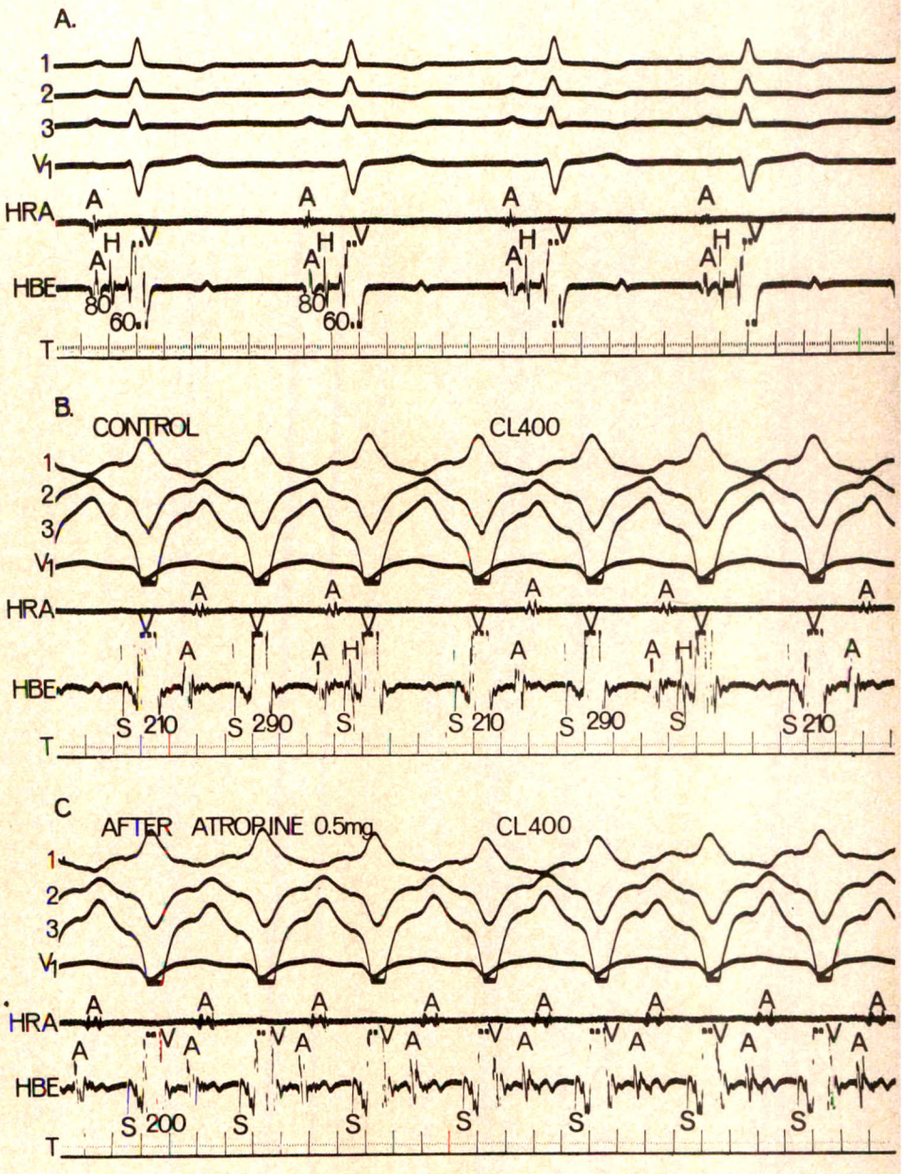

FIGURE 1. Case 11. Effect of atropine on retrograde conduction. **Panel A** shows sinus rhythm in which the sequence of atrial activation is from the high to the low right atrium. **Panel B** demonstrates that at a paced ventricular cycle length of 400 msec a 3:2 retrograde A–V nodal Wenckebach type of block with concealed reentry occurs repetitively. Note the low to high sequence of right atrial activation. **Panel C** shows that after administration of atropine 1:1 retrograde conduction occurs at the same paced cycle length of 400 msec. Each panel shows from top to bottom standard electrocardiographic leads I, II, III, V_1, high right atrial electrogram (HRA), His bundle electrogram (HBE) and time lines (T) recorded at 10 and 100 msec. CL = cycle length; S = stimulus artifact.

grade Wenckebach phenomenon occurred after atropine was greater than in the control period (Fig. 1).

Refractory Period Studies

Atrium: Atropine had no consistent effect on the effective refractory period of the atrium in the 11 patients studied. In nine patients the effect of atropine on the effective refractory period of the atrium was studied at a cycle length of 600 msec. In four (Cases 3, 9, 11 and 14), the effective refractory period decreased by 10 to 20 msec and in three (Cases 2, 5 and 6), it increased by 10 msec; in two patients (Cases 1 and 7), no change occurred.

A–V node: During the control period, the effective refractory period of the A–V node could be determined in only six patients. In the remaining five, the effective refractory period of the atrium was encountered first. Administration of atropine decreased the effective refractory period of the A–V node in all six patients by a mean of more than 51.5 ± 37.3 msec (P <0.001). After atropine, the actual or smallest value for the effective refractory period of the A–V node could not be determined since atrial refractoriness was encountered first in all instances. Figure 2 exemplifies the effect of atropine on the effective refractory period of the A–V node. In all patients atropine shortened the functional refractory period at one or more cycle lengths. The mean value for the functional refractory period of the A–V node was 417.9 ± 10.7 msec during the control period and 371.2 ± 6.4 msec after administration of atropine (P <0.001). The shortening of the functional refractory period after

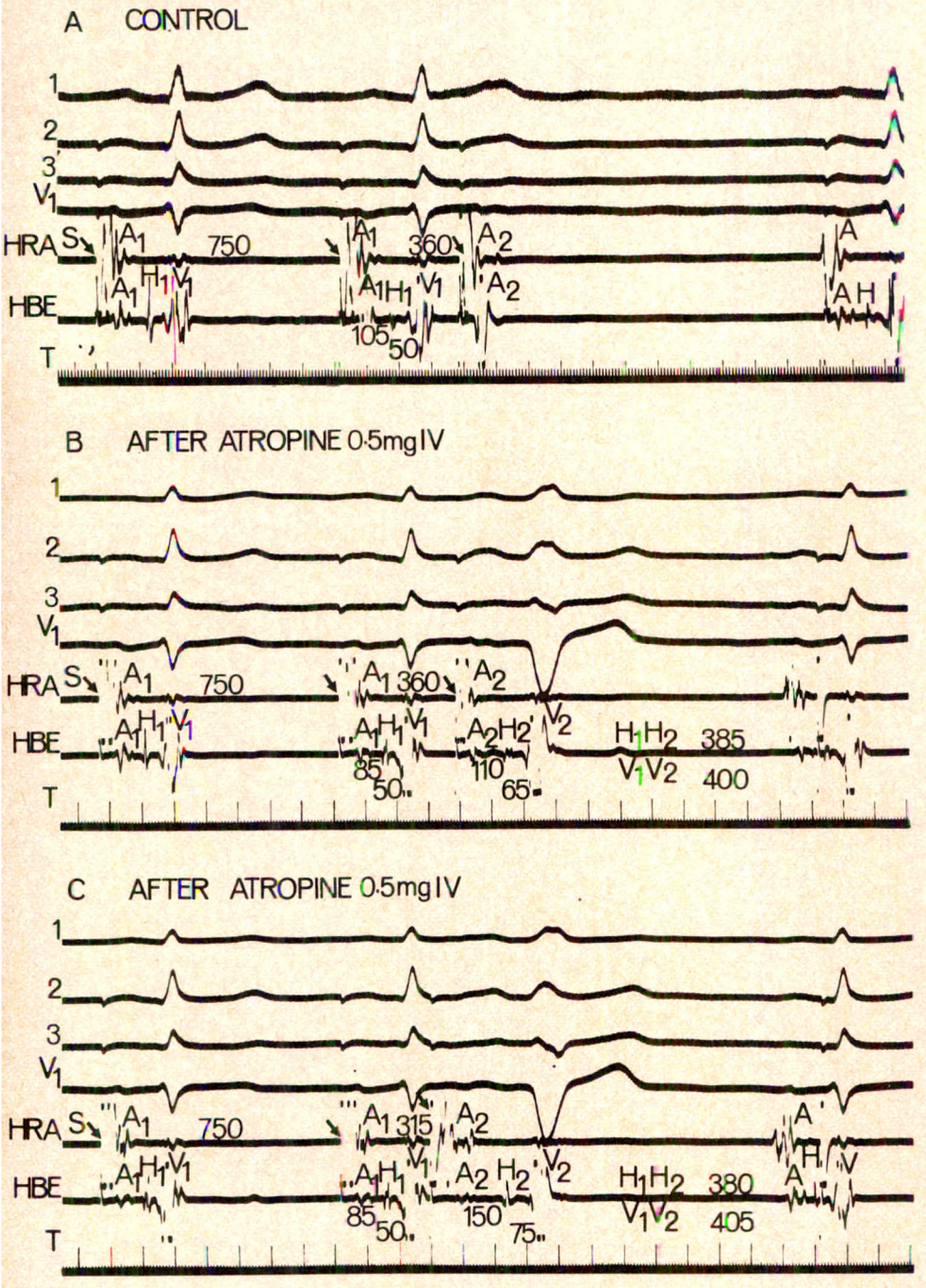

FIGURE 2. Case 1. Effect of atropine on the effective refractory period of the A–V node. In the control period **(panel A)** the effective refractory period of the A–V node is reached at an A_1–A_2 interval of 360 msec. After administration of atropine **(panel B),** the premature atrial beat (A_2) conducts to the ventricle at the same A_1–A_2 interval of 360 msec. The H_1–H_2 interval measures 385 msec and there is aberrant ventricular conduction of a left bundle branch block type with an H_2–V_2 interval of 65 msec. The degree of shortening of the effective refractory period of the A–V node is further exemplified by the fact that conduction to the ventricles occurred at an A_1–A_2 interval of 315 msec **(panel C).** Abbreviations in this and subsequent figures as in Figure 1.

atropine was greater at longer basic atrial cycle lengths.

His-Purkinje system: Atropine in the dose used did not appear to have a direct effect on refractoriness of the His-Purkinje system (Fig. 3). However, H–V prolongation and aberrant ventricular conduction during premature atrial stimulation occurred more frequently after administration of atropine than in the control period, especially at atrial cycle lengths of 700 msec and greater (Fig. 4). This increased frequency was caused by the enhanced A–V nodal conduction induced by atropine which, at any given atrial coupling interval, resulted in an H_1–H_2 interval shorter than that of the control period. The shorter H_1–H_2 interval permitted the impulse of the premature atrial beat to be conducted during the relative refractory period of the His-Purkinje system. In five patients (Cases 1, 2, 6, 7 and 9) the relative refractory period of the His-Purkinje system was encountered after administration of the drug but not before.

Figure 5 is representative of two patients who had no aberrant ventricular conduction when the basic cycle length of atrial stimulation was reduced during

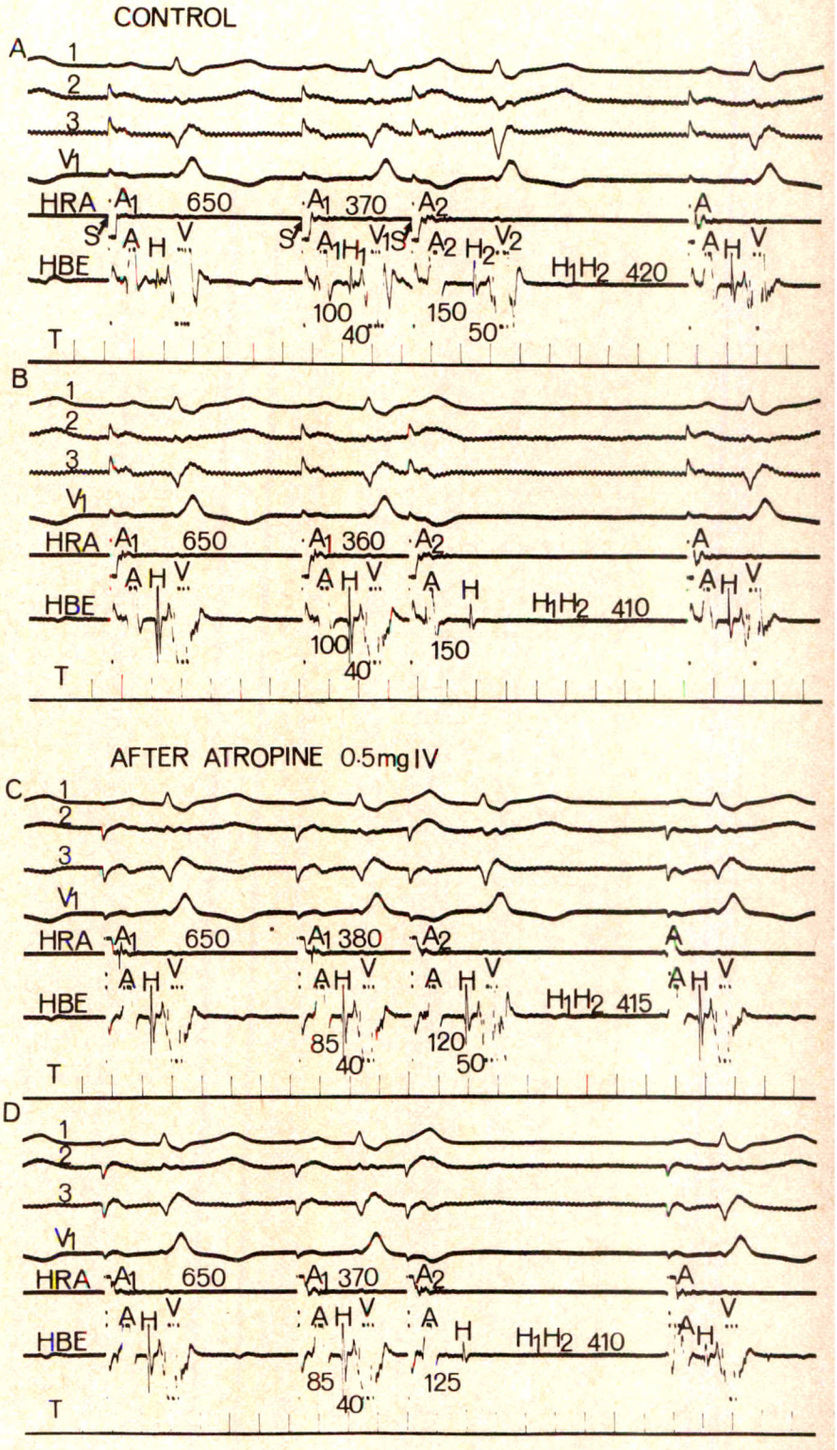

FIGURE 3. Case 14. Effect of atropine on the effective refractory period of His-Purkinje system. In **panels A** through **D** the atrial cycle length is constant at 650 msec. Before administration of atropine, at an A_1–A_2 interval of 370 msec, a premature atrial beat (A_2) conducts to the ventricles with a longer H–V interval (50 msec, **panel A**) than that of the basic drive. The H_1–H_2 interval is 420 msec, which is outside the effective but within the relative refractory period of the His-Purkinje system. By decreasing the A_1–A_2 interval by 10 msec **(panel B)** A_2 reaches the His-Purkinje system during its effective refractory period (410 msec) and blocks within this system. After administration of atropine, A_2 blocks within the His-Purkinje system **(panel D)** at the same H_1–H_2 interval of 410 msec as that of the control period **(panel B).** As shown in **panel C,** A_2 conducted to the ventricles during its relative refractory period (H_2–V_2 interval, 50 msec).

the control period but who manifested aberrant conduction at the shorter cycle lengths after administration of atropine.

In three patients (Cases 2, 3 and 14), at basic atrial cycle lengths of 800, 700 and 550 msec, respectively, the effective refractory period of the His-Purkinje system could be determined only after administration of atropine (Fig. 6 and 7).

In one patient (Case 3) atropine converted a type I gap in A–V conduction[11,13] (Fig. 8) into a type II gap[13] (Fig. 9). In panel B of Figure 8 a relatively late premature atrial depolarization (A_1–A_2 interval 445 msec) is initially blocked

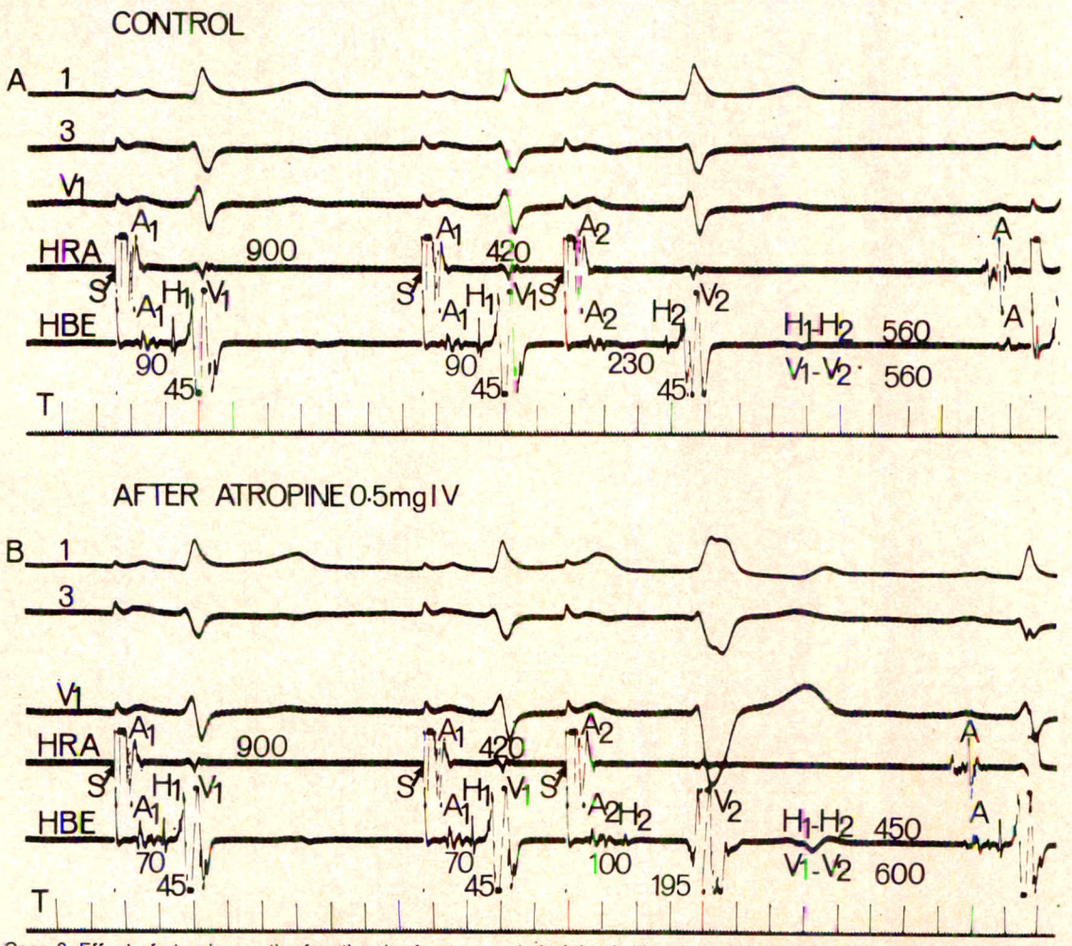

FIGURE 4. Case 3. Effect of atropine on the functional refractory period of the A–V node and the resultant His-Purkinje conduction. Atrial cycle lengths are constant at 900 msec. In the control period **(panel A),** a premature atrial beat (A_2) introduced at an A_1–A_2 interval of 420 msec encounters A–V nodal delay (A_2–H_2 interval 230 msec). The resultant H_1–H_2 interval is 560 msec, and normal ventricular activation occurs with a normal H–V interval of 45 msec. After administration of atropine **(panel B),** the premature atrial beat results in a shorter H_1–H_2 interval (450 msec) caused by enhancement of A–V nodal conduction time (A_2–H_2 interval 100 msec). The premature atrial beat is conducted during the relative refractory period of the His-Purkinje system as evidenced by the markedly prolonged H_2–V_2 interval (195 msec) and aberrant ventricular activation of a left bundle branch block type.

within the His-Purkinje system. The effective refractory period of the His-Purkinje system occurs at an H_1–H_2 interval of 510 msec. In panels C and D, A–V conduction resumes because earlier premature atrial depolarizations encounter greater A–V nodal delay and the resultant H_1–H_2 intervals (545 and 515 msec, respectively) are outside the effective refractory period of the His-Purkinje system.

Figure 9 (same patient) illustrates a type II gap in A–V conduction after administration of atropine. In panel B, a premature atrial impulse (A_2) blocks within the His-Purkinje system at an H_1–H_2 interval of 490 msec. In panel C, an earlier premature atrial depolarization was conducted to the ventricles although the H_1–H_2 interval of 430 msec was less than in panel B. In panel D, block again occurred within the His-Purkinje system when the A_1–A_2 interval was decreased and the resultant H_1–H_2 interval was shortened to 415 msec. This form of gap in A–V conduction has been explained as follows: In panel B, the premature atrial impulse encounters an area of maximal refractoriness within the *distal* His-Purkinje system. In panel C, it encounters conduction delay in the *proximal portion* of the His-Purkinje system which allows recovery of the distal area thereby permitting ventricular excitation. The H_2–V_2 interval is prolonged at 135 msec. In panel D, the premature atrial impulse is again blocked because it encounters the effective refractory period of the proximal portion of the His-Purkinje system.

Discussion

In this study we used a relatively small dose of atropine to avoid marked increases in sinus rate. With larger doses of 1 mg or more, it is not always possible to obtain refractory period studies at comparable cycle lengths before and after administration of the drug. In addition, if significant sinus acceleration were produced by a larger drug dose, the shorter cycle lengths would decrease the relative and effective refractory periods of the His-Purkinje system to such a degree that the indirect effects of atropine on

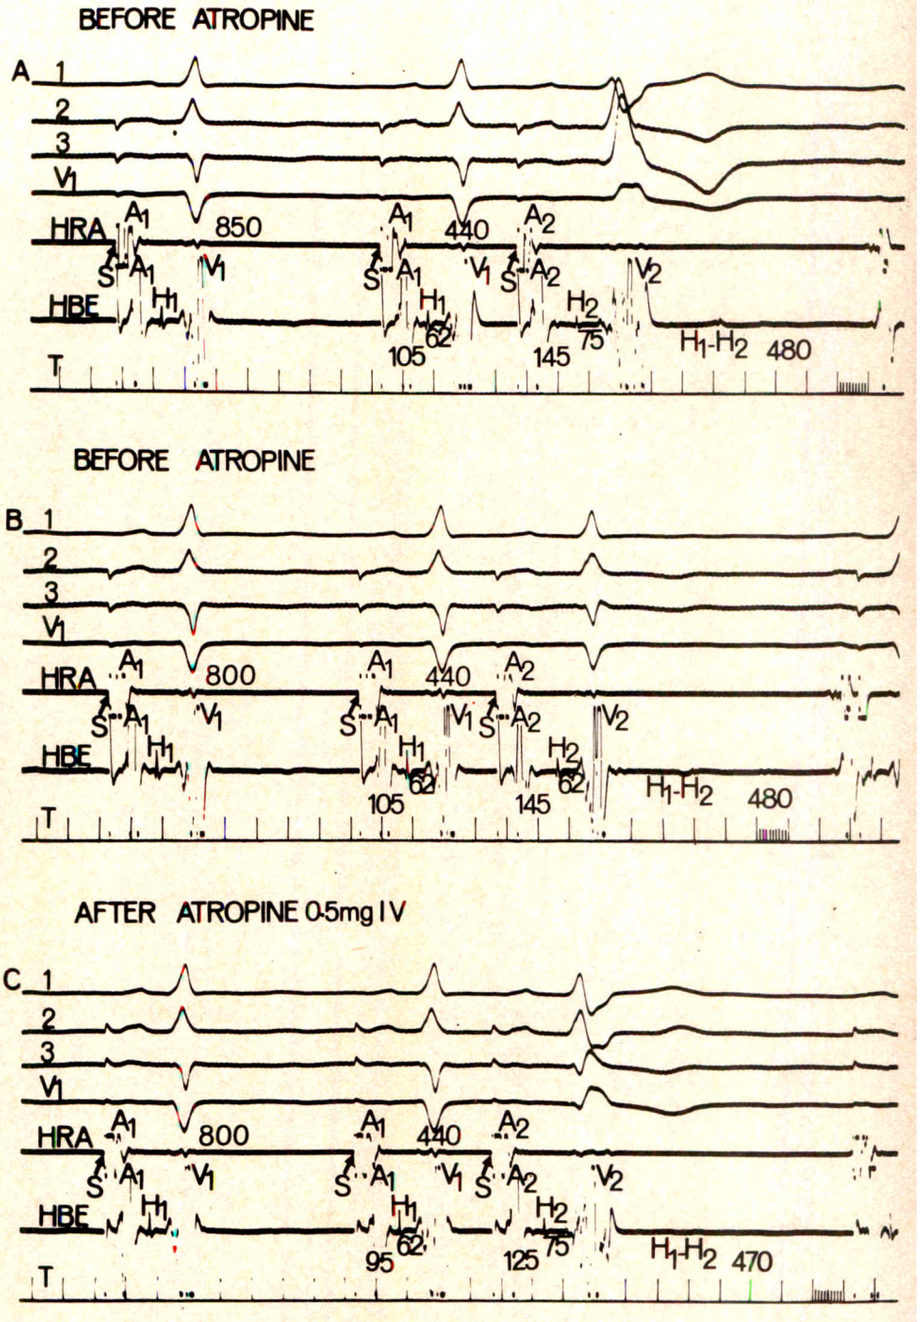

FIGURE 5. Case 2. Aberrant ventricular conduction elicited by atropine. **Panel A:** At a basic cycle length of 850 msec (A_1–A_1) and premature atrial coupling (A_1–A_2) of 440 msec, A_2 conducts to the ventricles aberrantly (right bundle branch block and right axis +120°). The premature atrial beat conducts with a longer H–V (H_2–V_2 75 msec) interval than that of the basic atrial beats (H_1–V_1 interval 62 msec). As shown in **panel B,** decreasing the basic atrial cycle length by 50 msec (A_1–A_1 interval 800 msec) abolishes ventricular aberration and H–V prolongation although the A_1–A_2 and H_1–H_2 intervals are the same in both **panels A** and **B** during the control period. **Panel C:** After administration of atropine, at a basic atrial cycle length (A_1–A_1 interval 800 msec) similar to that of **panel B,** ventricular aberration (right bundle branch block) with H–V prolongation (H_2–V_2 interval 75 msec) resumes. The aberrancy occurs because of a decrease in the functional refractory period of the A–V node (H_1–H_2 470 msec) permitting A_2 to conduct to the His-Purkinje system during its relative refractory period.

these variables would be obscured. We did not observe the initial slowing of sinus rate occasionally seen with administration of atropine.

The well known effects of atropine on the sinoatrial and A–V nodes were observed in all patients. Furthermore, the predictable shortening of both the functional and effective refractory periods of the A–V node was consistently seen.

Atropine appeared to have no direct effect on His-Purkinje conduction time or refractoriness. The greater frequency of His-Purkinje conduction delay, aberrant ventricular conduction and block within the His-Purkinje system after administration of atropine can be explained by the enhanced A–V nodal conduction (shorter A_2–H_2 interval) at a given atrial premature coupling interval, resulting in shorter H_1–H_2 intervals. At these shorter H_1–H_2 intervals the premature atrial impulse entered the His-Purkinje system during its relative or effective refractory period, or both. Thus, atropine may be used to determine the relative (Fig. 2, 4 and 5) and effective (Fig. 6 and 7) refractory periods of the His-Purkinje system in pa-

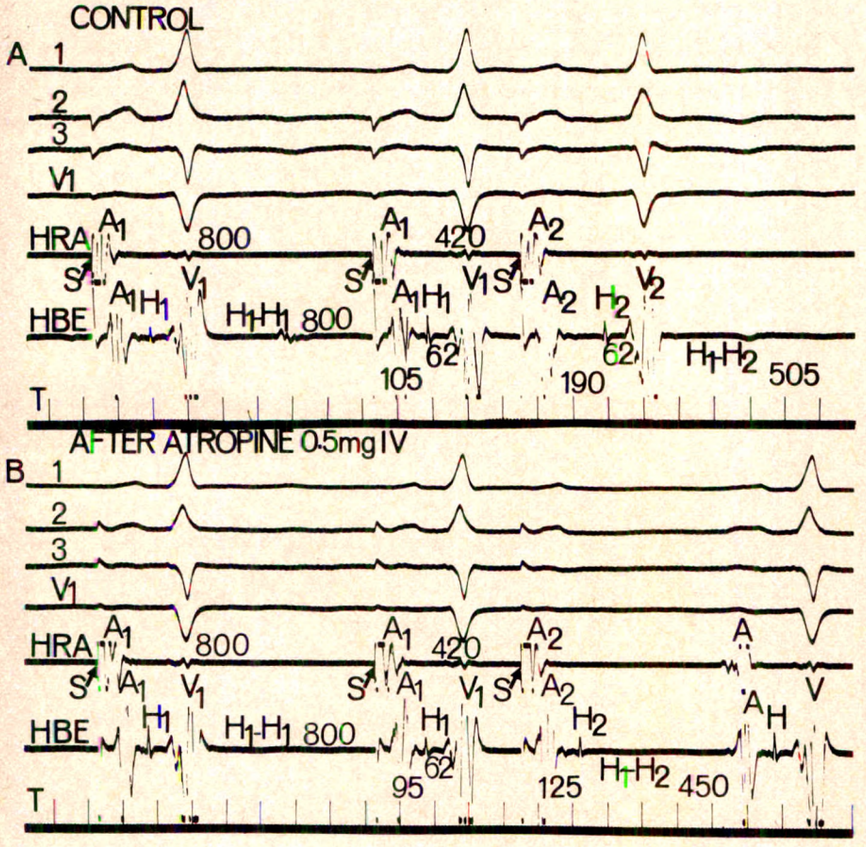

FIGURE 6. Case 2. Effective refractory period of the His-Purkinje system after administration of atropine. In both panels, the atrial cycle length is constant at 800 msec. In **panel A,** A_2 is conducted with a prolonged A–V nodal conduction time (A_2–H_2 interval 190 msec). The resultant H_1–H_2 interval is outside the relative and effective refractory periods of the His-Purkinje system, and therefore normal ventricular activation occurs. As shown in **panel B,** atropine shortens the A–V nodal conduction time of the premature atrial beat (A_2–H_2 interval 125 msec). The resultant H_1–H_2 interval is within the effective refractory period of the His-Purkinje system, and therefore block within this system occurs.

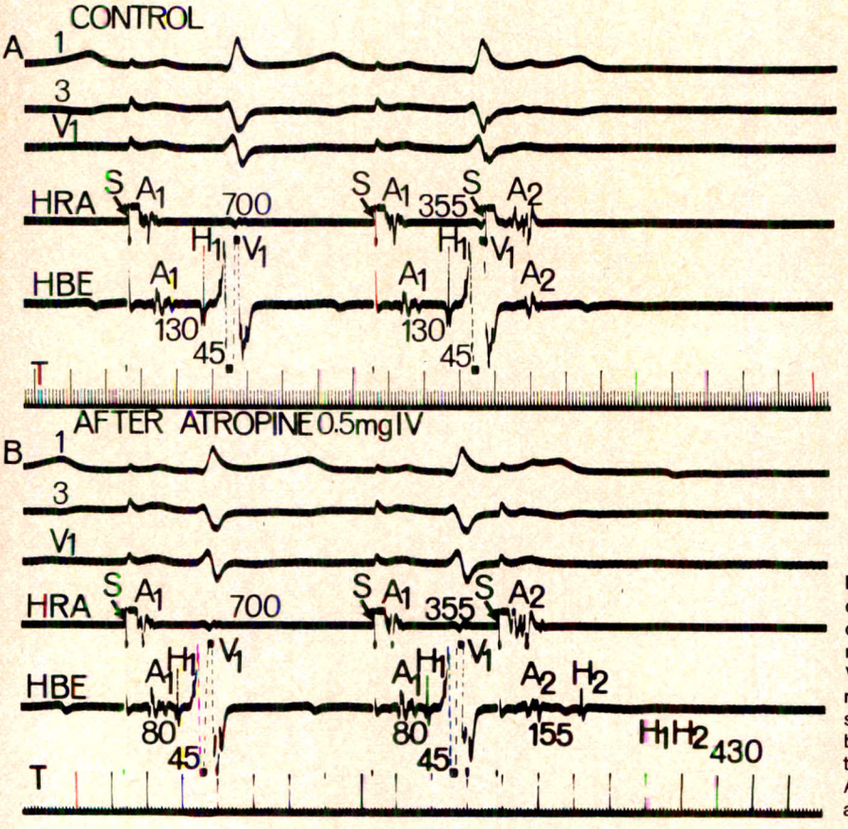

FIGURE 7. Case 3. Effective refractory period of the His-Purkinje system after administration of atropine. At a basic cycle length of 700 msec, the effective refractory period of the A–V node occurred at an A_1–A_2 interval of 355 msec **(panel A). Panel B** shows that atropine shortened A–V nodal conduction of the basic beat (A_1–H_1 80 msec) and the effective refractory period of the A–V node. At the same A_1–A_2 interval (355 msec), A_2 is conducted to and blocked within the His-Purkinje system.

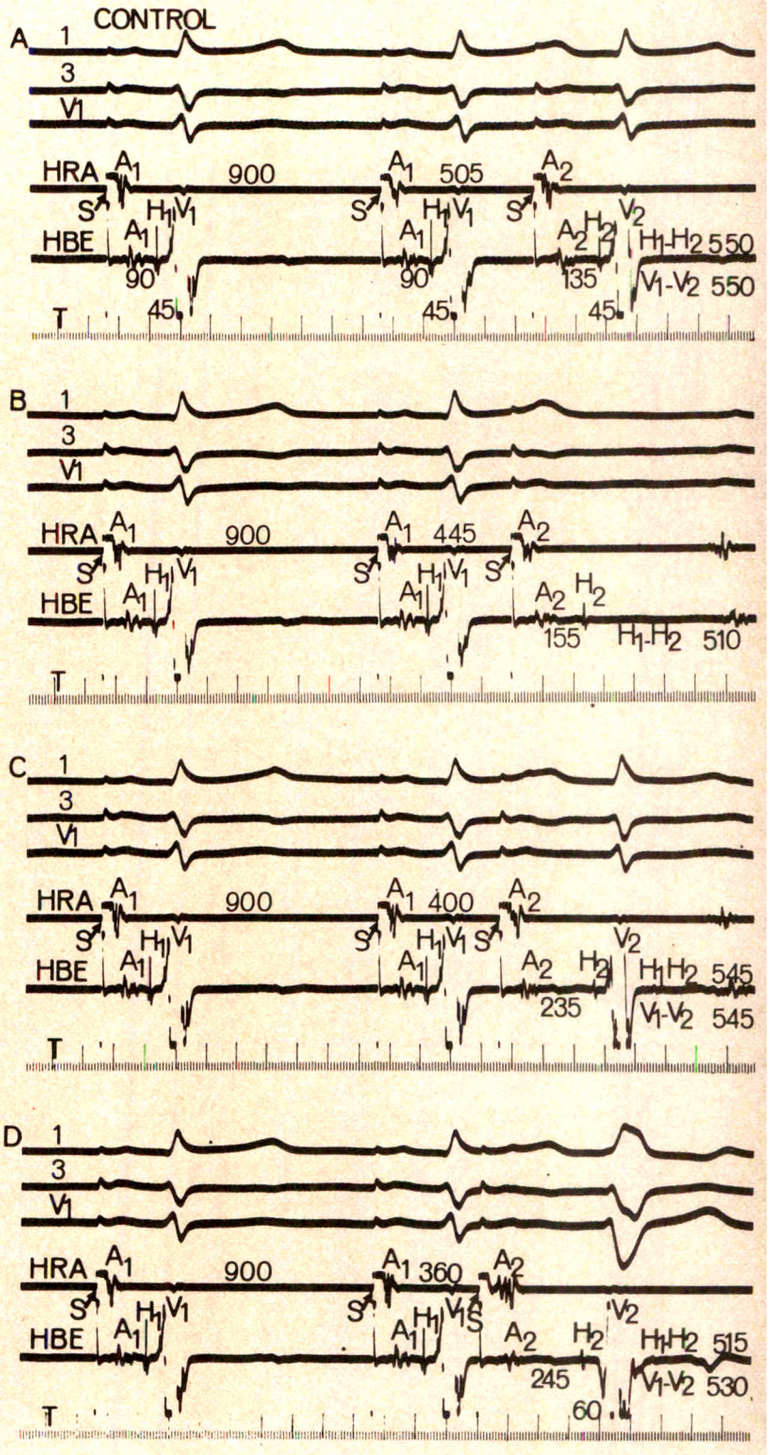

FIGURE 8. Case 3. Typical type I gap in A–V conduction occurred during the control period. The atrial cycle length is constant at 900 msec and the A_1–A_2 interval of the premature beat is progressively decreased in **panels A** through **D.** In **panel B,** the effective refractory period of the His-Purkinje system is reached at an H_1–H_2 interval of 510 msec. Thereafter (**panels c** and **D**), conduction to the ventricles is resumed at shorter A_1–A_2 intervals. The more premature atrial beats encounter greater A–V nodal delay (235 and 245 msec). The resultant H_1–H_2 intervals (545 and 515 msec) are now outside the effective refractory period of the His-Purkinje system, and conduction to the ventricles occurs.

tients who, during control studies, have relatively long functional and effective refractory periods of the A–V node that prevent such determinations.

In most patients the dual actions of atropine (sinus acceleration and enhancement of A–V nodal conduction) occur together. For this reason the drug is generally useful for treating (1) sinus bradycardia with or without first degree heart block, (2) the A–V nodal Wenckebach phenomenon, and (3) some cases of 2:1 A–V nodal block. However, under certain circumstances atropine may increase the severity or shift the site of A–V block. If the electrocardiographic pattern of type I second degree heart block is due to delay in the His-Purkinje system rather than delay in the A–V node, atropine may result in a higher degree of block. The increased severity occurs because (1)

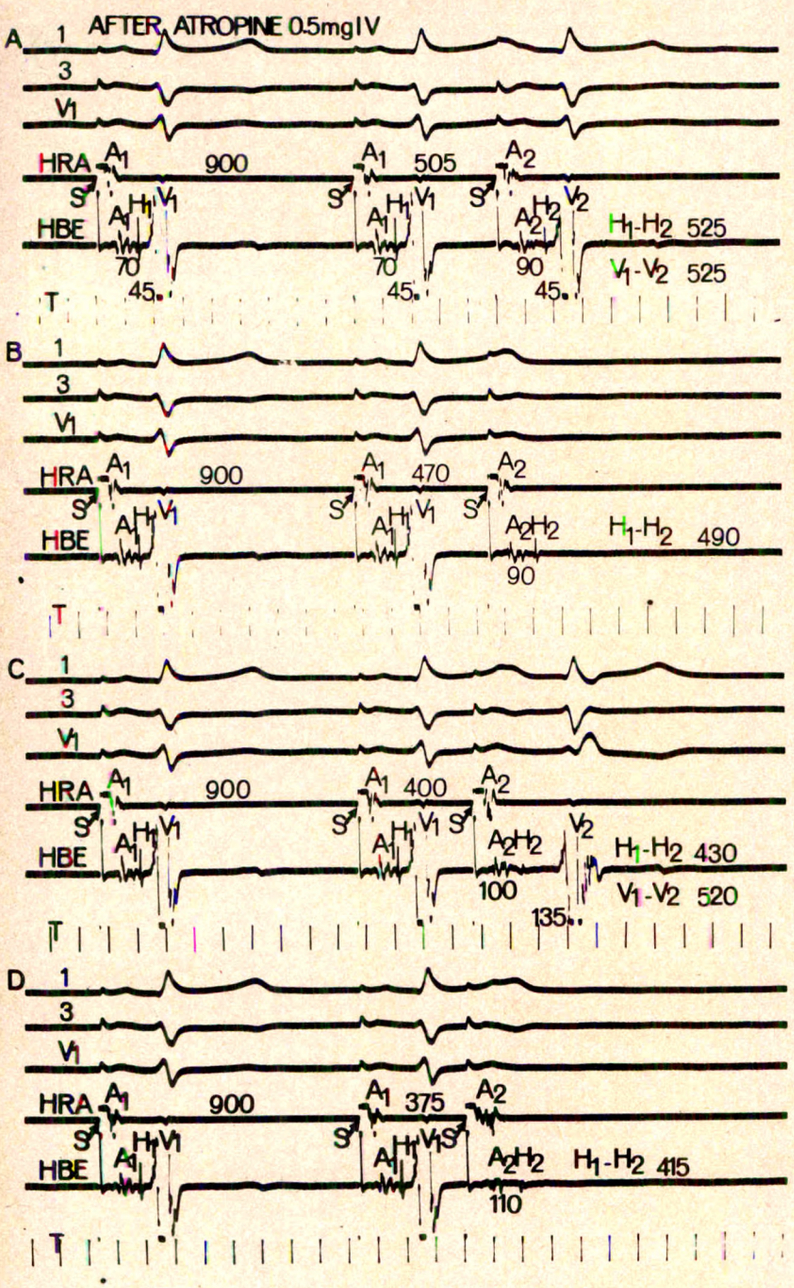

FIGURE 9. Case 3. Atropine converts a type I gap in A–V conduction to a type II gap. Atrial cycle lengths are constant at 900 msec. Atropine shortened A–V nodal conduction time (A_1–H_1 interval) of the basic beat to 70 msec. The premature coupling interval is progressively decreased in **panels A** through **D.** In **panel B,** the effective refractory period of same portion of the His-Purkinje system is reached at an H_1–H_2 interval of 490 msec. In **panel C,** A–V conduction resumes at shorter A_1–A_2 and H_1–H_2 intervals. In **panel D,** the effective refractory period of the His-Purkinje system is again encountered at an H_1–H_2 interval of 415 msec.

sinus acceleration and enhanced A–V nodal conduction result in shorter H–H intervals, and (2) atropine has no direct enhancing effect on His-Purkinje conduction. Figure 7 suggests the possibility that in 2:1 A–V block atropine may change the site of block from the A–V node to the His-Purkinje system. Shift in the site of block is more likely to occur after premature atrial beats. A functional form of 2:1 block below the His bundle was seen more frequently after administration of atropine.[12]

The mechanism involved in type I and type II gaps in A–V conduction have been previously presented.[11,13] The occurrence of gap phenomena depends upon a state of differential refractoriness within the A–V nodal and His-Purkinje systems and does not by itself indicate abnormality in the conducting system. The functional nature of the phenomena is further emphasized by the fact that the conduction gaps may be unmasked by drugs that enhance A–V nodal conduction (Fig. 8 and 9) or obscured by drugs, such as sympathetic beta receptor blocking agents, that prolong A–V nodal conduction.[11]

Effects of Digoxin on Atrioventricular Conduction Patterns in Man

Staten Island, New York

Digoxin was acutely administered to 17 patients, and its effects on atrioventricular (A–V) conduction were assessed. In the control state, before administration of digoxin, progressively premature atrial depolarization showed conduction delay and block confined solely to the A–V node in eight patients and to both the A–V node and the more distal His-Purkinje tissue in nine patients. His-Purkinje conduction delay was manifested on the surface electrocardiogram by ventricular aberration. After administration of digoxin, an early atrial premature impulse either was blocked in the A–V node or reached the distal intraventricular conduction system so late that block or conduction delay below the His bundle was reduced or no longer occurred. Ventricular aberration on the surface electrocardiogram was thus reduced or eliminated. These effects of digoxin on A–V conduction were due to its effect on the A–V node of slowing conduction of a premature impulse. Such action on the A–V node may abolish aberrant ventricular conduction in atrial fibrillation.

This clinical investigation was undertaken to study the effects of acutely administered digoxin on the conduction of an impulse from the atria to the ventricles. With use of His bundle electrograms obtained by the catheter technique,[1,2] atrioventricular (A–V) conduction time may be subdivided into its component parts. Thus, the time required for an impulse to pass through the A–V node may be separated from the time required for the impulse to traverse the more distal intraventricular His-Purkinje system.[3–5] With the introduction of properly timed premature atrial depolarizations, an atrial impulse will be delayed to various degrees or blocked in the A–V node or His-Purkinje system. The patterns of conduction delay and block of premature atrial depolarizations may be grouped and studied.[6–10] It is known from studies of the surface electrocardiogram that digoxin delays A–V conduction. However, use of His bundle electrograms permits the site of action of this commonly used cardiac glycoside to be more discretely localized to the A–V node or the His-Purkinje system and allows investigation of the alterations in A–V conduction patterns.

Methods

Seventeen subjects ranging in age from 21 to 63 years were studied in the postabsorptive, nonsedated state. All subjects had normal P–R intervals. Diagnoses of heart disease (Table I) were made by history and physical examination. Informed consent was obtained in all cases.

Recording techniques: With the patient under local anesthesia, a no. 7 tripolar catheter was introduced percutaneously into a femoral vein and fluoroscopically positioned across the tricuspid valve to record electrograms from the atrium, His bundle and ventricle.[1,2] These electrograms were displayed oscillographically on a multichannel recorder (Electronics for Medicine) within a frequency range of 40 to 500 Hz. A second bipolar catheter, used to

*Increased.

†Effective refractory period of the ventricular specialized conducting system was not reached because of block in the atrioventricular node.

A.R. = atria refractory; ASHD = arteriosclerotic heart disease; ERP = effective refractory period; FRP = functional refractory period; HCVD = hypertensive cardiovascular disease; NHD = no heart disease; Post = 30 to 45 minutes after intravenous administration of 0.75 mg of digoxin; Pre = before administration of digoxin.

stimulate the right atrium, was introduced percutaneously into a right antecubital vein and positioned fluoroscopically against the right lateral atrial wall. Standard electrocardiographic leads I, II, III, V_4 and V_6 were routinely recorded. Careful attention was paid to the grounding of all equipment.

Experimental procedure: The effects of a single premature atrial depolarization on A–V conduction were assessed before and 30 to 45 minutes after intravenous administration of 0.75 mg of digoxin.

The basic driving stimulus (S_1) and test stimulus (S_2) were delivered to the right atrium from Tektronix 160 series wave form and pulse generators and were suitably isolated from ground (Bioelectric Instruments type ISB). S_1, a 2 msec rectangular pulse twice diastolic threshold, was delivered to the atrium at a rate slightly faster than sinus rate. S_2, a 2 msec rectangular pulse three to four times diastolic threshold, was introduced by way of the same electrode after every 10th driving stimulus. By decreasing the S_1–S_2 interval in 5 to 10 msec decrements the entire atrial cycle was scanned.

Measurements: The A–V interval, measured on the His bundle electrogram from the onset of the atrial and ventricular deflections, was used to approximate total A–V conduction time. The A–H interval, measured from the onset of the atrial deflection to the onset of the His bundle deflection, was used to approximate A–V nodal conduction time. The H–V interval, measured from the onset of the His bundle deflection to the onset of the ventricular deflection, represented conduction time through the His bundle and remaining ventricular specialized conduction system. The A_1–A_2, H_1–H_2 and V_1–V_2 intervals were measured from the onset of the atrial, His bundle and ventricular deflections, respectively, of the last basic drive beat to the onset of the corresponding deflection of the premature atrial depolarization. Conduction delay in the ventricular specialized conduction system could be localized to the right or left bundle branch by detecting bundle branch block patterns on standard electrocardiographic recordings.

Definitions

The effective refractory period of the A–V conduction system was defined as the longest A_1–A_2 interval at which the atrial test response (A_2) failed to conduct to the ventricles. The effective refractory period of the A–V node was

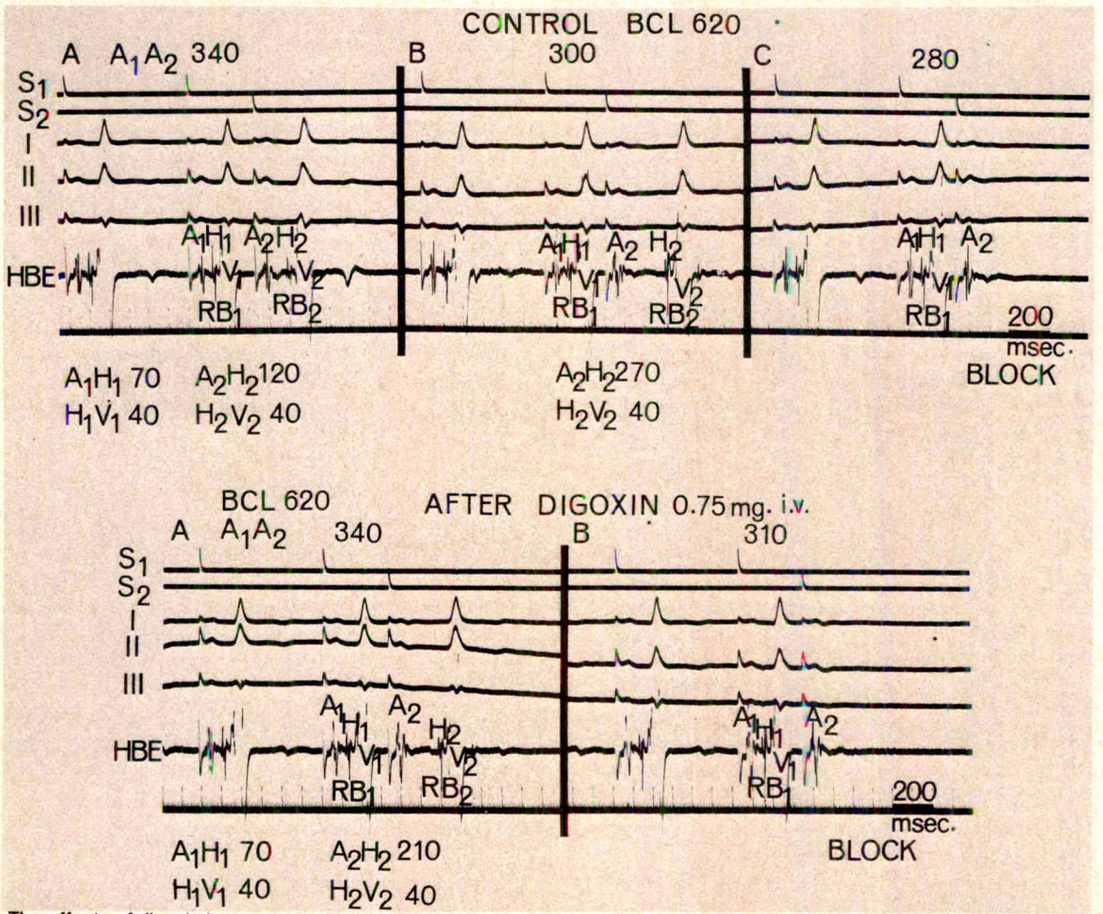

FIGURE 1. The effects of digoxin in a patient in Group I (delay of a premature impulse occurring solely in the A–V node during the control state). S_1 is the basic driving stimulus and S_2 is the premature stimulus. BCL = basic drive cycle length. I, II and III = standard electrocardiographic leads. HBE = His bundle electrogram. Time lines are indicated and values are in milliseconds. A_1, H_1, RB_1 and V_1 represent, respectively, atrial, His bundle, right bundle branch and ventricular depolarizations during the basic response. Those letters with subscript 2 represent depolarizations during the premature response. A_1A_2 is the time between basic and premature atrial depolarizations; A–H is an approximation of A–V conduction time and H–V is conduction time in the His-Purkinje system. Before administration of digoxin **(upper panels A, B and C),** as the introduced atrial depolarization is made progressively more premature, conduction time through the A–V node increases in a graded fashion from 120 **(panel A)** to 270 msec **(panel B).** In **panel C,** when A_2 is even more premature (A_1–A_2 interval 280 msec) A_2 is blocked above the His bundle within the A–V node. In this patient during premature atrial stimulation ventricular aberration was not seen nor was the H_2–V_2 interval prolonged. Thirty minutes after intravenous administration of 0.75 mg of digoxin **(lower panels A and B),** conduction time of a premature impulse through the A–V node is slowed. At an A_1–A_2 interval of 340 msec **(lower panel A),** the A_2–H_2 interval is 210 msec and represents a 90 msec increase compared to the value before digoxin at the same A_1–A_2 interval **(upper panel A).** Block above the His bundle, within the A–V node, now occurs at an A_1–A_2 interval of 310 msec **(lower panel B);** before digoxin, block first occurred at an A_1–A_2 interval of 280 msec. Conduction time through the His-Purkinje system remains unchanged.

considered the longest A_1–A_2 interval at which the atrial test response (A_2) failed to conduct to the His bundle.

The effective refractory period of the ventricular specialized conduction system was indicated by the longest H_1–H_2 interval at which the His bundle test response (H_2) failed to propagate to the ventricles.

The functional refractory period[11] *of the A–V conduction system* was defined as the minimal interval between two successive ventricular responses (V_1–V_2) propagated from the atrium,[12,13] and the functional refractory period of the A–V node, the minimal interval between two successive His bundle responses (H_1–H_2) propagated from the atrium.[14]

The relative refractory period of the A–V node was considered to begin when conduction of a premature atrial depolarization through the A–V node was first delayed. The relative refractory period of the ventricular specialized conduction system was considered to begin when conduction of a premature atrial depolarization through the His-Purkinje tissue was first delayed or when aberrant ventricular depolarization was observed on the surface electrocardiograms, or both.

Results

Effects of digoxin in Group I: The A–V conduction pattern in which conduction delay and block of a premature atrial impulse was confined solely to the A–V node was found during the control period (before administration of digoxin) in 8 of 17 patients studied (Group I, Table I). This delay appeared on

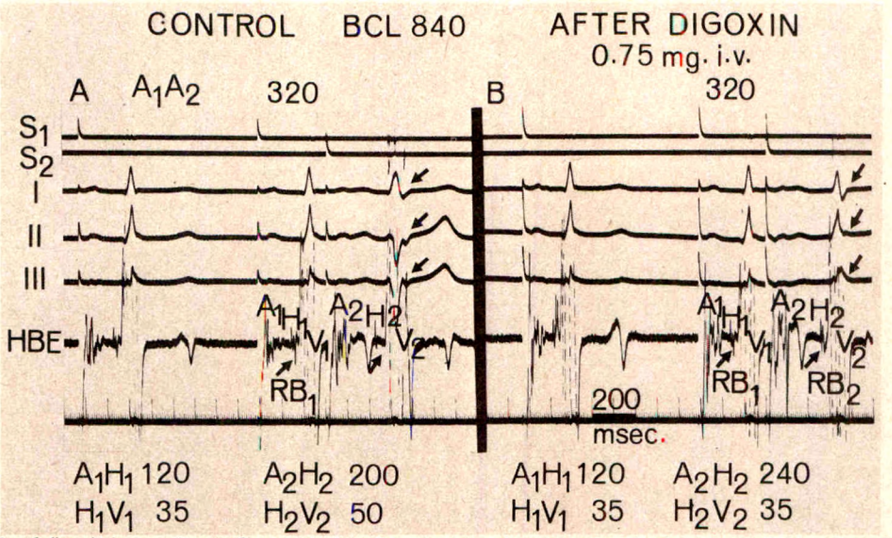

FIGURE 2. The effects of digoxin in a patient in Group II (delay of a premature impulse occurring in both the A–V node and His-Purkinje system). Abbreviations as in Figure 1. **Arrows** pointing to standard leads I, II and III emphasize changes in ventricular aberration after drug administration. In **panel A,** before digoxin, A–V nodal conduction time (A_2–H_2 interval) is 200 msec when the atrium is prematurely depolarized at an A_1–A_2 interval of 320 msec. This conduction delay in the A–V node is not sufficient to prevent the premature atrial depolarization from reaching the His-Purkinje system during its refractory period. Conduction time through the His-Purkinje system is thereby delayed as evidenced by the H–V interval, which increases from 35 msec during basic drive (H_1–V_1 interval) to 50 msec during premature stimulation (H_2–V_2 interval). The right bundle branch potential is absent, and ventricular aberration **(arrows)** probably represents right bundle branch and left anterior hemiblock.

In **panel B,** after intravenous administration of 0.75 mg of digoxin, A–V nodal conduction time is increased 40 msec (A_2–H_2 interval 240 msec) for the same premature atrial interval (A_1–A_2 interval 320 msec) shown in **panel A.** The delay in A–V nodal conduction allows the distal His-Purkinje system to recover more completely from the preceding impulse and to be less refractory. Thus, there is no evidence of conduction delay in the His-Purkinje system on the basis of the H_2–V_2 interval, which decreases to 35 msec, a value identical to that of the basic drive (H_1–V_1). The right bundle branch potential is now present in the premature response. Ventricular aberration on the surface electrocardiogram is clearly reduced. The S wave in lead I may indicate refractoriness of the more distal right bundle branch.

the surface electrocardiogram as an increased P–R interval of the premature beat with a corresponding increase in the R–R interval of the basic and premature beats. Examination of the His bundle electrograms obtained from these patients showed that A–V nodal conduction time of the premature beat (A_2–H_2 interval) increased progressively as the atrial depolarization became increasingly more premature (Fig. 1, upper panels A and B). When atrial depolarization was sufficiently premature, block above the His bundle occurred (Fig. 1, upper panel C). The H–V interval, which approximates conduction time through the His-Purkinje system, remained unchanged at all premature intervals because conduction through the more proximal A–V node was sufficiently slow to allow the more distal His-Purkinje system time to recover from the preceding impulse. Conduction of the premature impulse to the ventricles with aberration of the QRS complex on the surface electrocardiogram was uncommon in these patients.

Because the A–V node was the component of the A–V conduction system most refractory to the conduction of a premature impulse, the relative, functional and effective refractory periods of the A–V conduction system were determined by the refractory properties of the A–V node. Thus, the eight patients in this group had identical values for the functional and effective refractory periods of the A–V node and the A–V conduction system (Table I).

After administration of digoxin, conduction of an atrial depolarization through the A–V node was slowed, but conduction through the His-Purkinje system was unaffected. A–V nodal conduction time was increased compared to the control value at the same A_1–A_2 interval (Fig. 1, lower panel A). No change in the H–V interval was noted. After digoxin, block above the His bundle occurred at an A_1–A_2 interval longer than that of the control response (Fig. 1, lower panel B). In addition, there was an equal increase in refractoriness of the A–V node and the A–V conduction systems in all eight patients in this group (Table I). Therefore, digoxin acted solely on the A–V node to slow conduction of a premature impulse, thereby altering the pattern of A–V conduction.

Effects of digoxin in Group II: In this group of nine patients, conduction delay or block of a premature impulse, or both, occurred in both the A–V node and the His-Purkinje system during the control period (Group II, Table I; Fig. 2 and 3). Because conduction of the premature impulse through the A–V node was faster than in patients in Group I, the impulse reached the His-Purkinje tissue when this tissue was partially refractory. Therefore, conduction through the His-Purkinje system was delayed and the H_2–V_2 interval was prolonged (Fig. 2A and 3, A and B). The surface electrocardiogram showed conduction of the premature impulse to the ventricles with aberration of the QRS complex. In 5 patients in this group (Pa-

tients 9 to 13) the A–V node was the most refractory component of the A–V conduction system, and a sufficiently premature impulse was blocked first in the A–V node. In the remaining 4 patients (Patients 14 to 17) the His-Purkinje system was the most refractory component, and block below the His bundle occurred before block in the A–V node (Fig. 3C). In all of these latter 4 patients, when the impulse was even more premature, block also occurred in the A–V node (Fig. 3D).

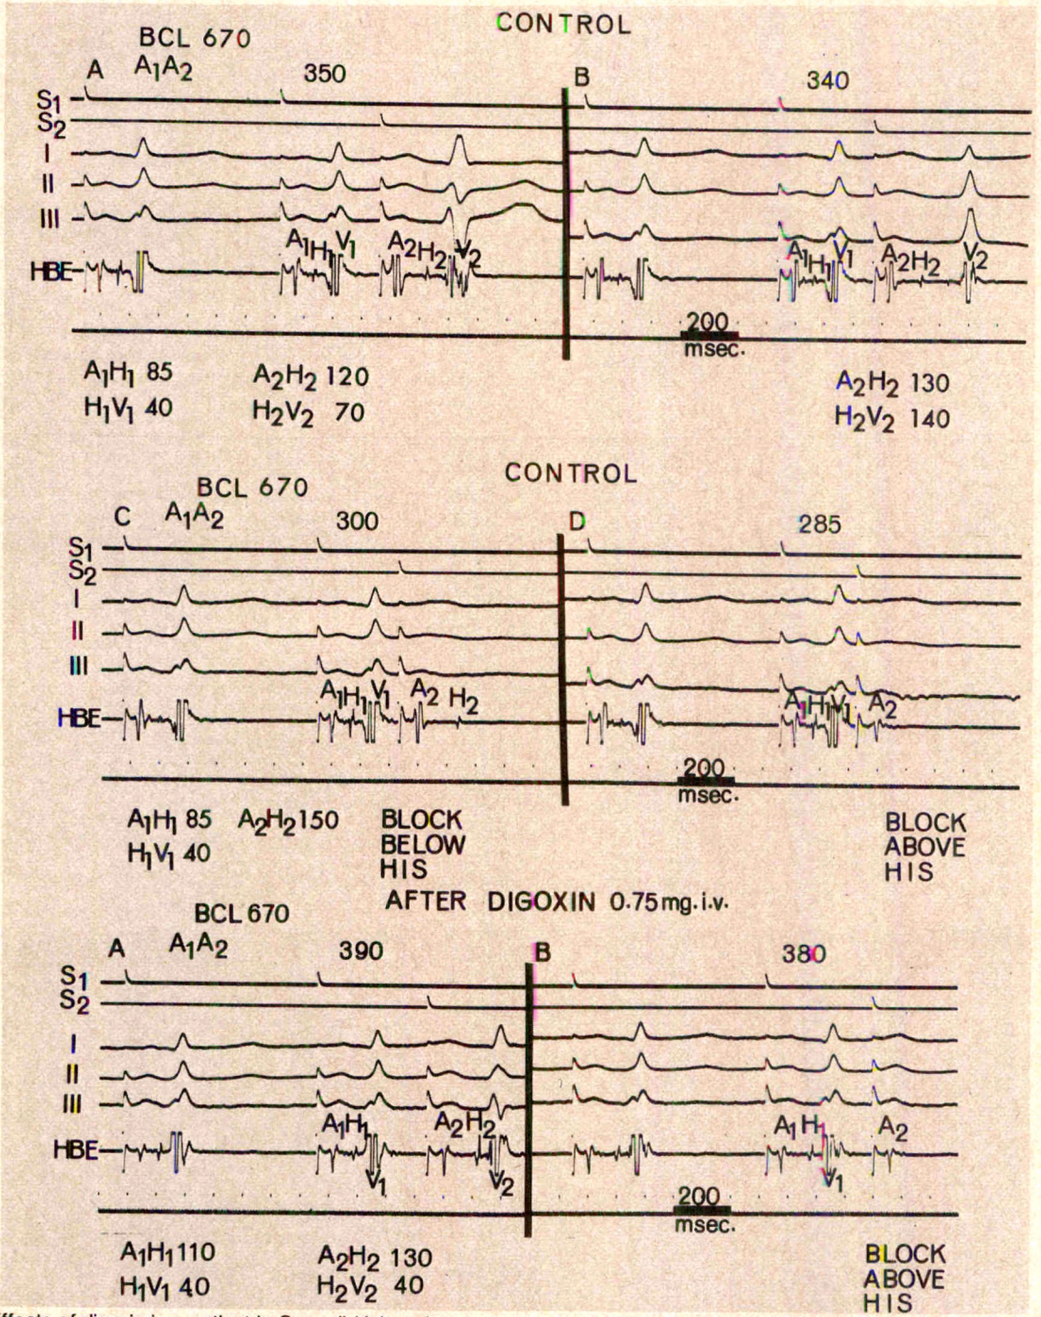

FIGURE 3. Effects of digoxin in a patient in Group II (delay of a premature atrial depolarization occurring in both the A–V node and His-Purkinje system and block occurring first below the His bundle during the control state). Abbreviations as in Figure 1. **Panels A** through **D** are recordings obtained before administration of digoxin. In **panel A**, at an A_1–A_2 interval of 350 msec, the A–H interval increases from 85 (A_1–H_1 interval) to 120 msec (A_2–H_2 interval) and the H–V interval from 40 (H_1–V_1 interval) to 70 msec (H_2–V_2 interval), indicating conduction delay in both the A–V node and His-Purkinje system. In **panel B**, at a more premature A_1–A_2 interval of 340 msec, the A_2–H_2 interval increases to 130 msec and the H_2–V_2 interval to 140 msec. Ventricular aberration is present in lead V_2 in both **panels A** and **B**. In **panel C**, at an A_1–A_2 interval of 285 msec, block occurs above the His bundle within the A–V node. After digoxin, A–V nodal conduction time increases from 85 (A_1–H_1 interval) to 110 msec (A_1–H_1 interval) at the same basic driving cycle length of 670 msec. In **panel A** (after digoxin), at an A_1–A_2 interval of 390 msec, the H_2–V_2 interval is 40 msec and ventricular aberration is minimal. In **panel B** (after digoxin), at an A_1–A_2 interval of 380 msec, block first occurs above the His bundle within the A–V node.

After administration of digoxin, in 6 patients in this group (Patients 9 to 14), conduction delay and block of a premature impulse were confined solely to the A–V node, and neither conduction delay nor block occurred in the His-Purkinje system (Fig. 2B and 3, lower panel A). Digoxin now slowed A–V nodal conduction sufficiently to allow the His-Purkinje system time to recover from the preceding impulse. Aberrant ventricular conduction of a premature impulse was reduced (Fig. 2B). The effective and functional refractory periods of the A–V node and A–V conduction system were identical after digoxin and were increased from pre-digoxin levels. In the remaining 3 patients, (Patients 15 to 17) A–V nodal conduction delay of a premature impulse was increased after digoxin, but not enough to prevent the impulse from reaching the His-Purkinje system outside its refractory period. Consequently, in Patients 15 and 16 block still occurred in the His-Purkinje system, and in Patient 17 delay in the His-Purkinje system preceded A–V nodal block. Digoxin had no apparent direct effect on conduction through the His-Purkinje system.

Discussion

The acute effects of digoxin on A–V conduction patterns in man depend primarily on the sensitivity of the A–V node to the cardiac glycoside. These effects of digoxin are related to delayed A–V nodal conduction[14–16] as a result of increased A–V nodal refractoriness.[12,17,18] Mendez and Mendez[19] found that ouabain and digitoxin in dogs increased refractoriness of the A–V conduction system to the point of complete A–V block. However, the response patterns were not detailed in their study, and His bundle electrograms were not available to localize more precisely the site of action of digitalis.

Clinically, the effects of digitalis on cardiac conduction during sinus rhythm may be unmasked by right atrial pacing[20]; on other occasions these effects may be readily manifested by a prolonged P–R interval.[21] Typically, a prolonged QRS complex has not been observed after administration of digitalis.[22,23] In these latter studies digoxin did not affect the His-Purkinje tissue directly to delay intraventricular conduction. Hoffman and Singer[14] found no direct evidence in man that digoxin affects refractoriness of the His-Purkinje system. However, in our studies digoxin did appear to have an indirect effect on conduction of a premature impulse through the His-Purkinje system. Digoxin, by prolonging A–V nodal conduction time, permitted the premature impulse to arrive at His-Purkinje tissue when this tissue was less refractory. Ventricular aberration was thereby reduced or eliminated. The elimination of ventricular aberration in dogs by delaying conduction of a premature atrial impulse in the A–V node with vagal stimulation has also been noted.[24]

After administration of digoxin in Patient 15, there was a paradoxical decrease in refractoriness of the A–V conduction system; that is, a ventricular response, V_2, could be elicited at a shorter A_1–A_2 interval after digoxin. This occurred because the increase in A–V nodal conduction time after digoxin allowed the ventricular specialized conduction tissue time to recover partially from its refractory state. Thus, after digoxin the net effect was a decrease in refractoriness of the A–V conduction system. This was the only case in which this phenomenon occurred.

In conclusion, the effect of acute intravenous administration of digoxin on A–V conduction was studied in 17 unsedated subjects. During the control period, conduction delay of a premature atrial impulse occurred solely in the A–V node in eight subjects (Group I) and occurred in both the A–V node and the His-Purkinje system in nine subjects (Group II). Because digoxin slowed conduction in the A–V node, a premature atrial depolarization could be prevented from reaching the His-Purkinje system during its refractory state and thus ventricular aberration was reduced or eliminated. Patterns of A–V conduction were altered. Clinically, digoxin may abolish aberrant ventricular conduction in atrial fibrillation by increasing A–V nodal refractoriness and thereby enhancing concealment within the A–V node. Digoxin in the dosage used did not affect refractoriness in the His-Purkinje system at the time of study (30 minutes after administration). In one subject, after administration of digoxin, a paradoxical decrease in refractoriness of the A–V conduction system was observed at a time when refractoriness in the A–V node increased.

Diagnostic Value of Clinical History, Exercise Testing and Atrial Pacing in Patients with Chest Pain

JAN PIESSENS, MD
WALTER VAN MIEGHEM, MD
HUGO KESTELOOT, MD
HILAIRE DE GEEST, MD

Leuven, Belgium

The clinical history and the electrocardiographic response to graded exercise testing and atrial pacing were correlated with the presence or absence of severe coronary artery disease, as demonstrated by coronary angiography, in 70 patients. A clinical history of angina pectoris was a very sensitive (90 percent) but less specific (80 percent) predictor of severe coronary artery disease. Ischemic S–T segment depression greater than or equal to 1 mm was the most accurate electrocardiographic predictor. When this criterion was used, the graded exercise test was less sensitive (65 vs. 72 percent) but more specific (83 vs. 70 percent) than atrial pacing. Results of a discriminant function analysis of several possible predictors of severe coronary artery disease indicated that atrial pacing does not contribute significantly to the diagnosis in patients submitted to a graded exercise test.

Exercise electrocardiography is a well accepted method of detecting coronary insufficiency in patients with a history of chest pain. The relation between horizontal and downsloping S–T segment depressions and the presence of severe coronary artery disease has been assessed in follow-up mortality studies.[1,2] More recently, these S–T segment changes were correlated with anatomic findings at coronary angiography.[3–6] Atrial pacing was introduced as another method of determining the anginal threshold.[7] By increasing the oxygen consumption of the heart, this procedure can precipitate angina pectoris and provoke ischemic S–T segment changes.

No studies are available comparing the value and limitations of exercise testing and atrial pacing in determining the presence or absence of severe coronary artery disease. In this study we compared the value of these two stress tests in predicting severe coronary artery disease in patients with chest pain. In addition, some clinical and electrocardiographic data were combined in an attempt to improve the predictive value. Finally, the additional independent contribution of various diagnostic variables was determined.

Methods

Selection of patients: Seventy patients (59 men and 11 women, aged 30 to 61 years [mean 47.2 years]) with a history of chest pain warranting coronary angiography were studied. Patients with congenital, hypertensive or rheumatic heart disease, intermittent claudication or a cardiothoracic ratio of more than 0.5 were excluded. Treatment with digitalis, quinidine, procainamide or beta adrenergic blocking agents was also a criterion for exclusion.

After the initial clinical history was obtained, the patients were classified as having typical angina pectoris or atypical chest pain. The former diagnosis was exclusively reserved for patients complaining of pain, pressure or constriction in the anterior area of the chest, usually precipitated by effort and relieved within 10 minutes by rest.

All patients with electrocardiographic findings at rest that were definitely abnormal except for discrete S–T wave changes were excluded from the study. Q waves were classified according to the Minnesota code,[8] and pa-

tients with Q waves classified between codes 1-1-1 and 1-2-8 were considered to have old myocardial infarction and excluded from the study.

Routine laboratory data were obtained in each patient; patients with anemia or abnormal hepatic or renal function were excluded. Serum cholesterol was determined according to the method of Pearson.[9] The graded exercise test, the atrial pacing test and selective coronary angiography were performed on 3 consecutive days, at least 2 hours after a light meal.

Graded exercise test: This test was performed on a calibrated bicycle ergometer (Elema-Schönander AM 368). The electrodes were attached to the patient sitting on the ergometer using a slight modification of the method of Mason and Likar.[10] Unipolar and bipolar limb and three precordial leads (V_4, V_5 and V_6) were continuously monitored on an oscilloscope and recorded on a three channel direct ink-jet recorder with an amplitude calibration of 1 mv/cm (Mingograf 32, Elema-Schönander). After a 5 minute rest period, exercise was started at an initial work load of 200 kg-m/min, which was augmented every 4 minutes in increments of 200 kg-m/min until definite angina pectoris or exhaustion occurred. The appearance of S–T segment depressions or elevations was not sufficient reason to interrupt the test. Electrocardiographic recordings were made before and every minute during the actual exercise and during the immediate postexercise period until the heart rate and electrocardiographic abnormalities, if present, returned to preexercise values. The exercise electrocardiograms were read independently by two cardiologists. Only horizontal or downsloping S–T segment depressions were taken into account, and the degree of depression was expressed in millimeters. The exercise and postexercise periods were considered separately and the maximal ischemic S–T depression observed during each period was used in the study. The maximal heart rate reached during exercise was noted.

Atrial pacing test: This test was performed by means of a bipolar pacing catheter introduced into a right antecubital vein and advanced to the junction of the superior vena cava and right atrium. After a 5 to 10 minute period of rest, atrial pacing was started at a rate 10 beats above the control level, using the minimal voltage to assure stable pacing (Electrodyne TR-3). Every minute the heart rate was increased by 10 beats until definite angina pectoris or atrioventricular dissociation occurred. A 12 lead electrocardiogram was recorded on an eight channel ink-jet recorder (Mingograf 81, Elema-Schönander) just before, every minute during and for 5 minutes after pacing. Fifteen minutes later the test was repeated. If atrioventricular dissociation occurred at a rate lower than 140 beats/min during the first test, 1 mg of atropine sulfate was injected intravenously before the second test. The patient was not informed of the beginning or end of the pacing and was asked to inform the physician as soon as chest pain occurred and to describe its characteristics as accurately as possible. S–T segment depressions, occurring during pacing, were evaluated as described for the graded exercise test, at the maximal obtained heart rate.

Selective coronary arteriography: This procedure was performed in multiple projections according to the Sones technique.[11] A 6 inch Siemens image intensifier was linked with a cine-pulse unit. Recordings were made with an Arriflex camera at a rate of 40 frames/sec.

Coronary arterial lesions were classified on the basis of the severest narrowing in any of the following branches: dominant right coronary artery, left main trunk, anterior

descending, major diagonal branches, circumflex and major lateral or posterolateral branches. Patients with at least an estimated 75 percent narrowing of one of these branches were considered to have a positive coronary angiogram. On the basis of this angiographic criterion, patients were classified into two groups: those with severe coronary artery disease (group I) and those with a normal coronary angiogram or minor lesions (group II). The classification in each case was performed on two occasions, several months apart, by an experienced observer who had no knowledge of the patients' history or test results. The two interpretations were concordant except for those of one angiogram, which was analyzed by two other observers with concordant interpretations.

Statistical methods: Mean values ± 1 standard deviation are given. The *t* test was used for comparisons of height, weight, age, maximal obtained heart rate and serum cholesterol in both groups.

The diagnostic performance of the tests was judged in terms of sensitivity ($n_1/n_2 \times 100$) and specificity ($n_3/n_4 \times 100$):

n_1 = number of cases with a true positive test (either true positive clinical history or true positive stress electrocardiogram).

n_2 = total number of cases with a positive coronary angiogram.

n_3 = number of cases with a true negative test (either true negative clinical history or true negative stress electrocardiogram).

n_4 = total number of cases with a negative coronary angiogram.

Discriminant function analysis (stepwise method) was used to assess the independent diagnostic contribution of various parameters.

Results

Coronary angiogram: Group I comprised 40 patients with at least one severely stenotic artery. In 4 patients a single, in 32 patients two and in 4 patients three severe stenoses were present. Group II comprised 30 patients, 25 with a completely normal coronary angiogram, 3 with some irregularities of the vessel wall and 2 with less than 75 percent stenosis.

Clinical and laboratory findings: In 36 of 42 patients with a typical history of angina pectoris a positive coronary angiogram was found. A negative angiogram was found in 24 of 28 patients with "atypical chest pain." The sensitivity of the clinical history was 90 percent and its specificity 80 percent. Mean height, mean weight, mean age and mean systolic and diastolic blood pressures were similar in both groups. Three of the 11 female patients were classified in group I and 8 in group II.

A higher mean value for serum cholesterol was present in group I than in group II (264 ± 60.0 versus 227 ± 49.7 mg/100 ml) ($P < 0.01$).

S–T segment changes during and after graded exercise test (Table I): During exercise, ischemic S–T segment depression equal to or greater than 1 mm was observed in 24 patients in group I and in 3 patients of group II. Two of these three patients had a normal angiogram and one had less than 50 percent stenosis of both the right and left circumflex coronary arteries. With use of the same criterion, a negative tracing during exercise became positive during the postexercise period in two patients of group I and two patients of group II. The two latter patients had a normal angiogram.

TABLE II

Electrocardiographic Response to Exercise Testing and Atrial Pacing

Exercise	Atrial pacing	Number of Patients	
		Group I*	Group II†
+	+	24	5
+	−	2	0
−	+	5	4
−	−	9	21

* Group I = severe coronary artery disease determined angiographically.

† Group II = normal coronary arteries or minor lesions.

+ and − = respectively, greater than or equal to and less than 1 mm ischemic S–T segment depression, provoked by exercise or atrial pacing.

For ischemic S–T segment depression greater than or equal to 1 mm, the sensitivity of the graded exercise test was 65 percent and its specificity 83 percent. For ischemic S–T segment depression greater than or equal to 0.5 mm, 28 patients of group I and 10 patients of group II had a positive test during or after exercise. The calculated sensitivity and specificity of this criterion were, respectively, 70 and 66 percent. In the patients with positive responses, the maximal S–T segment depression was invariably recorded in the precordial leads V_4, V_5 and V_6.

Mean maximal heart rate during exercise was lower in group I than in group II (135 ± 24 versus 155 ± 21 beats/min) ($P < 0.001$).

S–T segment changes during atrial pacing test (Table I): Twenty-nine patients of group I and nine of group II manifested ischemic S–T segment depression equal to or greater than 1 mm during pacing. The sensitivity for this criterion was 72 percent and its specificity 70 percent. For an ischemic S–T segment depression equal to or greater than 0.5 mm, the sensitivity remained unchanged, but the specificity decreased to 63 percent. Mean maximal pacing rate was not significantly different in groups I and II (152 ± 20 versus 161 ± 20). Mean maximal pacing rate in the nine patients of group II with an ischemic S–T depression equal to or greater than 1 mm was 160 beats/min.

Comparison of exercise testing and atrial pacing for ischemic S–T segment depressions: For an ischemic S–T segment depression greater than or equal to 1 mm, 24 patients of group I and 5 patients of group II had both a positive exercise and pacing test (Table II). Both tests were negative in 9 patients of group I and 21 patients of group II. In seven patients of group I and four of group II, the test results were discordant. Of the four patients whose electro-

TABLE III

Correlation Between Clinical History, Electrocardiographic Response to Stress and the Presence or Absence of Severe Coronary Artery Disease

	Graded Exercise Test		Atrial Pacing	
	Group I*	Group II†	Group I*†	Group II†
Angina pectoris + ischemic S–T depression ⩾ 1mm	24	1	27	1
Angina pectoris + ischemic S–T depression <1 mm	12	5	9	5
No angina pectoris + ischemic S–T depression ⩾1 mm	2	4	2	8
No angina pectoris + ischemic S–T depression <1 mm	2	20	2	16

* Group I = severe coronary artery disease determined angiographically.

† Group II = normal coronary arteries or minor lesions.

cardiograms remained normal during the exercise test but became positive during the postexercise period, all but one patient (from group I) also had a positive response to atrial pacing.

Combination of clinical and electrocardiographic data: Clinical history and ischemic S–T segment depressions provoked by exercise and atrial pacing were correlated with the presence or absence of severe coronary artery disease on coronary angiograms (Table III). The combination of a typical history of angina pectoris with a positive electrocardiographic response to exercise or atrial pacing occurred in 25 and 28 patients, respectively. Only one of these patients had a normal angiogram. When atypical chest pain was accompanied by a normal electrocardiographic response to exercise or atrial pacing, the coronary vessels were normal in 91 and 88 percent, respectively, of the subjects. A discrepancy between clinical history and electrocardiographic response to exercise or atrial pacing occurred in one third of the cases.

The clinical and electrocardiographic responses to exercise and atrial pacing were correlated with the presence or absence of severe coronary artery disease (Table IV). The graded exercise and atrial pacing tests induced typical angina pectoris combined with a positive electrocardiographic response in 22 and 26 patients, respectively. All had severe coronary artery disease except one patient, whose clinical history was judged atypical. When a negative clinical and electrocardiographic response to exercise or atrial pacing occurred, the coronary vessels were normal in more than two thirds of the subjects.

Clinical response to exercise testing and atrial pacing in patients with a typical history of angina pectoris: The 42 patients with a typical history of angina pectoris are classified in Table V. Angina pectoris could be reproduced in 31 patients by exercise or atrial pacing, or both. All 31 manifested severe coronary artery disease on angiography. Angina pectoris could not be induced in the six patients with a history of angina pectoris and normal coronary arteries although their mean maximal heart rate was 147.5 ± 21.4 beats/min for the graded exercise test and 161.67 ± 7.5 for the atrial pacing test.

Exercise and atrial pacing did not induce angina pectoris in 10 and 8 patients, respectively, with severe coronary artery disease and a typical history of angina pectoris. The mean maximal heart rates obtained during exercise and pacing in these patients were, respectively, 140.6 ± 17 and 152.5 ± 28 beats/min.

Discriminant function analysis of factors contributing to the diagnosis of severe coronary artery disease: The following variables were used in the analysis: maximal ischemic S–T segment depression during exercise, maximal ischemic S–T segment depression after exercise, maximal heart rate during exercise, maximal ischemic S–T segment depression during atrial pacing, maximal obtained pacing rate and serum cholesterol values.

The final discriminant function equation revealed three significant ($P < 0.05$) factors:

A. Maximal S–T depression during exercise, expressed in millimeters ($t = 3.88$)

TABLE IV

Correlation Between the Clinical* and Electrocardiographic Responses to Stress and the Presence or Absence of Severe Coronary Artery Disease

	Graded Exercise Test		Atrial Pacing	
	Group I†	Group II‡	Group I†	Group II‡
Angina pectoris + ischemic S–T depression ⩾1 mm	21	1	25	1
Angina pectoris + ischemic S–T depression ⩽1 mm	7	2	5	2
No angina pectoris + ischemic S–T depression ⩾1 mm	5	4	4	8
No angina pectoris + ischemic S–T depression ⩽1 mm	7	23	6	19

* Clinical indicates typical angina pectoris during exercise or atrial pacing tests.

† Group I = severe coronary artery disease determined angiographically.

‡ Group II = normal coronary arteries or minor lesions.

B. Maximal heart rate during exercise, expressed in beats per minute ($t = -4.45$)

C. Serum cholesterol, expressed in milligrams per 100 milliliters ($t = 2.21$).

The discriminant function equation for the significant factors was:

$$\text{Severe CAD (1.0)} = 1.085 + 0.125\,A - 0.00788\,B + 0.00189\,C$$
$$(R = 0.66;\ SEy = 0.38)$$

where CAD (1.0) = presence (1) or absence (0) of severe coronary artery disease, and y = the dependent variable, severe coronary artery disease.

The introduction as a dependent variable of N_1/N and $-N_2/N$ for presence and absence of severe coronary artery disease changed the constant from 1.085 to 0.531 but did not influence the other factors of the discriminant function. (N = total number of cases, N_1 = number of cases with severe coronary artery disease, and N_2 = number of cases without severe coronary disease.)

Discussion

The presence or absence of an estimated 75 percent coronary arterial stenosis on angiography delineated a first group of subjects with severe and extensive disease and a second group, whose large majority of patients had normal coronary arteries. No differences in age, weight, height and blood pressure were found between the groups. Since patients with previous myocardial infarction, definite electrocardiographic abnormalities at rest or cardiomegaly were excluded, the major difference between groups was the presence or absence of severe coronary artery disease as defined by angiography. More female patients were present in the group with normal findings (27 percent) than in the group with severe coronary artery disease (8 percent).

The presence of a typical history of angina pectoris without coronary artery disease has been discussed by others.[12,13] Our study included six patients with a typical history of angina pectoris in the absence of coronary or valvular lesions. The prevalence of 14 percent is comparable to the prevalence of 17 percent reported in other studies.[3,4,6] However, the two stress tests did not reproduce the typical symptoms in our patients and provoked a positive electrocardiographic response in only one. These findings suggest a bias introduced into the clinical history by the doctor or the patient.

In our selected group of patients, a typical history of angina pectoris was a more sensitive (90 percent) than specific (80 percent) predictor of severe coronary artery disease. But it is difficult to explain why angina pectoris could not be induced by exercise or atrial pacing in a significant number of patients with a typical history and severe coronary artery disease (Table IV). Insufficient cooperation of these patients does not appear to be a factor since the maximal heart rate obtained during exercise testing or atrial pacing in this group did not differ from that of the total group.

TABLE V

Clinical Response to Exercise Testing and Atrial Pacing in 42 Patients with a Typical Clinical History of Angina Pectoris

Exercise Testing	Atrial Pacing	Number of Patients: Group I*	Number of Patients: Group II†
+	+	23	0
+	−	3	0
−	+	5	0
−	−	5	6

* Group I = severe coronary artery disease determined angiographically.

† Group II = normal coronary arteries or minor lesions.

+ and − = respectively, presence or absence of typical angina pectoris provoked by exercise or atrial pacing.

All our patients with a typical history of angina pectoris, confirmed by a positive clinical response during stress, proved to have severe coronary artery disease but no conclusion could be made when this confirmation was lacking. The evaluation of ischemic S–T segment depressions during exercise in our patients resulted largely in a confirmation of the results reported by others. Sensitivity (65 percent) and specificity (83 percent) of an S–T segment depression greater than or equal to 1 mm are in good agreement with data from other studies[3–6] in which an estimated 50 percent stenosis was used as the criterion for a positive coronary angiogram. However, since in our study only two subjects with coronary artery disease had less than 75 percent stenosis, the use of a less severe criterion for a positive angiogram does not substantially influence the results.

In our study the sensitivity was increased slightly by using the criterion of S–T segment depression greater than or equal to 0.5 (70 versus 65 percent), but the specificity of the test decreased markedly (66 versus 83 percent). In other studies the use of this less severe criterion also resulted in a small increase in sensitivity, counteracted by a larger decrease in specificity.[3] Data obtained from use of the three precordial leads V_4, V_5 and V_6 alone contained all the diagnostic information provided by the exercise tests. This finding may be a result of the diffuse nature of the disease in the large majority of our patients.

Atrial pacing appears to be slightly more sensitive in provoking ischemic S–T segment depressions than the graded exercise test (72 versus 65 percent). Lau et al.[14] suggested that atrial pacing was more sensitive in provoking ischemic S–T segment depressions than the double Master two-step test in patients with angina pectoris. However, the greater sensitivity was counteracted in our study by a larger decrease in specificity (70 versus 83 percent). All patients with a

UNIVERSITY COLLEGE OF MEDICINE LIBRARY

false positive exercise test also had a false positive atrial pacing test. In other words, there were no patients with a normal coronary angiogram who had a positive exercise test who did not have a positive atrial pacing test as well. The difference between the tests is probably explained by the higher heart rates that could be obtained by pacing.

The clinical diagnosis combined with the electrocardiographic diagnosis was correlated with the presence or absence of severe coronary artery disease. Fewer false negative results were obtained when the clinical diagnosis was based on the initial history rather than on interpretation of the chest pain occurring during the stress tests. The combination of clinical history and stress electrocardiogram had a very high predictive value when the data were concordant. No definite conclusion was possible when the clinical diagnostic data and stress electrocardiogram were discordant, although a trend favored the clinical diagnosis. No major differences in predictive value were found whether the electrocardiographic diagnosis was based on exercise testing or on atrial pacing.

Conclusions: The discriminant function analysis indicated that the atrial pacing test does not contribute significantly to the diagnosis of severe coronary artery disease in patients submitted to a graded exercise test. It also appears that the maximal heart rate obtained during exercise negatively correlates with severe coronary artery disease and is the best predictor of its presence, a fact heretofore inadequately stressed. Although the final regression coefficient ($r = 0.66$, $P < 0.001$) was highly significant, it was not high enough to allow the use of the discriminant function equation as a predictor for the diagnosis in individual patients.

Pulmonary arterial diastolic pressure has been shown to be a reliable estimate of left ventricular filling pressure. In 91 patients with acute myocardial infarction, the Swan-Ganz flow-directed catheter was used to measure pulmonary arterial diastolic pressure, which was correlated with clinical and radiographic estimates of left ventricular failure. The physical findings of a third sound gallop and rales were significantly correlated with the level of pulmonary arterial diastolic pressure. In the absence of either a third sound gallop or rales, the pulmonary arterial diastolic pressure was found to be increased in 47 percent of the patients. The presence of rales was a less sensitive determinant of left ventricular dysfunction than a third sound gallop alone or in association with rales. Radiographic findings of increasing pulmonary congestion were significantly correlated with the level of pulmonary arterial diastolic pressure. In the absence of radiographic pulmonary congestion, 24 percent of patients had abnormal pulmonary arterial diastolic pressure. We conclude that measurement of pulmonary arterial diastolic pressure increases the objectivity of the clinical evaluation in patients with acute myocardial infarction.

In this era of coronary care units, myocardial failure is the most important factor determining hospital survival.[1] Evidence of heart failure on physical and radiographic examination is present in 40 to 50 percent of patients on admission to a coronary care unit, and the incidence reaches approximately 60 percent during the first 24 to 48 hours.[1–6] Previous studies from our laboratory[6] have revealed that a wide spectrum of hemodynamic changes is seen in patients with acute infarction studied early in their hospital course. The development of the balloon-tipped flow directed catheter by Swan and Ganz has introduced a rapid, safe and effective method for the measurement of right-sided cardiac pressures.[7]

The primary purpose of this study was to evaluate prospectively the correlation between pulmonary arterial diastolic pressure and several noninvasive clinical estimates of myocardial failure. The validity of the current system of subgrouping according to physical findings was investigated and a new radiographic classification is proposed.

Method

Ninety-one patients with acute myocardial infarction were studied. No patient had evidence of significant lung disease or mitral valve disease. The diagnosis of acute infarction was based on the following criteria: (1) a typical clinical history, and/or (2) electrocardiographic changes consisting of new Q waves or typical evolutionary ST–T changes, and (3) characteristic serial changes of serum enzymes including creatine phosphokinase (CPK), glutamic oxaloacetic transaminase (SGOT) and lactic dehydrogenase (LDH). The patients were studied in the catheterization laboratory in the Myocardial Infarction Research Unit. A no. 5 or no. 7 Swan-Ganz catheter was inserted into

FIGURE 1. Schematic representation of the five radiographic signs used in evaluating left ventricular failure **(left)** and normal findings **(right).** Four radiographic grades were defined using these five signs: grade I, the absence of all parameters; grade II, cephalization and vascular blurring; grade III, cephalization, vascular blurring and hilar haze or outer zone vessels, or both; and grade IV, all five variables.

an antecubital vein, either percutaneously or by cutdown procedure, and advanced into the right atrium. In the right atrium, the balloon was inflated and the catheter advanced into the pulmonary artery. A no. 16 or no. 18 Teflon® needle was placed in the radial or brachial artery. Pressures were measured using a zero reference point 10 cm above the surface of the catheterization table or bed. The pressures were measured with a Hewlett-Packard transducer (no. 1280C) and recorded on a Hewlett-Packard multichannel oscillograph.

Clinical criteria for heart failure: One hour before the hemodynamic study, three observers evaluated the clinical status of the patient. On the basis of physical findings, patients were assigned to one of four classes. Class I was defined as no clinical evidence of congestive heart failure, that is, absence of a third sound gallop or rales, or both. Class II was defined as the presence of a third sound gallop or wet rales, or both. Patients in class III had overt pulmonary edema or pulmonary rales extending to above the midportion of the scapula. Patients in class IV had cardiogenic shock (systolic blood pressure less than 90 mm Hg, urinary output less than 20 cc/hour, peripheral vasoconstriction and an altered sensorium).[8] Patients in class II were further subgrouped into those with rales alone, a third sound gallop alone or both a third sound gallop and rales.

Radiographic criteria for heart failure: Radiographic evaluations were carried out within 1 hour of the hemodynamic study. Six-foot pulmonary arterial chest films were taken with the patient seated. Five standard criteria were used to characterize increasing degrees of pulmonary congestion[9,10]: (1) *cephalization,* defined as basilar pulmonary venous constriction with central and upper venous dilatation; (2) *pulmonary vascular blurring,* the lack of clarity of the margins of individual veins; (3) *hilar haze,* defined as blurring of the perihilar structures; (4) *outer zone vessels,* the visualization of venous vessels in the outer third of the lung fields; and (5) *rosette formation,* the presence of small clusters of radiolucent areas surrounded by a haze of water density (Fig. 1). Two radiologists independently evaluated each film to determine its radiographic grade. Four radiographic grades, using these five criteria, were determined: grade I, the absence of all variables; grade II, cephalization and vascular blurring; grade III, cephalization, vascular blurring and hilar haze or outer zone vessels, or both; and grade IV, the presence of all five variables.

Statistical evaluation: The data obtained were evaluated, using a general linear model program in which it was possible to do univariate analysis of variance on designs with one dependent variable and multivariate analysis of variance on designs with more than one variable. The multivariate procedure yielded multivariate tests of significance, enabling the user to select from either Hotalling's Trace Criterion, Roy's Largest Root Criterion, or Wilk's Statistics. In addition, univariate F- statistics for each of the dependent variables were provided. By appropriate blocking of the design matrix, the same program was also used to compare regression equations over several groups.[11]

Results

The 91 patients who underwent these hemodynamic studies were compared with 614 patients with a diagnosis of acute infarction, admitted to our Myocardial Infarction Research Unit during the past 6 years. No significant difference was found with respect to (1) age, (2) sex, (3) frequency of previous infarction, or (4) frequency of a previous history of heart failure. When the 91 patients were grouped according to clinical class, their hospital mortality rate was no different from that of patients of a similar class in the larger group of 614. However, the mortality rate in our study group was 34 percent, compared to an overall mortality rate of 22 percent in the group of 614. This finding reflects the higher percentage of patients in classes II, III and IV and the lower percentage of patients in class I in this study group than in our total series with documented infarction. Despite our efforts to study all patients with suspected infarction, there was obvious selection in favor of sicker patients. Thus, our series is not representative of all patients with infarction, although we believe that the hemodynamic findings in any given clinical class of patients are representative of the findings in other patients in a similar class.

Pulmonary arterial diastolic pressure and mortality rate: The patients studied ranged in age from 35 to 85 years (mean age 60.2 years); 73 percent were male. The mean time between admission and study was 12 hours, and 90 percent of the patients were studied less than 24 hours after the onset of symptoms. In the 29 patients in class I, the pulmonary arterial diastolic pressure was 13.8 ± 4.6 mm Hg. In this group, three patients died (hospital mortality rate 10 percent). There were 41 patients in class II who had a pulmonary arterial diastolic pressure of 20.3 ± 5.8 mm Hg, and the hospital mortality rate was 22 percent (9 patients). Four patients in class III had a pulmonary arterial diastolic pressure of 38.3 ± 8.7 mm Hg and three of the four died. The

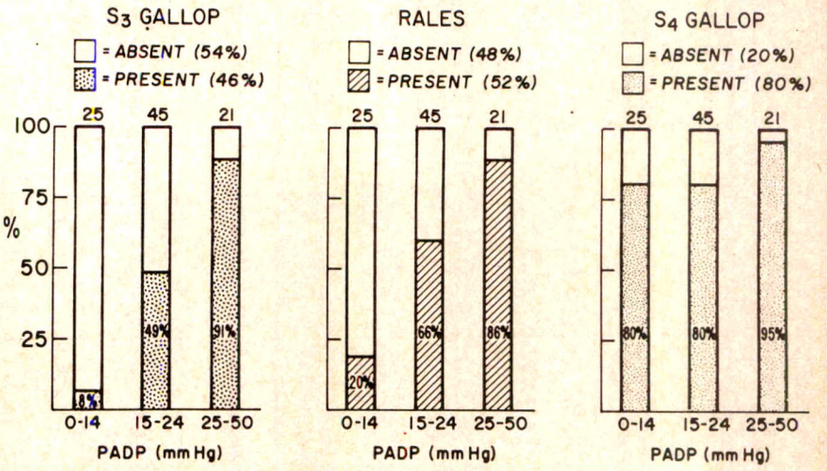

FIGURE 2. Relation of pulmonary arterial diastolic pressure (PADP) to the physical findings of third and fourth sound gallops and rales. The patients are classified into three categories on the basis of pulmonary arterial diastolic pressure. The number of patients in each pressure range is shown on top of the bar graphs. The percent of patients with the physical variable present, at each pressure range, is presented within the bar graphs.

pulmonary arterial diastolic pressure was 23.4 ± 9.5 mm Hg in 17 patients in class IV (hospital mortality rate 94 percent).

Correlation of pulmonary arterial diastolic pressure, third and fourth sound gallops, and rales: The relations of pulmonary arterial diastolic pressure to the physical findings of third and fourth sound gallops and rales are shown in Figure 2. The patients were classified in three categories on the basis of pulmonary arterial diastolic pressure: 0 to 14 mm Hg normal range; 15 to 24 mm Hg mild to moderate elevation; and 25 to 50 mm Hg severe elevation. A fourth sound gallop was noted in 80 percent of the patients and was found with equal frequency in all ranges of pulmonary arterial diastolic pressure. A third sound gallop was present in 46 percent (42 patients) of the total series. In these patients, the pulmonary arterial diastolic pressure was 24.4 ± 8.3 mm Hg compared to 15.1 ± 5.2 mm Hg in the 49 patients who had no third sound gallop. This difference was significant (P <0.001). Of 25 patients with a pulmonary arterial diastolic pressure of 14 mm Hg or less, only 2 (8 percent) had a third sound gallop. Of 21 patients with severely increased pulmonary arterial diastolic pressure, 18 (91 percent) had a third sound gallop. In the group with mild to moderate elevation, only 22 (49 percent) had a third sound gallop.

Rales were heard in 52 percent of the patients. The pulmonary arterial diastolic pressure in these 46 patients was 23.2 ± 9.1 mm Hg compared to 15.8 ± 5.4 mm Hg in the 45 patients without rales. This difference was significant (P <0.001). Five of the 25 patients (20 percent) with a normal pulmonary arterial diastolic pressure had rales, whereas 18 of the 21 patients (86 percent) with severe elevation had rales. In the group with mild to moderate elevation, rales were heard in 30 patients (66 percent). Thus, a third sound gallop and rales both correlated significantly with the level of pulmonary arterial diastolic pressure. However, although rales were heard in 20 percent of the patients with normal pulmonary arterial diastolic pressure, a third sound gallop was audible in only 8 percent of these patients.

The singular diagnostic value of the third sound gallop and pulmonary rales was further evaluated by substratification of patients (Fig. 3). In 34 patients without a third sound gallop or rales, the mean pulmonary arterial diastolic pressure was 15.2 ± 5.6 mm Hg; in 15 patients with rales but without a third sound gallop, this value was 16.5 ± 6.7 mm Hg. Eleven patients had a third sound gallop but no rales, and their pulmonary arterial diastolic pressure was 20.3 ± 6.2 mm Hg. In the 31 patients with both rales and a third sound gallop, the pressure was 25.8 ± 8.5 mm Hg. A significant difference (P <0.03) was found between the levels of pulmonary arterial diastolic pressure in patients with a third sound gallop (either alone or with rales) and those without a third sound gallop (with or without rales). No significant difference was noted between the group without rales or a third sound gallop and the group with rales only.

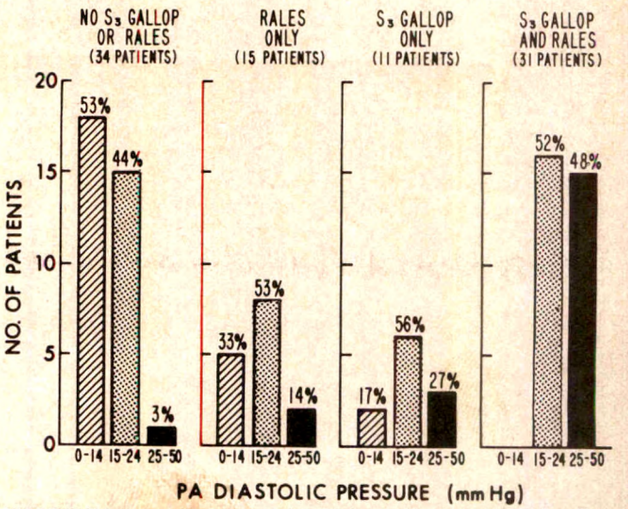

FIGURE 3. Diagnostic value of the third sound gallop and rales related to pulmonary arterial diastolic pressure. The number of patients at each pressure range in each subgroup is noted on the ordinate. The percent of the total group of patients within each subgroup at the three pressure ranges is presented above the bar graphs. PA = pulmonary arterial.

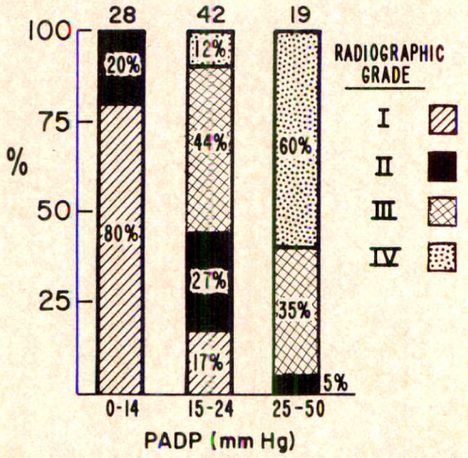

FIGURE 4. Pulmonary arterial diastolic pressure related to the radiographic evaluation. The number of patients within each pressure range is noted at the top of each bar graph. The percent of patients with the estimated radiographic grade within each pressure range is presented within the bar graphs.

Correlation of pulmonary arterial diastolic pressure and radiographic findings: The radiographic severity of pulmonary congestion and its relation to pulmonary arterial diastolic pressure is shown in Figure 4. This includes an evaluation of 88 technically satisfactory chest roentgenograms. Of 28 patients with a normal pulmonary arterial diastolic pressure, 80 percent had no radiographic evidence of pulmonary congestion. The remaining six patients in this group had all received a diuretic agent within 24 hours of study; the finding of a normal pulmonary arterial diastolic pressure but grade II X-ray changes in these patients may reflect the previously described lag between hemodynamic improvement and demonstration of radiographic improvement after therapy.[10] All 19 patients with severely increased pulmonary arterial diastolic pressure had radiographic evidence of pulmonary congestion and, in 18 of these, the radiographic grade was III or IV. Eighty-three percent of the patients with mild to moderate elevation of pulmonary arterial diastolic pressure had radiographic evidence of pulmonary congestion. Thus, of 59 patients with definite evidence of pulmonary congestion on X-ray film, 90 percent had an abnormal pulmonary arterial diastolic pressure. Of the 29 patients without radiographic evidence of pulmonary congestion, 76 percent had a normal pulmonary arterial diastolic pressure.

Discussion

Left ventricular filling pressure is a major determinant of ventricular performance through the well-known Frank-Starling relation.[12] Several studies of patients with acute myocardial infarction have revealed that right atrial pressure frequently does not reliably reflect changes of left ventricular filling pressure.[1,5,6,13,14] Thus, direct or indirect means of estimating left ventricular filling pressure are desirable. Although direct measurements of left ventricular pressure have been carried out, the need for arterial cannulation and the risk of ventricular irritability have made this procedure less than optimal.[5,15,16] At the end of diastole the left ventricle, left atrium and pulmonary vasculature form a functional conduit with only a small pressure gradient in the direction of flow.[17] Thus, in the absence of obstruction to pulmonary venous flow, a good correlation is expected between left ventricular filling pressure and pulmonary arterial diastolic or wedge pressures. In general, most studies have found a good correlation between pulmonary wedge and pulmonary arterial diastolic pressure and left ventricular end-diastolic pressure in patients with normal or only mildly abnormal left ventricular filling pressure.[17–20] However, a discrepancy in these two pressure measurements has been found with increasing degrees of left ventricular dysfunction.[17,20,21]

Correlation of pulmonary arterial diastolic pressure and clinical evidence of myocardial failure: The importance of the physical examination in patients with acute myocardial infarction has been previously emphasized.[22–24] An atrial (fourth sound) gallop is a frequent finding in the setting of acute myocardial infarction.[24,25] In our study it occurred frequently at all ranges of pulmonary arterial diastolic pressure and was not significantly related to this pressure. The presence of either a third sound gallop or rales has previously been considered an indication of left ventricular failure, and absence of both findings an indication of normal ventricular function.[8] In our patients with failure manifested by a third sound gallop or rales, or both, 85 percent had increased pulmonary arterial diastolic pressure. Furthermore, a significant difference in the pulmonary arterial diastolic pressure was noted when patients with a third sound gallop or rales were compared with patients who did not have these physical findings. Sjögren[2] found a similar significance when relating pulmonary arterial diastolic pressure to clinical rales and a third sound gallop. Hamosh and Cohn[5] measured left ventricular pressure directly and found a significantly higher level of end-diastolic pressure in patients with clinical evidence of failure than in those without failure.

Two important exceptions to the relation between a third sound gallop or rales and hemodynamic evidence of myocardial dysfunction were found in our study. Increased pulmonary arterial diastolic pressure was found in 47 percent of patients without clinical evidence of failure. The elevation of pulmonary arterial diastolic pressure or left ventricular filling pressure values in patients with acute infarction but no physical findings of failure has been noted previously.[1,5,16,26–29] Thus, although the presence of a third sound gallop and rales is highly significant and indicates increased filling pressure of the left ventricle, absence of these findings does not exclude the presence of left ventricular dysfunction in a large

number of cases. Furthermore, the presence of pulmonary rales in the absence of a third sound gallop was a less sensitive determinant of left ventricular dysfunction, manifested by increased pulmonary arterial diastolic pressure, than a third sound gallop alone or in association with rales. One third of the patients in the group with rales alone had a normal pulmonary arterial diastolic pressure.

Correlation of X-ray findings and signs of left ventricular failure: The conventional chest roentgenogram may provide one of the earliest signs of left ventricular failure. Derangements of left ventricular function lead to an increase in pulmonary venous pressure and the development of pulmonary venous hypertension.[9,10] Further degrees of left ventricular failure lead to added signs of interstitial edema including pulmonary venous blurring, hilar haziness, prominence of outer third venous markings and peri-acinar fluid transudation.[9,10,30] Harrison et al.[30] noted in their radiographic evaluation of patients with acute infarction that frequent radiographs were important for the early detection of left ventricular failure. Frequently, radiographic findings of congestion were noted before physical signs of cardiac failure. Our study demonstrated a significant correlation between increasing grades of pulmonary congestion on roentgenogram and increasing levels of pulmonary arterial diastolic pressure. More than 90 percent of patients with radiographic evidence of pulmonary congestion had abnormal pressure. All patients with grade III or IV radiographic changes had a pulmonary diastolic pressure greater than 15 mm Hg. Similar findings relating pulmonary arterial wedge pressure to radiographic signs of pulmonary congestion were noted by McHugh et al.[31] Sjögren[2] also reported a significant increase of pulmonary arterial diastolic pressure with increasing grades of pulmonary congestion. Hamosh and Cohn[5] found, in evaluating left ventricular end-diastolic pressure in acute infarction, that all patients with radiographic evidence of pulmonary congestion had pressures greater than 19 mm Hg. Discrepancies between the level of pulmonary arterial wedge pressure and the radiographic state of the lungs occurred in 10 percent of cases studied by McHugh et al.[31] These discrepancies were attributed to "preclinical failure," "post-therapeutic phase lag" or severe hypoxemia.[10,27] Our studies revealed some discrepancy in pulmonary arterial diastolic pressure in patients with normal radiographic findings. Twenty-four percent of patients without radiographic evidence of pulmonary congestion had increased pulmonary arterial diastolic pressure. Thus, like the third sound gallop, the presence of radiographic signs of pulmonary congestion correlates well with increased pulmonary arterial diastolic pressure but, like both a third sound gallop and rales, their absence does not exclude increased filling pressure.

In view of these findings of an abnormal level of pulmonary arterial diastolic pressure in the absence of clinical and radiographic evidence of left ventricular failure, it is important to recognize that increased left ventricular filling pressure does not necessarily signify left ventricular failure.[32,33] Previous studies[34] have revealed that serial changes in left ventricular size occur in many patients with acute infarction. In these patients an increase in end-diastolic volume and filling pressure is a reflection of impaired ventricular function and the use of the Frank-Starling mechanism to improve cardiac output.[35] Recent studies[32,36,37] have revealed in both the experimental animal and in man that reductions in left ventricular compliance are common in the setting of acute infarction. This decrease in compliance has been attributed to stiffening of the infarcted myocardium. In experimental studies of acute infarction, an increase in left ventricular end-diastolic pressure has been noted in the absence of an increase in end-diastolic volume and other findings of left ventricular failure.[36] The relative influence of an increase in end-diastolic volume and a change in compliance on the level of pulmonary arterial diastolic pressure in our patients cannot be determined from our study.

Clinical implications: It is clear from our study that hemodynamic measurements in the setting of acute myocardial infarction have improved understanding of the dynamics of infarction, and increased the objectivity of the clinical evaluations. Continuous monitoring of pulmonary arterial diastolic pressure can be useful in providing a clue to early hemodynamic derangements of the left ventricle.[29,38] With an increased understanding of left ventricular dysfunction, the proper interventions in this early state may prevent progressive deterioration. The measurement of pulmonary arterial diastolic pressure has been found useful in determining therapy, especially a need for volume expansion in some of the more severely ill patients, and has also proved important in the diagnosis of certain complications such as acute mitral insufficiency and ventricular septal rupture.[39,40] Much still needs to be learned about the hemodynamic effects of various agents, including digitalis and diuretic drugs, in the setting of acute myocardial infarction so that these agents can be used optimally.[2] The use of pulmonary arterial diastolic pressure as an index of left ventricular filling pressure will facilitate these studies.

The measurement of pulmonary arterial diastolic pressure thus has an important role in the daily management of patients with acute myocardial infarction and will provide a tool by which greater insight in the future management of patients will be possible. Our study has established the value of the pulmonary arterial diastolic pressure determination in one important capacity: improved understanding of the meaning of physical and radiographic findings.

Early Sequential Changes in Left Ventricular Dimensions and Filling Pressure in Patients After Myocardial Infarction

McKAMY SMITH, MD, PhD*
ROBERT A. RATSHIN, MD
FRANK E. HARRELL, Jr., BS
RICHARD O. RUSSELL, Jr., MD, FACC
CHARLES E. RACKLEY, MD, FACC

Birmingham, Alabama

Early consecutive changes in pulmonary arterial end-diastolic pressure (PAEDP) and echocardiographic left ventricular dimensions were measured in 14 patients within the first 8 days after acute myocardial infarction. Left ventricular volumes were estimated from echocardiographic left ventricular dimensions. Left ventricular compliance was assessed by three formulas, $\Delta V/\Delta P$, $\Delta V/ESV/\Delta P$ and $LVID_d/PAEDP$, where ΔV = echocardiographic stroke volume, ΔP = a derived left ventricular diastolic pressure change from the lowest level of early diastolic to the end-diastolic pressure, ESV = left ventricular end-systolic volume, and $LVID_d$ = echocardiographic left ventricular end-diastolic dimension. To compare pressure, dimension and compliance values, linear relations were assumed between values for left ventricular end-diastolic volume, end-systolic volume, pulmonary arterial end-diastolic pressure and the day after infarction. The estimated third day values for the variables obtained from these linear relations were used so that each patient's values would contribute equal weight to the statistical analysis.

The estimated third day compliance values from each formula correlated highly with one another (r = 0.69–0.82). Neither $\Delta V/\Delta P$ nor $\Delta V/ESV/\Delta P$ had a significant correlation with $LVID_d$. Echocardiographic end-diastolic volume correlated with both end-systolic volume (r = 0.89) and echocardiographic stroke volume (r = 0.62) but not with pulmonary arterial end-diastolic pressure. When the first and last measurements for each patient are used, large changes in pulmonary arterial end-diastolic pressure associated with no or small alterations in echocardiographic left ventricular end-diastolic dimension in 12 patients imply acute changes in ventricular compliance. Sequential compliance values ($\Delta V/\Delta P$) increased in seven survivors and decreased in one. $\Delta V/\Delta P$ decreased in the five patients who died or had electrocardiographic evidence of extension of infarction. Early sequential changes in filling pressure, echocardiographic dimensions, and left ventricular compliance had a close correlation with the clinical course of the patients in our series and these data may assist in the management of patients with hemodynamic instability after acute myocardial infarction.

Hemodynamic measurements made in patients soon after hospitalization for acute myocardial infarction have demonstrated various changes in left ventricular performance.[1–14] Several of these initial determinations have been useful in the early identification of patients with a poor prognosis. Among the measurements associated

with a high mortality rate are a pulmonary arterial end-diastolic pressure greater than 28 mm Hg, a combination of this pressure greater than 15 mm Hg and cardiac index less than 2.3 liters/min per m^2,[9] maximal value for the first derivative of left ventricular pressure (dP/dt) less than 1,000 mm Hg/sec,[2] left ventricular work less than 2.5 kg-m/min,[5] left ventricular stroke work index less than 25 g-m/beat per m^2,[10] and various indirect determinations of ventricular function made during isovolumic systole.[11–13] However, consecutive measurements of ventricular performance are required to identify progressive myocardial functional impairment in patients whose initial hemodynamic data do not indicate a poor prognosis.

An index of ventricular stiffness, which may be obtained for groups of patients, has been shown to be higher in patients studied 2 to 25 hours after acute myocardial infarction than in normal subjects or patients with coronary artery disease but no previous infarction.[14] Duplicate studies performed within a few days and 3 to 5 weeks after infarction have revealed that left ventricular end-diastolic pressure remains increased in many patients.[15,16] Increased left ventricular end-diastolic pressure and normal echocardiographic end-diastolic left ventricular internal dimension have been observed in five patients with clinical left ventricular failure within 24 hours after infarction.[16] The increased left ventricular end-diastolic pressure and normal echocardiographic internal dimensions persisted in the three patients studied 3 weeks after infarction. Increased left ventricular end-diastolic pressure and normal end-diastolic volume have been reported 4 and 8 weeks, respectively, after experimental myocardial infarction.[17] Thus, the decreased ventricular compliance measured within the first few hours of infarction appears to persist through the healing phase of the infarction. However, the relation between early sequential changes in left ventricular filling pressures, dimensions and compliance during the first few days after acute myocardial infarction in man have not been investigated. The purpose of the present study was to examine these relations and to determine their clinical significance.

Methods

Selection of Patients and Procedures

Fourteen patients, admitted to the Myocardial Infarction Research Unit (MIRU) of the University of Alabama Hospital because of severe chest pain, were studied by consecutive daily echocardiograms and simultaneous pulmonary arterial pressure recordings. The diagnosis of acute myocardial infarction was documented by the development of Q or QS waves on the electrocardiogram and characteristic serial serum enzyme changes. The nature and risks of the investigation were explained to the patient and a responsible family member, and informed consent was obtained in accordance with the Declaration of Helsinki.[18]

The patients ranged in age from 31 to 79 years (mean 54 years); 10 were male and 4 were female. The location of the infarct, as demonstrated by electrocardiogram, was anterior in three patients (Cases 4, 10 and 13, Table I), inferior in five (Cases 3, 5, 9, 11 and 12), anterolateral in three (Cases 1, 7 and 14), anteroseptal in one (Case 2) and inferolateral in one (Case 6). Patient 7 had a left bundle branch block pattern. Twelve patients (Cases 1 to 3, 5, 6 and 8 to 14) were studied because of systemic hypotension, one patient because of pulmonary edema (Case 7) and one for an extensive precordial impulse and a loud third sound gallop (Case 4). Four patients (Cases 4, 5, 9 and 12) had experienced a previous myocardial infarction. Seven patients gave a history of hypertension (Cases 1, 7, 9 to 12 and 14). Of six patients (Cases 1, 2, 7, 8, 12 and 14) who described symptoms of congestive heart failure, four (Cases 1, 7, 12 and 14) also had hypertension and one (Case 12) had had a previous myocardial infarction. A third sound gallop was heard in nine patients (Cases 1, 2, 4, 6, 8, 10 and 12 to 14). A fourth sound gallop was heard in 11 patients (Cases 1 to 4, 6, 7, 9 to 12 and 14) and third and fourth sound gallops were audible in 7 patients (Cases 1, 2, 4, 6, 10, 12 and 14).

Pulmonary arterial pressure was measured using a no. 7 Swan-Ganz catheter,[19] a P23D strain gauge and an 1800 IBM computer programmed to select the median pressure contour from a 9 second sample of consecutive contours. The procedure for continuous pressure monitoring has been described in detail previously.[1,7] Zero pressure reference was taken as 10 cm above the patient's back.

Echocardiograms were obtained at approximately the same time of day in each patient using a Smith-Kline Ekoline-20 Ultrasonoscope with 2.25 megaHz transducers "focused" at 5 or 10 cm. For analysis of left ventricular dimensions, the transducer was placed in the fourth left intercostal space and directed posteriorly and laterally to resolve clearly the interventricular septum and left ventricular free wall endocardium and epicardium simultaneously. Echoes from the posterior leaflet of the mitral valve were recorded anterior to the left ventricular endocardium so that the position in the left ventricle at which consecutive dimensions were measured was essentially the same for each patient (position two as designated by Feigenbaum[20]). Echocardiographic left ventricular volumes were estimated as the cube of the end-diastolic ($LVID_d$) and end-systolic ($LVID_s$) internal left ventricular dimensions assuming a prolate ellipsoid reference figure for the left ventricle and a major to minor axis ratio of 2:1.[21] The echocardiographic $LVID_d$ was measured as the vertical distance in centimeters between the left ventricular side of the interventricular septum and the left ventricular endocardium at the time of the R wave of a simultaneously recorded electrocardiogram. The $LVID_s$ was measured as the shortest vertical distance between interventricular septum and left ventricular endocardium during systole.[20]

Evaluation of Left Ventricular Compliance

Left ventricular compliance was assessed by three formulas:

$$\Delta V/\Delta P \quad (1)$$

$$(\Delta V/ESV)/\Delta P \quad (2)$$

$$LVID_d/PAEDP \quad (3)$$

where ΔV = the diastolic volume change in milliliters or the end-diastolic volume (EDV) minus the end-systolic volume (ESV), both volumes calculated from echocardiographic dimensions of the left ventricle; ΔP = the left ventricular diastolic pressure change, in millimeters of mercury, which was estimated from the pulmonary arterial end-diastolic pressure; ESV = the end-systolic volume, in mil-

ΔP = left ventricular diastolic pressure change, estimated from pulmonary arterial end-diastolic pressure; ΔV = diastolic volume change or end-diastolic volume minus end-systolic volume, calculated from echocardiographic dimensions of the left ventricle; ΔV/ESV = fractional diastolic volume change; EDV = end-diastolic volume; Est. = estimated; ESV = end-systolic volume; LVEDP = left ventricular end-diastolic pressure; $LVID_d$ = echocardiographic left ventricular end-diastolic internal dimensions; $LVID_s$, = echocardiographic left ventricular end-systolic internal dimensions; PAEDP = pulmonary arterial end-diastolic pressure; SV = stroke volume.

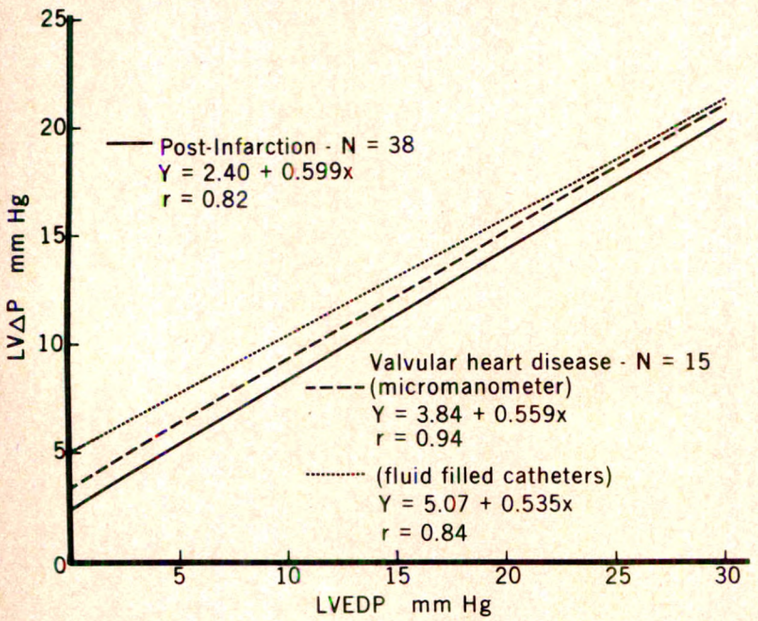

FIGURE 1. Regression lines for the relation between change in left ventricular diastolic pressure (LVΔP) and left ventricular end-diastolic pressure (LVEDP) for 38 patients with ischemic heart disease and 15 patients with valvular heart disease.

liliters, calculated as echocardiographic $(LVID_s)^3$; ΔV/ESV = the fractional diastolic volume change; $LVID_d$ = the echocardiographic left ventricular end-diastolic internal dimensions, in centimeters; PAEDP = pulmonary arterial end-diastolic pressure, in millimeters of mercury.

Two assumptions were required for the estimation of left ventricular diastolic pressure change (LVΔP) from the pulmonary arterial end-diastolic pressure. First is that LVΔP has a significant relation with left ventricular end-diastolic pressure (LVEDP). In 38 postinfarction patients studied previously in our laboratory, diastolic LVΔP had a significant linear correlation with LVEDP ($r = 0.82$; $P = 6.0 \times 10^{-7}$). The regression line between diastolic LVΔP and LVEDP for the 38 postinfarction patients illustrated in Figure 1 compares very favorably with regression lines from 15 patients with valvular heart disease whose left ventricular pressures were measured by both micromanometer and fluid-filled catheters in our laboratory. The formula relating diastolic LVΔP and LVEDP for the postinfarction patients is: LVΔP = 2.40 + 0.599 (LVEDP).

The second assumption is that the pulmonary arterial end-diastolic pressure is a reasonable estimate of the left ventricular end-diastolic pressure. For 95 observations made in 12 patients studied independently in the Myocardial Infarction Research Unit after acute myocardial infarction, PAEDP correlated linearly with simultaneous or contiguous LVEDP ($r = 0.86$ and $P < 0.001$ for PAEDP values ranging from 10 to 50 mm Hg).[22] The formula relating LVEDP to PAEDP is LVEDP = 7.34 + 0.78 (PAEDP). Since simultaneous left ventricular and pulmonary arterial pressures were not obtained in these patients, no direct correlation between PAEDP and diastolic LVΔP was possible. Therefore, diastolic LVΔP was estimated from PAEDP using the previously described relations.

Data Analysis

To examine the relations between early changes in left ventricular dimensions, filling pressures and compliance, the data were processed to permit values for each patient to contribute equal weight to the statistical analysis. The 14 patients did not always undergo measurements on successive days and data collection was not always started on the day of onset of chest pain (day zero). A straight line was fitted to values for end-diastolic volume versus values for the day after onset of chest pain for each patient. A similar linear relation was used for echocardiographic end-systolic volume and for pulmonary arterial end-diastolic pressure values versus day after the onset of chest pain since the data did not contradict the assumption of linear daily trends for these variables. For comparison of pressure and left ventricular dimension and compliance variables, estimated values for the third day after onset of chest pain were selected since most patients underwent measurements on or close to this day.

The slopes and intercepts of the relations between end-diastolic volume, end-systolic volume, pulmonary arterial end-diastolic pressure and the day after the onset of chest pain were used to obtain an equation by multiple regression analysis that would predict death or extension of the infarction. Multiple regression analysis was performed using the slopes and intercepts as independent variables and extension of the infarction or death as the dependent variable. A regression equation was calculated from the data using values for the dependent variable of zero for survival without electrocardiographic evidence of extension of infarction and one for extension of infarction or death. Extension of infarction occurred in 2 patients who survived (Case 10 and 13) and was defined as the development of elevated S–T segments and, subsequently, Q waves or persistent loss of R wave voltage in electrocardiographic leads other than those that demonstrated abnormalities upon admission. Evidence of extension of infarction occurred on day 2 in both patients.

Results

Values for echocardiographic left ventricular dimensions, filling pressures, ventricular volumes, estimated ΔP, and compliance indexes for the 14 postinfarction patients are presented in Table I. In Table II the slope and intercept values of the linear relations

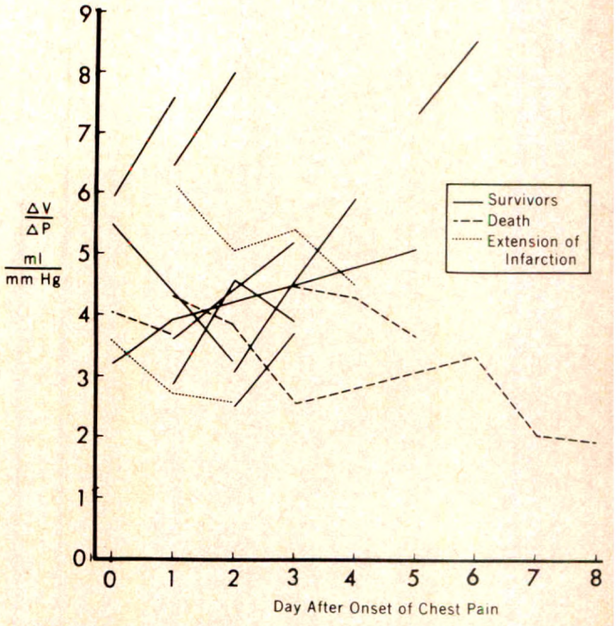

FIGURE 2. Early sequential changes in compliance after acute myocardial infarction. $\Delta V/\Delta P$ = echocardiographic stroke volume divided by left ventricular diastolic pressure.

between end-diastolic volume (EDV), end-systolic volume (ESV), and pulmonary arterial end-diastolic pressure (PAEDP) and day after infarction are displayed for each patient. The estimated third day values for the volume, pressure and compliance variables were determined from these relations.

Correlation of left ventricular volume, pressure and compliance variables: Utilizing the estimated third day values for all 14 patients, the three compliance indexes had significant direct linear correlations with each other. $\Delta V/\Delta P$ correlated with $\Delta V/ESV/\Delta P$ ($r = 0.869$; $P = 2.5 \times 10^{-4}$) and with $LVID_d/PAEDP$ ($r = 0.820$; $P = 8.6 \times 10^{-4}$), and $\Delta V/ESV/\Delta P$ correlated with $LVID_d/PAEDP$ ($r = 0.689$; $P = 0.009$). Neither $\Delta V/\Delta P$ nor $\Delta V/ESV/\Delta P$ had significant correlations with $LVID_d$. Correlations between single volume and pressure variables revealed that end-diastolic volume had a very significant direct linear relation with end-systolic volume ($r = 0.886$; $P = 9 \times 10^{-5}$), a reduced direct linear relation with stroke volume ($r = 0.617$; $P = 0.018$) and no significant correlation with pulmonary arterial end-diastolic pressure. The latter variable had no significant correlation with either end-systolic volume or stroke volume.

Figure 2 presents left ventricular compliance measured as $\Delta V/\Delta P$ versus day after the onset of chest pain. The lower limit of normal for $\Delta V/\Delta P$ obtained from nine normal subjects studied in our laboratory was 8.0 ml/mm Hg.[23] An increase in $\Delta V/\Delta P$ above initial values was associated with survival in eight patients. A decrease in $\Delta V/\Delta P$ from relatively low initial values was associated with either electrocardiographic evidence of extension of the infarction (two patients) or death (three patients). One survivor, who demonstrated a reduction in $\Delta V/\Delta P$ from an initial value of 5.5 ml/mm Hg, had an extensive precordial impulse on admission that diminished in size coincident with the decrease in compliance.

The relation between alterations in $LVID_d$, pulmonary arterial end-diastolic pressure and left ventricular compliance obtained with use of the first and last values for these variables is presented in Table III. Nine of the 14 patients showed less than 5 percent variation in $LVID_d$. Six of these demonstrated an average decrease in pulmonary arterial end-diastolic pressure of 32 percent and an increase in $\Delta V/\Delta P$ of 28 percent. Three had an average increase of 69 percent in pulmonary arterial end-diastolic pressure and a decrease of 31 percent in $\Delta V/\Delta P$. Five of the 14 patients had 5 to 20 percent changes in $LVID_d$ associated with much larger changes in $\Delta V/\Delta P$. There was no consistent relation between the directional changes for $LVID_d$ and $\Delta V/\Delta P$, nor was there a statistically significant correlation between the changes in $LVID_d$ and changes in $\Delta V/\Delta P$. In 12 of the 14 patients, alterations in $\Delta V/\Delta P$ were primarily related to changes in filling pressure.

Prediction of death or extension of infarction: The linear relations of end-diastolic volume, end-systolic volume and pulmonary arterial end-diastolic pressure versus values of the day after infarction were used to predict death or extension of the infarction. Using the intercepts of values for end-diastolic and end-systolic volume and the slope and intercept of pulmonary arterial end-diastolic pressure as independent variables and death or extension of the infarction as the dependent variable, multiple regres-

<±5%	− (average 32%)	+ (average 28%)	6
	+ (average 69%)	− (average 31%)	3
+ 5 to 10%	+ (average 134%)	− (average 25%)	2
− 10 to 20%	− 50%	+ 37%	1
	+ 8%	− 77%	1
+10 to 20%	0	+ 33%	1

* Data based on first and last values for these variables in the 14 cases.

− = decrease; + = increase; ± = increase or decrease; 0 = no change.

$\Delta V/\Delta P$ = echocardiographic stroke volume divided by left ventricular end-diastolic pressure; $LVID_d$ = echocardiographic left ventricular end-diastolic internal dimensions; PAEDP = pulmonary arterial end-diastolic pressure.

sion analysis yielded a regression equation ($r^2 = 0.63$ and $P = 0.044$) that accurately predicted death or extension of the infarction in the 14 patients. The r^2 value represents the square of the multiple linear correlation coefficient and provides an estimate of the predictive power of the regression equation. The equation is:

$$y = -0.873 + 0.010(I_{EDV}) - 0.015(I_{ESV}) + 0.047(I_{PAEDP}) + 0.122\,(S_{PAEDP})$$

where: y = the predictive index; I_{EDV}, I_{ESV} and I_{PAEDP} = intercept values for end-diastolic volume, end-systolic volume and pulmonary arterial end-diastolic pressure; and S_{PAEDP} = the slope value of pulmonary arterial end-diastolic pressure (mm Hg/day). The average predictive index of patients who lived was 0.13 and that for patients who died or had extension of infarction was 0.76. In the group of 14 patients, every patient whose predictive index was less than the mid-point between these two averages (0.45) lived, and every patient with a value above 0.45 either died or had extension of infarction.

Discussion

The use of pulmonary arterial end-diastolic pressure to represent left ventricular filling pressure and echocardiographic left ventricular dimensions to estimate left ventricular volumes provides a convenient approximation of these variables in acutely ill patients. Pulmonary arterial end-diastolic pressure has been challenged[24,25] and supported[9,26] as an indicator of left ventricular end-diastolic pressure in patients with acute myocardial infarction. The use of pulmonary arterial end-diastolic pressure to estimate diastolic LVΔP assumes that the former adequately reflects left ventricular end-diastolic pressure and that there is a significant relation between the latter and diastolic LVΔP. These assumptions have been supported by data obtained from patients with ischemic and valvular heart disease. A direct correlation between pulmonary arterial end-diastolic pressure and diastolic LVΔP was not obtained in our group of postinfarction patients since simultaneous recordings of pulmonary arterial and left ventricular end-diastolic pressure were not available.

Although some workers[27] have described poor correlations between echocardiographic and single plane cineangiographic left ventricular volume values in patients with left ventricular asynergy, others[28] have demonstrated significant correlations when echocardiographic ventricular volumes are calibrated against more accurate biplane cineangiographic left ventricular volume determinations. In the latter study the correlation for end-diastolic volumes was slightly greater than that for end-systolic volumes, suggesting that regional abnormalities of myocardial contraction may have a greater effect on ultrasound estimates of end-systolic volume than on estimates of end-diastolic volume in the absence of marked distortion in the diastolic ventricular configuration due to aneurysm. Preservation of myocardial function at the base of the heart where echocardiographic dimensions are measured for volume determinations could result in a falsely low value for end-systolic volume, an overestimation of stroke volume (or diastolic ΔV) and, thus, less abnormal compliance values for the postinfarction patients. These errors may be less significant in comparing relative sequential changes in dimension and compliance in the same patient since the magnitude of the error probably would remain relatively constant for any particular patient during the first few days after infarction.

The substantially greater sequential changes in left ventricular filling pressure than in left ventricular dimensions in 12 of the 14 postinfarction patients imply shifts from one diastolic pressure-volume curve to another rather than changes in slope along the same curve. Under a particular set of circumstances, an intact ventricle operates along a certain segment of a longer diastolic pressure-volume curve which could be obtained from a wide range of diastolic pressure and volume measurements. Since this segment approaches linearity, its slope may be expressed by the formula $\Delta V/\Delta P$, as defined in this study, or its reciprocal ($\Delta P/\Delta V$), as used in previous investigations.[14] Changes in values for $\Delta V/\Delta P$ after myocardial infarction could result from alterations in ventricular volume alone or from changes in the physical characteristics of the ventricular wall. Since little change was observed in sequential left ventricular dimensions in our study, sequential changes in compliance may be attributed mainly to alterations in the physical properties of the ventricular wall.

Theoretically, the incorporation of fractional diastolic volume change ($\Delta V/ESV$) into the compliance formula would distinguish between two ventricles of different size with similar diastolic pressure-volume

slopes (that is, with the same $\Delta V/\Delta P$ value). However, since sequential changes in ventricular dimensions were small, the evaluation of sequential changes in compliance in a particular patient was not enhanced by calculating fractional diastolic volume change, as evidenced by the high correlation between $\Delta V/\Delta P$ and $\Delta V/ESV/\Delta P$ ($r = 0.87$; $P = 2.5 \times 10^{-4}$).

Prognostic value of sequential compliance measurements: The determination of $\Delta V/\Delta P$ from pulmonary arterial end-diastolic pressure and echocardiographic left ventricular dimensions requires several assumptions that have been discussed previously. The significant correlation between $\Delta V/\Delta P$ and the ratio of $LVID_d/PAEDP$ suggests that this ratio may provide a convenient guide to consecutive compliance changes in patients with acute myocardial infarction. The formulas $\Delta V/\Delta P$ and $LVID_d/PAEDP$ are not interchangeable since $\Delta V/\Delta P$ represents the slope of and $LVID_d/PAEDP$ denotes a point on the diastolic pressure-volume curve. Nevertheless, the direction and magnitude of change in these two variables were similar in our study. A decrease in left ventricular compliance during the first few days after acute myocardial infarction, as observed in patients who died or had electrocardiographic evidence of extension of infarction, appears to indicate a progressive increase in the amount of ischemic myocardium. An increase in compliance values in patients who survived suggests that some initially ischemic areas of left ventricle recovered within the first few days.

In addition to assessment of the prognostic value of sequential compliance measurements, a predictive equation was determined by multiple regression analysis of the slopes and intercepts of the linear relations of echocardiographic end-diastolic and end-systolic volumes and pulmonary arterial end-diastolic pressure versus day after infarction. In the small series described here, values from the predictive equation separated the patients who died or had extension of infarction from those who survived. Therefore, the monitoring of early trends in left ventricular dimensions and filling pressure may aid in the management of patients with hemodynamic instability after acute myocardial infarction.

Birmingham, Alabama

The relations between left ventricular (LV) A wave amplitude and left ventricular dimensions, compliance, systolic function, and the size of abnormally contracting segments (ACS) of the left ventricle were examined in 42 patients studied within 1 year after acute myocardial infarction. Left ventricular A wave amplitude was measured from left ventricular pressure tracings both from zero (A_0) and from pre-A wave pressures (A_{PAP}). Left ventricular compliance was calculated from left ventricular volumes obtained from biplane angiograms and the left ventricular pressure recorded immediately before angiograms. Left ventricular compliance was evaluated by three formulas: $\Delta V/\Delta P$ (angiographic stroke volume/left ventricular end-diastolic pressure (LVEDP) minus lowest early diastolic pressure); ΔV/LV end-systolic volume/ΔP; and $dV/dP_{ED} \times 1/EDV/m^2$. Percent ACS was measured as the akinetic or dyskinetic length along the end-diastolic perimeter on biplane left ventricular angiograms expressed as a percentage of the total left ventricular diastolic perimeter.

A_0 had a direct quadratic relation with A_{PAP} ($r^2 = 0.72$), and A_0 had high inverse quadratic correlations with $\Delta V/\Delta P$ ($r^2 = 0.59$), $\Delta V/ESV/\Delta P$ ($r^2 = 0.63$), and $dV/dP_{ED} \times 1/EDV/m^2$ ($r^2 = 0.72$). A_0 correlated directly with LVEDP ($r^2 = 0.76$), end-diastolic volume ($r^2 = 0.32$), LV mass ($r^2 = 0.22$) and percent ACS ($r^2 = 0.36$), and inversely with ejection fraction ($r^2 = 0.43$).

Seven of the 42 patients were studied by dextran infusion. Diastolic volume change ($\Delta V_{Ind.-Dil.}$) calculated from indicator-dilution cardiac output values, left ventricular diastolic pressure change (ΔP), and A_0 were obtained before infusion and after each 200 ml infusion. Values for diastolic pressure-volume slope ($\Delta P/\Delta V_{Ind.-Dil.}$) and A_0 increased with dextran infusion in all seven patients. The $\Delta P/\Delta V_{Ind.-Dil.}$ slopes had a significant direct linear relation with corresponding left ventricular A wave amplitudes. Thus, the slope of the diastolic pressure-volume curve for any ventricle, as reflected by the compliance values, is a major determinant of the increase in left ventricular A wave amplitude for a particular volume of dextran infused.

In summary, increased left ventricular A wave amplitudes in patients after myocardial infarction signify a decrease in both left ventricular diastolic compliance and systolic function.

The A wave in left ventricular pressure records coincides with atrial systole, and increased A wave amplitudes have been observed in patients with aortic stenosis, aortic stenosis and insufficiency and ischemic heart disease.[1–4] These large A waves in left ventricular pressure tracings have been attributed to forceful left atrial contractions that elevate left ventricular end-diastolic pressure above the level of mean left atrial pressure and thus enhance left ventricular end-diastolic fiber stretch in ventricles with diminished diastolic distensibility.[1,3] In the absence of mitral stenosis the degree to which left ventricular

diastolic myocardial fiber stretch is augmented by atrial contraction is dependent upon the slope of the diastolic pressure-volume curve at the time of atrial systole and the force of atrial contraction.[1–6] Left atrial systole has been demonstrated to contribute an average of 29 percent of the left ventricular end-diastolic volume in patients with aortic stenosis, 27 percent in patients with ischemic heart disease and 21 to 26 percent in control subjects.[2,3]

Increased A wave amplitudes of apex cardiograms have been reported at rest, after exercise and during chest pain in many patients with ischemic heart disease.[7,8] An increase in A ratio (A wave amplitude divided by the maximal vertical excursion of the apex cardiogram) has been correlated with increased left ventricular end-diastolic pressure,[8,9] and prominent A waves in apex cardiograms have been associated with large A waves in simultaneously recorded left ventricular pressure tracings.[8–13] The magnitude of A waves in both left ventricular pressure tracings and apex cardiograms has been attributed to the left ventricular pressure before atrial contraction, left ventricular volume, left ventricular compliance and left atrial function.[1–7,9] It has been suggested that decreased left ventricular compliance or distensibility is a major determinant of the increased left ventricular A waves observed in patients with ischemic heart disease.[7,10,13–15] However, no quantitative study relating left ventricular A wave amplitude to left ventricular dimensions, diastolic pressure-volume relations and systolic performance has previously been performed in patients with ischemic heart disease. In this investigation the magnitude of A waves in left ventricular pressure tracings was related in a quantitative manner to left ventricular pressure, volume, compliance, systolic function and the extent of left ventricular segmental disease in patients studied within a year after acute myocardial infarction.

Methods

After receiving an explanation of the procedure and giving consent, 42 patients underwent cardiac catheterization and left ventriculography. Patients were studied supine in the fasting state 2 to 12 months after acute myocardial infarction to evaluate persistent chest pain or symptoms of congestive failure. The diagnosis of acute myocardial infarction was based on the clinical presentation, the development of Q or QS waves in the electrocardiogram of 0.03 second's duration and characteristic serial serum enzyme changes.

Left ventricular pressure was recorded with fluid-filled catheters, a P23D pressure transducer and a multichannel recorder. In all patients zero pressure was taken as that obtained 10 cm above the top of the table. Special care was taken to optimize the frequency response of the pressure recording system.[16] The system was thoroughly flushed to remove visible air bubbles. A screw clamp damping valve, with semirigid Tygon tubing (4 cm long; internal diameter 1/16 inch; external diameter 1/8 inch) running through it, has been employed for "critical damping" of pressure recordings in our laboratory. The pressure transducer is connected to one end of this valve. The catheter is attached to the other end of the valve by a three-way stopcock. A saline-filled syringe is also attached to this stopcock so that a "square wave" signal may be produced by maintaining constant manual pressure on the syringe while rapidly turning this pressure into and out of the transducer with the stopcock. The screw on the valve is tightened until minimal "undershoot" appears on the downstroke of the "square wave."

Simultaneous recordings of left ventricular pressure with undamped fluid-filled and micromanometer tip catheters in our laboratory have revealed that the diastolic pressure change between lowest early diastolic and end-diastolic pressures may be overestimated 15 to 30 percent by undamped fluid-filled catheters. For nine patients studied in our laboratory, the average diastolic pressure change obtained from "critically damped," fluid-filled catheters was only 1.6 mm Hg (7 percent) greater than the average diastolic pressure change calculated from micromanometer tip catheter tracings.

Left ventricular A wave amplitude was measured both from zero pressure (A_0) and from the pre-A wave pressure (A_{PAP}). Final A wave values were averages of A wave amplitudes measured from 10 consecutive cardiac cycles.

Values for left ventricular compliance were calculated from left ventricular volumes obtained from biplane angiograms taken at a rate of 6 or 12 frames/sec and left ventricular pressures recorded immediately before the angiograms. Angiograms were made after left ventricular pressure injection of 50 to 60 ml of 76 percent sodium and meglumine diatrizoate using a technique described previously for this laboratory.[17] Ventricular volumes were calculated during sinus rhythm by the area-length method.[18,19] Left ventricular end-diastolic and lowest early diastolic pressures were averaged from 10 consecutive cardiac cycles.

Left ventricular compliance was calculated from three formulas:

$$\Delta V/\Delta P \quad (1)$$

$$(\Delta V/ESV)/\Delta P \quad (2)$$

$$dV/dP_{ED} \times 1/EDV/BSA \quad (3)$$

where ΔV = the left ventricular diastolic volume change or the angiographic stroke volume calculated as the end-diastolic volume (EDV) minus the end-systolic volume (ESV) in milliliters; ΔP = the left ventricular diastolic pressure change calculated as the end-diastolic pressure (LVEDP) minus the lowest value for early diastolic pressure (LErDP); $\Delta V/ESV$ = the diastolic volume change divided by the end-systolic volume to calculate diastolic fractional volume change; dV/dP_{ED} represents the reciprocal of the slope of the diastolic pressure-volume curve at end-diastole and is calculated according to the method of Gaasch et al.,[20] which assumes a linear log-pressure versus volume relation and a constant positive pressure intercept at zero volume for all patients; BSA = body surface area in square meters.

The assumptions, advantages and limitations of these three formulas have been discussed in detail previously.[20,21]

Seven of the patients (Cases 1 to 3, 14, 19, 22 and 39, Table I) were studied by infusion of 200 to 600 ml of low molecular weight dextran (Rheomacrodex®). Left ventricular A wave amplitude measured from zero pressure, left ventricular diastolic pressure change (ΔP) and cardiac output were determined before infusion and after each 200 ml incremental infusion. Indicator-dilution (indocyanine green) cardiac output values were obtained by a method previously described for this laboratory.[22] Stroke volume or diastolic volume change ($\Delta V_{Ind.-Dil.}$) was calculated by dividing cardiac output by heart rate. Values for both diastolic pressure-volume slope ($\Delta P/\Delta V_{Ind.-Dil.}$) and A wave

ACS = abnormally contracting segment; A_{PAP} = pre-A wave pressures; A_0 = left ventricular A wave amplitudes measured from zero; BSA = body surface area; dV/dP_{ED} = reciprocal of the slope of the diastolic pressure-volume curve at end-diastole; ΔP = left ventricular diastolic pressure change calculated as EDP minus LErDP; ΔV = left ventricular diastolic volume change or angiographic stroke volume calculated as EDV minus ESV; EDP = end-diastolic pressure; EDV = end-diastolic volume; EF = ejection fraction; LErDP = lowest early diastolic pressure; LV = left ventricular.

amplitude were calculated from data collected from all seven patients before infusion and after each 200 ml incremental infusion. None of the patients studied by infusion had valvular insufficiency.

Segmental disease of the left ventricle, expressed as percent abnormally contracting segment (percent ACS), was determined from left ventricular biplane angiograms by the method of Feild et al.[23] The end-systolic perimeter of the left ventricular cavity was superimposed on the end-diastolic perimeter in both the anteroposterior and the lateral projections using a marker for the central X-ray beam and the lower border of the X-ray film. The percent of the total end-diastolic perimeter that was contracting abnormally or the percent abnormally contracting segment is the akinetic or dyskinetic length along the end-diastolic circumference divided by the total end-diastolic circumference. The end-diastolic ventricular perimeter and the length of the akinetic or dyskinetic segment were determined by a map measurer (Eugene Dietzgen Co.). The percent abnormally contracting segment in the anteroposterior and lateral views was averaged for the final value for each patient. Differences in percent ACS determined independently by two investigators ranged from 0.13 to 1.06 percent ACS (mean difference 0.45).

Left ventricular ejection fraction (EF) was calculated as the angiographic left ventricular stroke volume divided by the end-diastolic volume. Left ventricular mass was determined by the area-length and left ventricular wall thickness method of Rackley et al.[24]

The correlations in this study were expressed as r^2 values since many of the relations are not linear. In cases of nonlinear relations the hypothesis that the particular relation being examined was linear was tested and rejected at the 0.05 confidence level using an F test. The r^2 value, the square of the correlation coefficient, is the percentage of the total deviation in observed Y values about the mean Y value accounted for by the regression equation. An estimate of the predictive ability of the regression equation is given by the r^2 value.

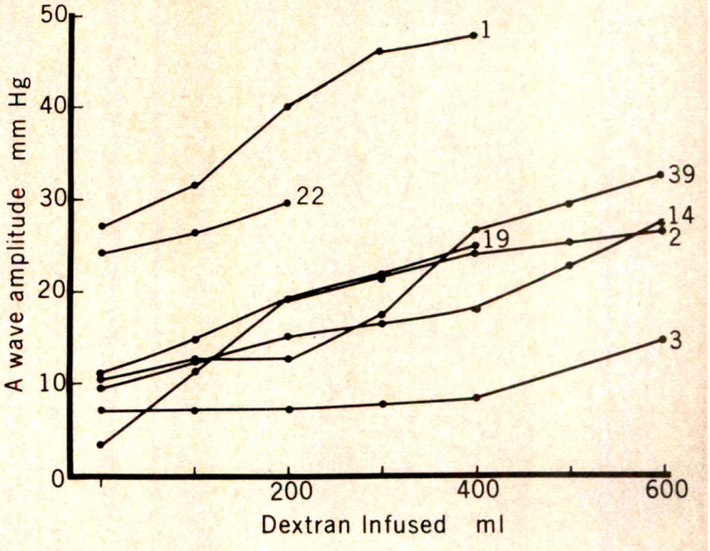

FIGURE 1. Left ventricular A wave amplitude in millimeters of mercury versus the volume of dextran infused in milliliters for seven patients after myocardial infarction.

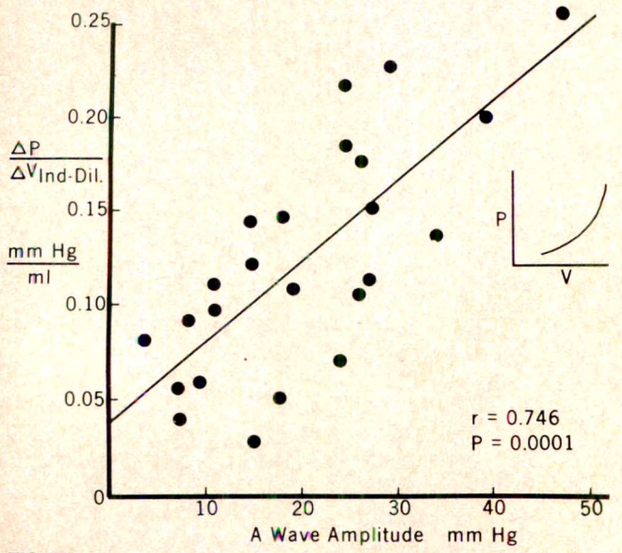

FIGURE 2. Values for diastolic pressure-volume slope ($\Delta P/\Delta V_{Ind.-Dil.}$) versus corresponding left ventricular A wave amplitudes for the seven patients given dextran infusions. Both $\Delta P/\Delta V_{Ind.-Dil.}$ and A wave height were obtained from data collected from the seven patients before infusion and after each 200 ml incremental infusion. ΔP = left ventricular end-diastolic pressure minus lowest early diastolic pressure; ΔV = diastolic left ventricular volume change.

tracting segments, three indexes of left ventricular compliance, left ventricular A wave amplitudes measured from zero (A_0) and the pre-A wave pressures (A_{PAP}) for the 42 patients studied after infarction are presented in Table I. A_0 has a direct quadratic relation with A_{PAP} ($r^2 = 0.72$; $P = 2.0 \times 10^{-7}$). The regression equation is $A_0 = -1.08 + 2.98\ (A_{PAP})$ minus $0.060\ (A_{PAP})^2$.

Correlation of A wave amplitude and measurements of compliance: Table II presents the type of relation and r^2 and P values for the correlations between A_0 and A_{PAP} and the three measurements of compliance, percent ACS, EF, EDV, EDV/BSA, EDP and LV mass. A_0 has high correlations with the three compliance indexes and lower but significant correlations with percent ACS, EF, EDV, EDV/BSA and LV mass. A_0 correlates inversely with the three compliance indexes and EF and directly with percent ACS, EDV, EDV/BSA and LV mass. A_0 has a high direct quadratic correlation with EDP. A_{PAP} has either lower or no significant correlation with all these variables.

A wave amplitude (A_0) increased after dextran infusion in all seven patients studied by infusion (Fig. 1). A wave amplitudes before infusion had significant relations with all three compliance indexes (r^2 values 0.68 to 0.82). Maximal postinfusion A wave amplitude had no statistically significant relation with any of the three compliance indexes although r^2 values ranged from 0.44 to 0.59. Maximal percent increase in A wave amplitude after infusion had a significant relation only with $dV/dP_{ED} \times 1/EDV/BSA$ ($r^2 = 0.86$; $P = 0.021$). The correlations with the other two compliance indexes were not statistically significant probably because of the small number of patients in the dextran infusion series.

Correlation of A wave amplitude and diastolic pressure-volume curve: Figure 2 presents a plot of diastolic pressure-volume slope values ($\Delta P/\Delta V_{Ind.-Dil.}$) versus their corresponding A wave amplitudes. $\Delta P/\Delta V_{Ind.-Dil.}$ and A_0 were measured from data collected from all seven patients before dextran infusion and after each 200 ml incremental infusion. An example of a left ventricular diastolic pressure-volume curve that could be obtained by making measurements over a range of pressures and volumes for a particular ventricle is shown in the inset. It should be appreciated that the ventricle would operate along only a segment of the curve under any particular set of circumstances. The statistically significant relation between A wave height and $\Delta P/\Delta V$ ($r^2 = 0.557$ or $r = 0.746$; $P = 0.0001$) indicates that an increase in left ventricular A wave amplitude produced by dextran infusion is associated with movement of the portion of the pressure-volume curve over which the ventricle is operating up the curve to a region of steeper slope. Thus, the slope of the diastolic left ventricular pressure-volume curve for any ventricle, as reflected by the compliance values, is a major determinant of the magnitude of change in A wave height for a particular volume of dextran infused.

For the 42 patients, $\Delta V/\Delta P$ correlated with $\Delta V/ESV/\Delta P$ ($r^2 = 0.74$; $P = 2 \times 10^{-7}$, linear) and $dV/dP_{ED} \times 1/EDV/m^2$ ($r^2 = 0.45$; $P = 3.4 \times 10^{-5}$, linear). $\Delta V/ESV/\Delta P$ had a direct quadratic relation with $dV/dP_{ED} \times 1/EDV/m^2$ ($r^2 = 0.42$; $P = 0.0002$). Percent ACS had significant relations with $\Delta V/\Delta P$ ($r^2 = 0.30$; $P = 6.5 \times 10^{-4}$, linear), $\Delta V/ESV/\Delta P$ ($r^2 = 0.70$; $P = 1.3 \times 10^{-6}$, cubic), and $dV/dP_{ED} \times 1/EDV/m^2$ ($r^2 = 0.23$; $P = 0.0029$, linear).

Discussion

The use of left ventricular pressures recorded immediately before left ventricular angiograms for the determination of left ventricular A wave amplitude and left ventricular compliance assumes that little change in pressure occurs during the period of left ventricular opacification at which time ventricular volumes are measured. Minimal changes in left ventricular end-diastolic pressure and end-diastolic and end-systolic volumes have been reported during ventricular opacification.[25] Similar observations using micromanometer tip catheters and left ventricular biplane cineangiograms have been made in our laboratory.

Diastolic pressure-volume relations: The relation between left ventricular pressure and volume or some index of ventricular dimensions, obtained either during diastole or during passive distension of the ventricle, has been reported to be curvilinear or exponential by some workers[5,26–31] and virtually linear by others.[32,33] In animal studies acute interventions such as intravenous administration of isoproterenol or methoxamine[27] and increasing the heart rate

to more than 180 to 200 beats/min[34] have produced configurational changes in control pressure-volume curves. However, neither stellate ganglion nor vagal stimulation has altered diastolic pressure-volume or pressure-myocardial segment length relations under various experimental conditions.[35–37] Thus, the diastolic pressure volume relation is subject to the conditions under which it is examined.

Because of the complexity of diastolic pressure-volume relations, several methods for quantitating these relations have been evaluated. Some workers[38] have used a simple ratio of simultaneous pressure and volume measurements (that is, EDV/EDP). Others[3,21,39,40] have assumed a linear pressure-volume relation for a portion of the diastolic interval (during atrial contraction or the period between the lowest early diastolic to the end-diastolic pressures). Another method consists of calculating the reciprocal of the slope of the pressure-volume curve at end-diastole assuming a linear log-pressure versus volume relation and a constant positive pressure intercept at zero volume for all subjects. In a study of left ventricular compliance changes in animals subjected to long-term volume overload, the relation between left ventricular end-diastolic pressure and end-diastolic diameter determined over a range of end-diastolic pressure was demonstrated to be essentially linear.[33] Hence, various types of linear diastolic pressure-volume relations have been useful in characterizing changes in ventricular compliance.

Evaluation of left ventricular compliance: The evaluation of left ventricular compliance in patients after myocardial infarction is complicated by the fact that both an increase in ventricular size and changes in the physical properties of the ventricular wall may result in decreased values for compliance. A reduction in compliance values secondary to an increase in ventricular size alone could result from a shift of the portion of the pressure-volume curve over which the ventricle is operating to a steeper segment of the same curve that existed before infarction. However, changes in the physical properties of the ventricular wall would alter the pressure-volume relation so that a higher level of pressure would be associated with any ventricular volume.

Thus, the compliance of ventricles of similar size could be adequately evaluated by a simple formula such as $\Delta V/\Delta P$ since variation in the physical characteristics of the ventricular wall would account primarily for differences in diastolic pressure-volume slopes for these ventricles. For our patients, however, end-diastolic volumes ranged from 64 to 331 ml/m^2 and ventricles of different sizes had similar values for $\Delta V/\Delta P$ (Table I). Differences in ventricular size are accounted for by $\Delta V/ESV/\Delta P$ (formula 2) and $dV/dP_{ED} \times 1/EDV/m^2$ (formula 3). Formula 2 incorporates fractional diastolic volume change, which is analogous to fraction volume changes measured in studies of pulmonary[41] and blood vessel[42] distensibility. In formula 3 a value representing the slope of a tangent to the pressure-volume curve at end-diastole is divided by EDV/BSA. However, values for formula 3 have a very high correlation with EDP ($r^2 = 0.96$) since both the natural logarithm of EDP and EDP itself are required for its calculation.

Despite the differences among the three compliance formulas, values for these formulas correlated significantly with one another. Values for these formulas have been demonstrated to be more sensitive to changes in the physical properties of the ventricular wall as represented by percent ACS than changes in ventricular size in postinfarction patients.[21] The selection of a particular formula for the evaluation of compliance would depend upon the objectives of the study, the methods available, the types of disease or experimental preparation being investigated, the duration of the disease (acute versus chronic), and the size of the ventricles.

Correlation of left ventricular A wave and compliance: A high inverse correlation between left ventricular A wave amplitude and left ventricular compliance might have been expected for patients studied after infarction because of the increased resistance to filling of diseased ventricles at the time of atrial systole and forceful left atrial contractions.[1,5,6] The similarity of the correlations between A wave height and all three compliance indexes may be related to two factors. First, A wave amplitude was demonstrated to have a significant relation with diastolic pressure-volume slope ($\Delta P/\Delta V$ or the reciprocal of formula 1) in the dextran infusion studies. Second, A wave amplitude had a relatively low correlation with EDV and EDV/BSA. Thus, one would not expect the correlations between the formulas that account for ventricular size (such as $\Delta V/ESV/\Delta P$) and A wave amplitude to be significantly higher than the correlation between pressure-volume slope and A wave height.

Elevations in left ventricular A wave height with dextran infusion were closely associated with increases in the steepness of diastolic pressure-volume slopes. These data corroborate the findings of high inverse correlations between A wave amplitude and the left ventricular compliance indexes measured in the 42 patients. Patients with larger left ventricular A wave heights have ventricles that are operating along steeper diastolic pressure-volume curves. Results of the dextran studies suggest that alterations in left ventricular A wave height due to acute interventions such as volume loading or diuresis may be used to estimate the slope of the pressure-volume curve for the ventricle being studied.

Correlation of left ventricular A wave and segmental disease: The significant relation between left ventricular A wave amplitude and extent of abnormally contracting segment (percent ACS) is probably related to the correlation of both of these variables to left ventricular compliance. The correlations between left ventricular A wave height and the compliance indexes were higher than the correlations between A wave amplitude and percent ACS. Two factors may be responsible for these results. First, A wave ampli-

tude has a very high correlation with left ventricular end-diastolic pressure ($r^2 = 0.76$), which is required for the calculation of compliance, whereas percent ACS has a much lower correlation with this pressure ($r^2 = 0.34$; $P = 2.4 \times 10^{-4}$, linear). The high correlation between A wave amplitude and left ventricular end-diastolic pressure might be expected since the energy expended during atrial systole would result in a greater increase in left ventricular pressure for any volume delivered to a less compliant ventricle.[1-6] Second, values for left ventricular A wave amplitude and left ventricular compliance are probably influenced both by the abnormally contracting segment as measured by ACS and small areas of fibrosis or ischemia in the ventricular wall outside the ACS.

The inverse relation between left ventricular A wave amplitude and ejection fraction demonstrated in our study suggests that augmentation of left ventricular end-diastolic fiber length by atrial systole may be particularly important in optimizing the performance of ventricles with decreased systolic function. The extent of left ventricular segmental disease after myocardial infarction apparently is responsible for both the increased stiffness of the ventricular wall, which is reflected in increased left ventricular A wave amplitude, and the decrease in systolic function of the ventricle.[43] Thus, increased left ventricular A wave amplitudes in patients after myocardial infarction denote a decrease in both left ventricular compliance and systolic performance.

The contraction patterns induced by ectopic ventricular premature beats and ventricular tachycardias occurring in man during left ventriculography were analyzed. These were compared with contraction patterns induced by ventricular premature beats and tachycardias produced in five dogs by epicardial left ventricular apical or basilar stimulation. Two patterns of contraction observed in the animals corresponded to two patterns observed in man. Apically stimulated left ventricular beats produced an "hourglass" type of contraction pattern and were hemodynamically more effective than beats arising from basilar stimulation, which produced an inverse "teardrop" pattern. The same patterns were reproduced by experimental ventricular tachycardias. These observations stress the importance of a normal sequence of ventricular contraction to optimal cardiac function in man and warn against the hazards of misinterpretation of the left ventricular contraction pattern if the beat originates ectopically during ventriculography.

The hemodynamic consequences of ectopic cardiac stimulation were first described by Wiggers[1] in 1925. He believed that "a certain orderliness in the mode of contraction may be necessary in order to produce a maximal effect on intraventricular pressure." Further clinical interest in this subject was engendered by the advent of the permanent epicardial pacemaker lead for treating complete heart block. Complete agreement still does not exist as to the optimal site for epicardial pacing. Corday et al.[2] described both a "benign" and "malignant" ventricular tachycardia based upon the hemodynamic response to apical versus basilar stimulation of the left ventricle, respectively. Clinical left cineventriculography has confirmed that ventricular premature beats are associated with asynchronous patterns of contraction.[3]

The purpose of this report is to describe the various patterns of left ventricular contraction in catheter-induced ectopic beats during cardiac catheterization in man and to correlate these with the contraction patterns of ectopically stimulated intact dog hearts.

Material and Methods

Studies in Man

Left cineventriculograms with normal contraction patterns were selected from patients undergoing diagnostic cardiac catheterization. Ventriculograms were obtained in the 30° right anterior oblique position and recorded on 16 mm film at 60 frames/sec utilizing a 9 inch X-ray image intensifier system; 35 to 45 ml of 75 percent sodium and meglumine diatrizoate was injected over 2 seconds by a power injector through a catheter in the left ventricle.[4] The electrocardiogram and brachial arterial blood pressure were recorded simultaneously with the ventriculogram. An event marker system permitted exact matching of this graphic information with each cine frame, thus permitting accurate identification of ventricular premature beats. The ventriculograms included in this study had to meet the following criteria:

From the Cardiovascular Division, Department of Medicine, Division of Cardiothoracic Surgery, Department of Surgery, Peter Bent Brigham Hospital and Harvard Medical School, Boston, Mass. 1. A premature beat was studied if it followed a normally conducted beat, with which it was then compared.
2. If the premature beat occurred first, it was compared with a beat at least once removed from the immediate postextrasystolic beat.

The ventriculograms were projected to life-size dimensions based upon known catheter diameter. A normally conducted beat and a premature beat occurring during the same injection were traced frame by frame. Motion analysis was carried out by a method previously described[3] but, to minimize error, the minor axes drawn perpendicular to the long axis were considered as total segments rather than as hemisegments representing anterior and inferior wall contractions. This procedure will be further illustrated in the text. Ten ventriculograms in 10 patients with minimal or no coronary artery disease satisfied the criteria cited and were of sufficient radiographic quality to be included in the study.

Animal Experiments

The response of the left ventricle to ectopic stimulation was observed during multiple ventriculographic studies conducted in five dogs. Observations were made with both single ectopic beats and ventricular tachycardia. With the animals under general anesthesia, a thoracotomy was performed and pacemaker wires were sutured epicardially to the left ventricular apex, left ventricular outflow tract, right atrium and mid-right ventricle. A metal clip was placed on the myocardium at the site of each pacemaker wire. These wires were passed to the exterior through a stab wound in the chest and labeled as to site. A cannula inserted and fixed in the left atrium was also passed to the exterior and capped for future use. The dogs were permitted to recover and maintained in their quarters. They were studied 4 days to 2 weeks after operation according to the following protocol:

Anesthesia was provided with use of morphine-Nembutal® or morphine-chloralose and urethane. Each dog was intubated and put on a mechanical respirator and then secured to a rotating table top. The left ventricle was entered retrograde across the aortic valve with either a Statham SF1 catheter or a metal cannula fashioned from a large standard transseptal needle introduced by way of the carotid artery and connected directly to a pressure transducer. A standard catheter was placed in the aortic arch by way of the femoral artery.

The dogs were permitted to maintain their own sinus rhythm. An experimental triggered pacemaker was connected to each lead and programmed so as to deliver a premature stimulus after every third or fourth sinus beat. This instrument had a coupling interval adjustable from 0 to 1 second, a refractory interval adjustable from 0.1 to 10 seconds and a 2 msec pacemaker impulse adjustable from 0 to 25 volts. The degree of prematurity was regulated in successive studies so as to produce early and late premature ventricular beats. The intensity of the stimulus was adjusted to the lowest level that would produce a mechanical response. In the same animal, sustained ventricular tachycardia was produced from the same pacemaker sites and studied ventriculographically. The animal was placed in the right anterior oblique position. Hand injections of 20 to 30 cc of 75 percent sodium and meglumine diatrizoate were made through the left atrial cannula. The ventriculograms were recorded at 60 frames/sec. An average of six ventriculograms were obtained in each animal. A 20 minute interval between successive ventriculograms allowed subsidence of ventricular depression induced by the contrast agent. As in the human studies, each cine frame could be matched with pressure and electrocardiographic events through the use of an event marker.

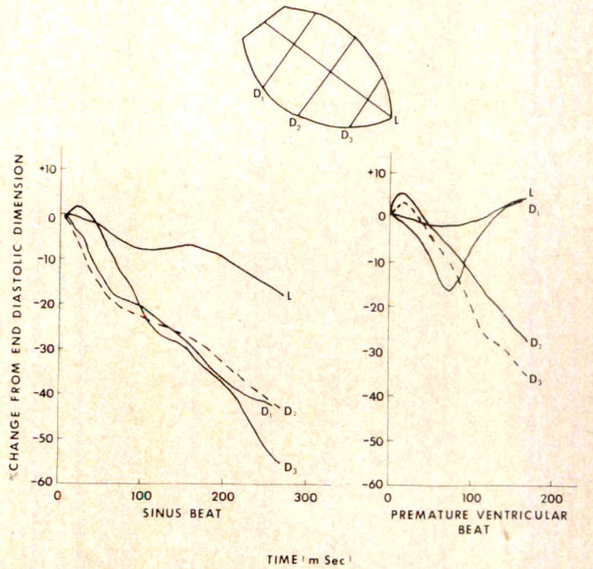

FIGURE 1. Comparison of the motion analysis of a sinus beat **(left)** with that of a premature ventricular beat **(right)** occurring in the same ventriculogram in a normal patient. The code for the segments involved is illustrated in the figure. L represents the long axis of the ventricle drawn from apex to the midportion of the aortic valve. D_1, D_2 and D_3 represent three minor axes constructed perpendicular to L quadrisecting the long axis. The percent change of each segment from its end-diastolic length is plotted against time. Expansion of a segment is plotted as a positive change from zero, and contraction or shortening as a negative change. In comparison with the sinus beat, the premature beat resulted in slight movement of the major axis and periapical asynchrony. This pattern is similar to that observed in experimental animals during epicardial stimulation of the apex.

Results

Studies in Man

Each premature beat that could be identified electrocardiographically as ventricular in origin produced an abnormal contraction pattern in comparison with its control beat. Figure 1 illustrates motion analyses of two beats from the same ventriculogram. The premature beat produced long axis akinesis and periapical asynchrony.

Figure 2, A and B, illustrates the left ventricular silhouette during control and ventricular premature beats in a patient with normal coronary arteries and hemodynamic status. The left ventricle has a "crenated" appearance during the ventricular premature beat and a symmetrical pattern of reduction in size during the normal beat. Even ventricular premature beats occurring with long sinus beat to premature beat intervals produce abnormal contraction patterns. Figure 3 graphically analyzes the motion of the beats drawn in Figure 2. In comparison to the control beat, the premature beat produces dyskinesis of all the minor axes with the only progressive shortening occurring in the major ventricular axis.

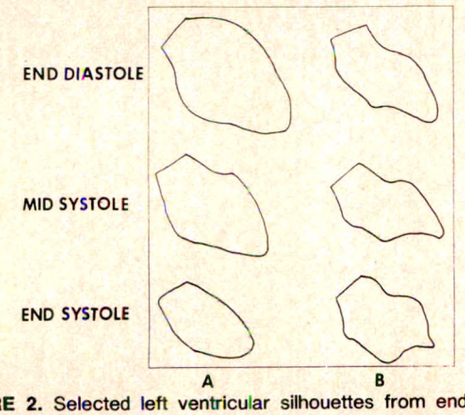

FIGURE 2. Selected left ventricular silhouettes from end-diastole, mid-systole and end-systole with a normal sinus beat **(A)** and a premature beat **(B)** in the same ventriculogram. Note the highly irregular and almost "crenated" appearance of the ectopically stimulated ventricle during contraction.

In general, ventricular premature beats tended to produce several distinctive contraction patterns. The two most often seen have already been illustrated. In Figure 1, contraction occurred mostly in the peribasilar and midportion minor axes. The periapical segment displayed asynchrony or dyskinesis, or both. The long axis exhibited minimal shortening. The net effect of this pattern would be to "propel" blood toward the apex. Another common contraction pattern of ventricular premature beats is illustrated in Figure 3 and has as its net effect the formation roughly of a globular shaped left ventricle with the long axis shortening at the "expense" of the minor axes.

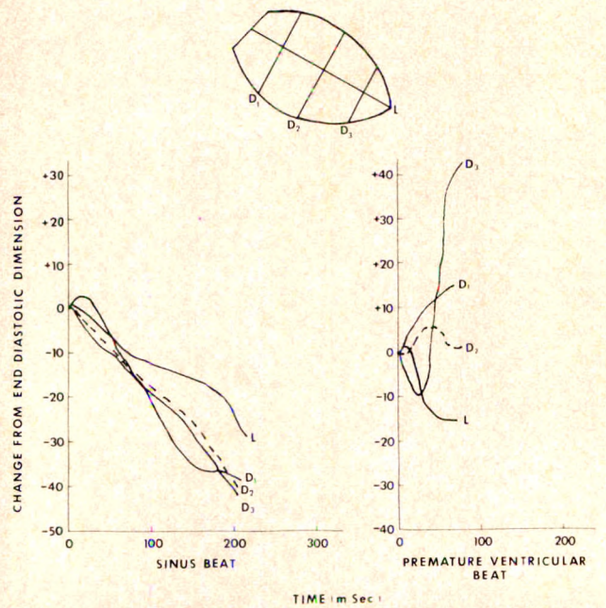

FIGURE 3. Motion analyses of the two beats drawn in Figure 2. There is paradoxical systolic expansion of all segments except the long axis.

Two runs of ventricular tachycardia were analyzed, but, unfortunately, the ventriculograms in these cases did not contain sinus beats for comparison. The ventricular contraction patterns induced by ventricular tachycardia did not differ appreciably from those observed during isolated ventricular premature beats. Beats occurring serially during ventricular tachycardia tended to produce a similar but not necessarily identical contraction pattern.

Studies in Animals

Ventricular premature beats: Adequate comparison between apically and basally stimulated left ventricular ectopic beats was made in two ventriculograms from each of three dogs. Stimuli applied to the left ventricle produced two distinct patterns of contraction depending on whether the apex or base was stimulated. In either instance, the initial salient feature was an expansion of the segment adjacent to the site of the stimulus. This pattern was observed regardless of the timing of the premature beat. Figure 4A illustrates selected silhouettes and a motion analysis of an apically stimulated ventricular premature beat. There was paradoxical systolic expansion of the periapical segments with vigorous contraction of the base and midportion of the ventricle. These findings should be contrasted with results of the premature beat illustrated in Figure 4B, taken from a subsequent ventriculogram in the same animal. In this case, the ventricle was stimulated by means of the wire attached to the left ventricular outflow tract. Here, the basilar portion of the left ventricle expanded paradoxically whereas the periapical portion contracted. From these two distinct contraction patterns simplified conceptual models may be constructed. Apical stimulation results in trapping of blood in the apical regions, whereas basilar stimulation results in a more globular left ventricular configuration with blood being sequestered in an expanded outflow tract region.

The hemodynamic correlates of apical versus basilar stimulation can be illustrated by comparison of the two beats cited. Table I shows the R–R interval for the normal control beat and the ventricular premature beat, left ventricular volumes and peak pressures for control and ventricular premature beats originating with apical and basilar stimuli. The data were derived from two sequential ventriculograms in one experimental preparation. Apical stimulation was more effective hemodynamically than outflow tract stimulation when beats with the same diastolic filling period were compared. Stimulation of the apex produced a greater percent of control aortic pressure and a larger ejection fraction than did stimulation of the base. This was true in all ventricular premature beats which appeared late enough to open the aortic valve. When the beats appeared too early to produce a rise in aortic pressure, the patterns of contractions were the same as those just described. When ejection of blood did not occur, early ventricular stimulation gave rise to an internal rearrangement of the ventric-

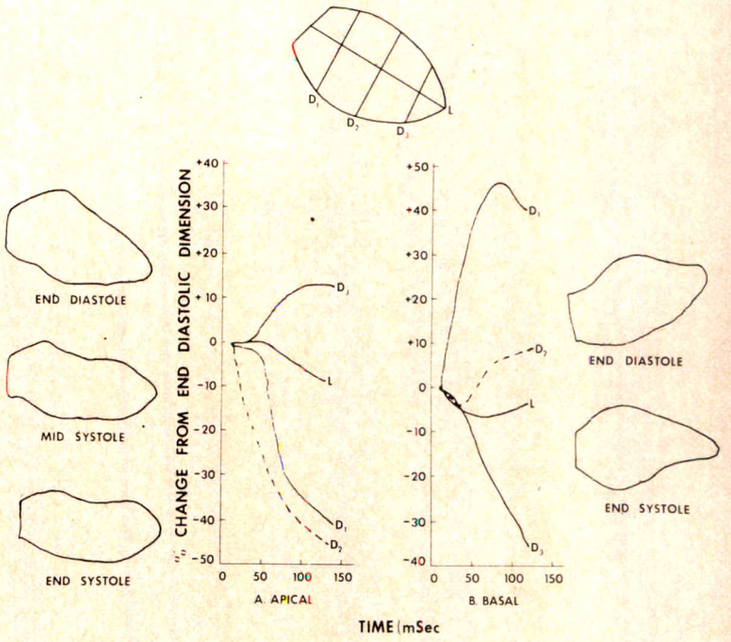

FIGURE 4. Selected silhouettes and motion analysis after apically stimulated **(A)** and basally stimulated **(B)** ventricular premature beats in a dog. Note the paradoxical systolic expansion of the periapical segment D_3 in **A** and the marked paradoxical expansion of the peribasilar segment D_1 in **B.**

ular contents. It is also possible that mitral regurgitation occurred with these beats.

Ventricular tachycardia: Experimental ventricular tachycardia was produced by stimulating the left ventricular apex or base at a rate sufficient to drive the ventricle (190 to 210 beats/min). The ventriculograms obtained during the arrhythmia showed patterns similar to those produced by single ventricular premature beats in each area. However, when the ventricle was apically stimulated, there tended to be more paradoxical expansion in the long axis than with the single ventricular premature beat. Figure 5A shows a sequence of four silhouettes during a typical beat of apical ventricular tachycardia. In mid to late systole, the lengthening of the major axis and the circumferential contraction of the midportion of the left ventricle about the minor axis gave an "hourglass" appearance to the left ventricular cavity. This was most notable when the ventriculogram was projected at normal film speed. Ventricular tachycardia produced by stimulation of the base showed expansion of the basilar area with normal shortening of the major axis. The ventricle became more globular in appearance, resembling an inverse teardrop with the point toward the apex. Selected silhouettes drawn from the ventriculogram obtained during a basally stimulated ventricular tachycardia beat are shown in Figure 5B.

Discussion

The apparent regional expansion of the stimulated portion of the left ventricle has been noted by others.[5,6] Our study confirms these observations for left ventricular apical and basilar ventricular premature beats and tachycardias. The general patterns of contraction observed are unrelated to preload, diastolic filling periods, or even the presence or absence of aor-

tic ejection, but are determined solely by the point of stimulus application.

The relative importance of ventricular asynchrony and the temporal relation between atrial and ventricular activation in producing a hemodynamic deficit with epicardial pacing has been studied in the dog heart. Daggett and co-workers[7] compared atrial, atrioventricular and right ventricular epicardial pacing in a dog preparation. They demonstrated that atrioventricular pacing at properly adjusted intervals tended to override hemodynamically the adverse effect of having the ventricular impulse applied ectopically. From this observation they concluded that the interval between atrial and ventricular systole was a more important determinant of ventricular function during cardiac pacing than the site of entry of the impulse to the ventricle. In another series of experiments, Daggett et al. utilized the isovolumic left ventricle to study the hemodynamic effects of pacing from various epicardial sites. They showed that better performance was obtained with stimulation of the left ventricular apex than with stimulation of the right ventricle. However, their study did not mention the influence of atrioventricular sequential pacing in the intact heart when the pacing site was varied on the left ventricle itself. In our study, the production of single ventricular premature beats showed a hemodynamic and morphologic difference depending upon stimulus site when diastolic filling time was constant. This mechanism should be independent of atrial systolic–ventricular systolic interval (As–Vs) in experiments of the type illustrated in Table I. It is conceivable that basilar stimulation may produce more mitral regurgitation than apical stimulation even at fixed As–Vs intervals, since these patterns of contraction are so different. In our animal experiments, quantification of mitral regurgitation was not possible since the injections were made by way of the left atrium to avoid unwanted stimulation of the ventricle during injection of dye.

In the dog experiments, there was a constant directional hemodynamic difference between apical and basilar stimulation of the left ventricle. Stimulation of the apex resulted in a greater percentage of aortic pressure even when R–R intervals and end-diastolic volumes were constant. This finding is in contradistinction to some earlier observations.[8,9] Our data emphasize the hemodynamic importance of synchronous ventricular contraction patterns that operate independently of atrial transport function. Experimentally produced asynchrony with its attendant shortened ejection time vitiates the Starling effect. In the one example listed in Table I, the end-diastolic volumes of the control and apically stimulated beat were practically the same, but the ejection fraction of the latter beat was considerably reduced.

Our study encompassed observations on similar phenomena in man and dogs. During clinical diagnostic ventriculography, the occurrence of ventricular premature beats is commonplace. Careful examination of a number of these beats revealed two major contraction patterns that were similar to those evoked with epicardial stimulation in dogs. It is difficult to make a direct comparison of these patterns in man to those in experimental animals since the exact stimulus site in each clinical case is unknown. A catheter passed retrograde across the aortic valve may stimulate the outflow tract by direct contact or stimulate the apical region by a jet stream of contrast material during the injection. To relate the two aspects of this study, two assumptions must be made: (1) that endocardial stimuli induce the same contraction pattern as epicardial stimuli, and (2) that in the human observations, the stimulus sites were indeed similar to those applied in the experimental animals. The minimal conclusion to be drawn from the human observations is that ventricular premature beats in man vary in their associated patterns of left ventricular contraction and that these may be categorized.

Clinical implications: Our study showed that ventricular stimulation either of the single ventricular premature beat type or of the repetitive tachycardia type results in a similar pattern of contraction. The observation that apically induced ventricular premature beats are more hemodynamically effective than basilar ventricular premature beats supports the concept of Corday et al.[2] that ventricular tachycardias may be benign or malignant depending upon their site of origin within the ventricle.

Some of the contraction patterns observed in our study bore great similarity to those seen during sinus rhythm in patients with segmentally diseased or ischemic ventricles.[10] The slower ventricular tachycardias occurring during ventriculography in the normal patient might lead to an erroneous diagnosis of asynergy. Our results emphasize the importance of maintaining and documenting normal sinus rhythm before assessing a left ventricular contraction pattern from the ventriculogram. If ectopic beats occur, it is essential to recognize them as such. In our study, it was possible to identify the site of application of a stimulus to the dog's left ventricle by the type of contraction pattern produced. Interpretation of ventriculograms in which ectopic beats occur can be subject to serious error.

In 16 dogs, by appropriate filtering and digital averaging on a PDP-9 computer, we were able to enhance the detection of electrical activity of interest in the P–R segment of the electrocardiogram. In instances (1) when such activity in the surface record coincided temporally with the internal recording from the bundle of His area, (2) when, with atrioventricular nodal block, the electrical activity of interest continued to be associated with the internally recorded His bundle deflection and not with atrial activity, and (3) when, with production of transmission delay between the bundle of His and the ventricle, the surface signal of interest continued to be associated with the internal His bundle deflection, a common signal source was considered likely. In certain instances the surface signal of interest in the P–R segment occurred well after the internally recorded His bundle deflection but about 15 msec before the earliest evidence of ventricular activity. In these instances, when the tests cited were applied and the blip of interest was associated with ventricular activity, the origin of the blip was thought to be in the region of the bundle branches.

In the 16 animals studied, one or more pieces of the evidence described were present to localize the origin of the signal. In seven animals, the signal was thought to originate from the bundle of His, in six from the region of the bundle branches and in three from both the bundle of His and bundle branches.

Since Scherlag and co-workers first described the catheter technique for recording His bundle activity in the dog[1] and in man,[2] there has been a renaissance in extracellular approaches to electrophysiologic-electrocardiographic correlations. Interest in the subject has been intense and reporting logarithmic, especially regarding diagnostic and prognostic information now available in the fractionated P–R segment.

During the course of multiple lead, high-speed, high-frequency surface recordings for other purposes, we noted apparent cardiac electrical activity in the P–R segment. The possibility that the activity might arise from the conduction system below the atrial level but above the ventricular level, and still be accessible through noninvasive means, seemed worthy of exploration.

Figure 1 is an example of the type of data that aroused our interest. The top recording is from a surface site on the chest of a dog slightly anterior to the anterior axillary line in the fifth intercostal space. The middle record is a bipolar intracardiac electrogram recorded from a site near the bundle of His, and the bottom tracing is from the conventional V_5 position, although inverted. A 2:1 block at the atrioventricular (A–V) node is indicated by the failure of the second pacemaker impulse to be conducted below the atrial level. The His bundle deflection from the intracardiac lead and electrical activity of interest in the P–R segment (referred to as $blip_1$ [B_1] and $blip_2$ [B_2]) are ab-

sent at the expected point in time, noted by the arrows. This finding suggests that the site of origin of B_1 and B_2 is somewhere below the level of A–V block.

The decreased rate of rise and overall amplitude of the His bundle signals from the internal lead can be attributed to the fact that this animal was one of a series in a study on the toxic effects of halogenated hydrocarbons known to have this effect on the His bundle deflection. The 50 beat computerized averages seen in Figure 2 exemplify an effort to amplify the P–R segment in another animal from the same series of toxicologic experiments.

Methods

In 16 healthy mongrel dogs—4 anesthetized with morphine sulfate and pentobarbital and 12 with pentobarbital alone—intubation and controlled respiration and normal base-line blood gas values were established. A bipolar pacing catheter was introduced transvenously into the high right atrium, and an intracardiac recording catheter capable of recording from three bipolar sites—1 mm, 1 cm or 1.1 cm apart—was introduced to the region of the bundle of His by the technique described by Scherlag et al.[1] An intra-arterial luminal catheter was introduced retrograde from the left femoral artery and positioned just distal to the aortic valve near the coronary ostia for delivering medications; an intravenous catheter was positioned in the inferior vena cava for similar purposes.

Pacing was instituted from the bipolar pair of recording electrodes that recorded the largest biphasic His bundle deflection, and the chest was mapped in order to find the site of maximal negative and maximal positive potential from the pacemaker impulse. These points were identified on the chest and usually lay to the left and anterior for the maximal positive deflection, and to the right, slightly higher and posterior for the maximal negative deflection. It was hoped that these peak positive and negative points also approximately defined the electrical axis of the bundle of His, which should roughly parallel the axis generated by these electrodes (Fig. 3). The identification of such a site should

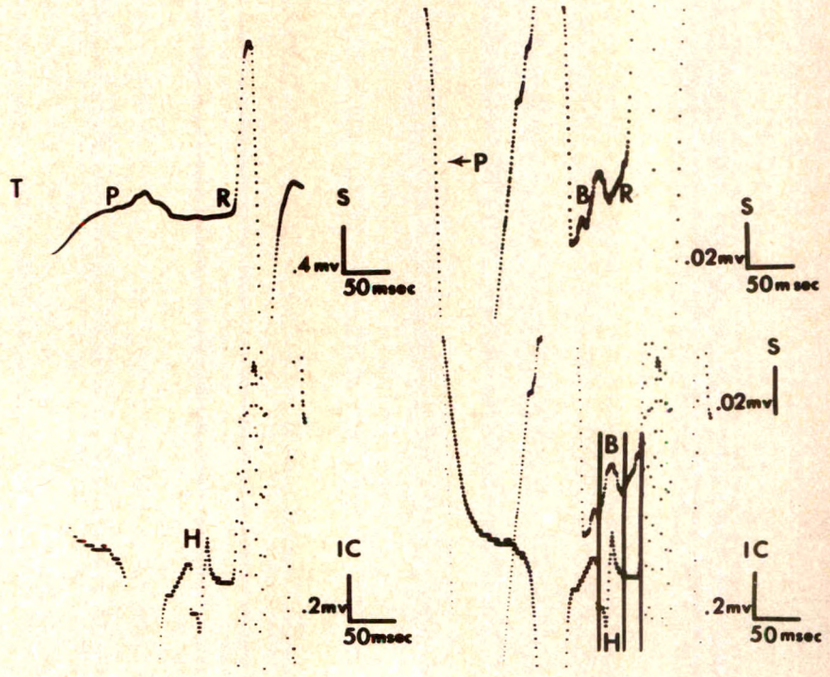

FIGURE 2. These 50 beat averages, taken at a sampling rate of 2,000/sec, are illustrative of our efforts to amplify the P–R segment in another animal from the same series of toxicologic experiments. At the **top left** is the surface signal; at the **bottom left,** the intracardiac recording from the His bundle area. The **top right** shows the amplified P–R segment with the surface blip of interest labeled B. The **bottom right** shows the temporal association of the surface signal of interest above, and the intracardiac recording from the His bundle region below. help to optimize the chance of correspondence between the most parallel current flow lines of the His bundle and the lead field of an exploring electrode (Fig. 4).

An arrangement of electrodes of the bipolar probe type was then designed with an exploring center surrounded by five indifferent points, connected by resistances to give a balanced bipolar configuration (Fig. 5). The site of the exploring electrode was placed at the point of peak positivity, and the immediate vicinity was searched for an area that gave a repetitive surface deflection at approximately the same time as that of the His spike in the intracardiac electrogram. A similar search was performed on the negative side.

The surface signal from the exploring electrode was fed into a Tektronix 26A2 differential amplifier and amplified 100,000 times, filtered between 0.1 and 3,000 Hz initially, and finally with a low-frequency cutoff between 1 and 80 Hz and a high-frequency cutoff of 600 Hz. Time synchronization was achieved by a special triggering network that also served to trigger the PDP-9 computer for averaging. After analog to digital conversion, either single cardiac cycles or 50 or fewer averaged beats were displayed on a storage oscilloscope for analysis and hard copy preparation. The constantly recorded signal on an Ampex FR 1300 tape recorder was available for later analysis, further averaging or preparation in hard copy form of sequential cycles photographed by a Grass oscilloscopic camera (Fig. 6).

Results

Figure 7 shows a recording from the intracardiac (IC) lead above, and the surface (S) recording below at a pacing rate of 90 beats/min. The blip of interest in the P–R segment is labeled. The initially prolonged conduction time of 76.6 msec from the low atrium through the A–V node (A–H interval) is accounted for by the anesthesia induced by morphine and pentobarbital. The base-line conduction time from the bundle of His to the earliest evidence of ventricular activity (H–V interval) was 31.6 msec. In the surface recording, the atrial to blip (P–B) interval was even longer than the A–H interval since atrial activity is detected earlier on the surface. From the surface blip of interest in the P–R segment to the earliest onset of ventricular activity (B–R), the time lapse was 20 msec. With pacing, the A–H and P–B intervals increased proportionately, whereas the H–V

and B–R intervals remained fixed. As A–V nodal delay increased with the increased pacing rate, the surface blip of interest emerged as a discrete electrical phenomenon seen in the lower panel. The origin of the surface blip is difficult to ascertain. The shorter duration of the B–R interval compared to that of the H–V interval suggests that the blip might have arisen from one of the bundle branches rather than from the bundle of His. On the other hand, much of the apparent shortening in the B–R interval is due to greater ability of the more distal surface lead to detect the earliest evidence of ventricular activity when compared with the much more local His bundle electrogram with its constricted lead field.

Efforts were made to remove the atrial activity from the region of interest by causing first degree A–V block by administration of propranolol as demonstrated in Figure 8. The bottom pair of records are 50 beat averages of the intracardiac electrogram, and an average of the same 50 beats recorded from a surface lead, identified by the probe technique. The top two records represent the same lead and surface counterpart after administration of 10 mg of propranolol, also a 50 beat average. As the A–H interval spreads, note how B_1 and B_2 fail to move with the atrial activity, but seem to continue to be associated with the intracardiac His bundle deflection and ventricular activity. The timing of B_1 in the cycle with respect to its relation to ventricular activity and to the internally recorded His bundle activity suggests that the blip probably represents surface evidence of His bundle activity. B_2 probably arises from lower down in the conduction system.

Figure 9 demonstrates results of an effort to remove ventricular activity from the area of interest by causing conduction delay between the His bundle and the ventricle with administration of procainamide. The top sample is the intracardiac electrogram; the second is the surface counterpart after administration of 750 mg of procainamide. The third record is the intracardiac lead demonstrating H–V prolongation after administration of 1,500 mg of procainamide. Continued association with the surface deflection is seen, with the blip moving neither with atrial nor with ventricular activity but with the His deflection. The B–R intervals are in each instance 7.5 msec shorter than the intracardiac H–V counterparts. The phenomenon can be accounted for in this animal solely by the earlier appearance of ventricular activity as recorded from the surface. The slight difference in appearance of the surface evidence of atrial activi-

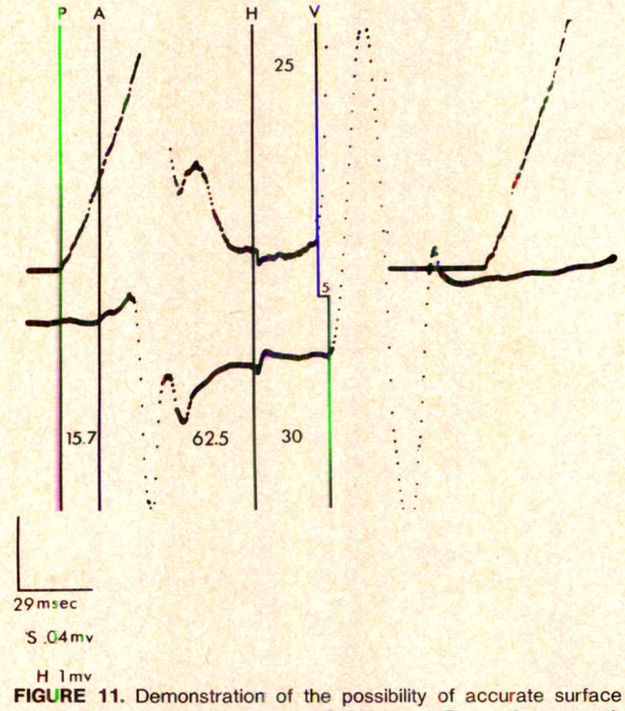

FIGURE 11. Demonstration of the possibility of accurate surface measurements of the fractionated P–R interval. The surface recording **(top)** and the internal recording **(bottom)** are each averages of the same 50 cardiac cycles. The shorter surface His-ventricular interval is accounted for by the earlier appearance of ventricular activity viewed from the surface. Intervals are in msec. AH = atrial–His interval; H = His bundle activity; HV = His–ventricular interval; PA = high to low right atrial interval; S = surface lead; V = ventricular activity.

ty at the two dose levels can be explained by the fact that the low-frequency cutoff at the time of the 750 mg dose of procainamide was 30 Hz, whereas the low-frequency cutoff at the time of the 1,500 mg dose was 10 Hz. The synchronizing lines were determined by computer with reference to the trigger and should represent true simultaneity.

Figure 10, from another animal, again demonstrates the movement of a deflection recorded from the surface lead (S) with the His bundle deflection recorded from the intracardiac lead during progressive and comparable B–R and H–V prolongation with administration of additional amounts of procainamide.

Discussion

Verification of suspected His bundle activity in amplified surface P–R segment: There are three ways of attempting to verify the origin of electrical activity recorded in the surface P–R segment. The first is simply temporal association with a carefully verified internal event. The success or believability of this means of verification depends upon an interference-free record and relative lack of activity on either side of the surface recording of alleged His bundle activity and upon an appropriate interval between this deflection and the onset of ventricular activity (Fig. 11). Because the surface evidence of ventricular activity always precedes internal evidence of such activity by 5 to 11 msec, the interval between the suspected surface His bundle activity and surface evidence of ventricular activity is necessarily shorter than that recorded from the internal lead. However, if the interval is within acceptable ranges, and if the surface signal does not significantly precede the internal His bundle signal, but coincides with it or is only slightly later, there is circumstantial evidence for a common origin of these signals. More supporting evidence is presented if, in addition, atrial pacing can cause A–V nodal transmission delay and consequent prolongation of the intracardiac A–H interval, and if the alleged His activity on the surface remains associated with the verified His activity from the internal lead. Rather convincing evidence is offered if, further, with pacing at a constant rate, and pharmacologic intervention with agents that remove atrial activity from the region of the His bundle by introducing A–V nodal delay or remove ventricular activity from His bundle activity by introducing His–ventricular delay, the electrical events of interest in the surface lead continue to associate themselves with the His bundle deflection from the internal lead.

It is important to eliminate any possibility of signal leak from amplifier to amplifier since this is a known hazard in multiple lead, simultaneous recording. This possibility was carefully eliminated in our series of experiments by physically removing the internal catheter and verifying the persistence of the surface signal.

Implication: As facility is achieved in finding the optimal surface recording site, and as a volume of experience with configuration and timing of internally verified surface signals is accumulated, the examination of the amplified surface P–R segment should become an important addition to the noninvasive approaches of cardiac evaluation.

Microelectrode Study of Wenckebach Periodicity in Canine Purkinje Fibers

JAMES R. WENNEMARK, MD
JACK P. BANDURA, PhD

Memphis, Tennessee

Electrophysiologic mechanisms responsible for Wenckebach periodicity produced experimentally in a segment of blocked canine Purkinje fibers were investigated with multiple microelectrode recordings. Transmission through the zone of block was electrotonic. The Wenckebach mechanism was related to a progressive decrease in the efficacy of the transmitted electrotonic potential as a stimulus for the regenerative response at the distal block boundary with successive impulses of the cycle. This was manifested in the transmembrane potentials as a progressive decrease in upstroke velocity and a voltage change that caused the electrotonic potential to become progressively removed from the threshold for stimulation. The immediate cause of this phenomenon was a progressive increase in the voltage level (more negative) from which the electrotonic potential originated and a resulting change in voltage-dependent membrane resistance that further attenuated the signal with successive impulses of the cycle.

Two main mechanisms appeared to be responsible for these phenomena: (1) a progressive increase in maximal repolarization voltage (more negative) of the transmembrane potential, and (2) a progressive decrease in the diastolic interval that, in the presence of enhanced phase 4 diastolic depolarization, caused the voltage level from which the electrotonic potential originated to become further removed from the stimulation threshold with successive impulses of the cycle.

Previous studies from this laboratory have attempted to formulate concepts of block mechanisms in terms of observed phenomena manifested in the transmembrane potential recorded throughout segments of blocked canine ventricular conduction tissue.[1–4] Our initial investigations indicated that such studies must be performed in preparations with a defined segment of block not exceeding a critical length. A suitable preparation was developed using an electrical depolarizing current in which the magnitude of block could be critically controlled by varying the intensity of the blocking current.[1,3]

Wenckebach periodicity has been previously demonstrated experimentally and clinically in the atrioventricular (A–V) junction,[5–10] distal intraventricular conduction system[11–13] and ventricular myocardium.[12,13]

This type of cyclic conduction disturbance has most often been produced experimentally by overdrive at rapid rates, although it has been demonstrated in experimental microelectrode studies at slower rates of stimulation.[7,14–16] The mechanism of Wenckebach periodicity has previously been attributed to progressive encroachment upon refractoriness of the preceding impulse,[5,6] "decremental conduction" [10,11,16] or progressive inhomogeneity of electrical wave fronts in multifibered cardiac tissue.[7,15] It has also been suggested that a concealed (abortive) form of reentry may occur continuously throughout the Wenckebach cycle producing progressive prolongation of the P–R

interval and an eventual nonconducted impulse.[17,18] This phenomenon involves the induction of progressive refractoriness.

Our investigations of mechanisms of second degree conduction disturbances operative over an entire spectrum of stimulation rates have explored variables that have previously been given little attention. In these studies we have used a preparation in which the length of the blocked segment is limited so as to constitute an elementary block unit, thus simplifying data interpretation.

Extensive microelectrode investigations in these *blocked segments* have revealed no data that might be interpreted as "decremental conduction" or "slow active propagation," and we are not convinced that these phenomena have actually been demonstrated in published reports.

Method

Eighteen adult dogs weighing from 10 to 15 kg were anesthetized with 30 mg/kg of sodium pentobarbital. A lateral incision was made in the fourth intercostal space and the heart was rapidly excised. The left ventricular posterior false tendon along with conducting fibers of the posterior division of the left bundle branch were carefully dissected and placed in a divided Lucite® chamber filled with oxygenated Tyrode solution maintained at 37° C with a thermistor temperature controller. Composition of the Tyrode solution in millimoles per liter was sodium chloride 137.0; sodium bicarbonate 12.0; sodium phosphate 0.18; magnesium chloride 0.5; potassium chloride 2.7; calcium chloride 2.7 and glucose 5.5. The chamber was a rectangular well composed of two compartments separated by a thin latex membrane. The dimensions of each compartment were 1.5 by 1.0 by 0.45 cm. The flow rate was adjusted to 4 ml/min in each half of the chamber. The false tendon was threaded through a small preformed hole in the membrane separating the two chambers. The anatomic proximal portion of the preparation from which the microelectrode recordings were obtained was located in the right side of the chamber (Fig. 1). The Purkinje fibers of the preparation were stimulated at a rate of 1.0 to 2.0 cycles/sec from the left side of the chamber with a small bipolar electrode (E_s, Fig. 1). The stimulus consisted of a 4 to 10 volt square wave of 1 msec duration delivered by a Grass stimulator and isolation unit. Although Wenckebach cycles could readily be produced at slower stimulation rates, the rates cited were desirable for routine use because of enhancement of automaticity by the blocking current. An electrogram was obtained with a small bipolar electrode (E_r, Fig. 1) from the functional distal portion of the preparation in the right side of the chamber. It is apparent that the location of the preparation in the chamber was such that conduction occurred in an anatomic retrograde fashion throughout the experiments.

An electrical blocking current was supplied by a 280 volt battery source. The positive polarizing electrode (B+, Fig. 1) was placed in the left side of the chamber and the negative polarizing electrode (B−, Fig. 1) in the right side of the chamber. The current strength was regulated by a rheostat.

Transmembrane action potentials were obtained with glass capillary microelectrodes filled with 3M potassium chloride by boiling under vacuum. Electrodes with a resistance of 5 to 10 megohms were used in these experiments. The first stage input consisted of high impedance, capacitance neutralized amplifiers (NF-1, Bioelectric Instruments, Inc.). The indifferent electrode was placed in the right side of the recording chamber near the preparation. Liquid-metal junctions were made with silver-silver chloride electrodes. A square wave voltage calibrator was placed between solution and ground.

Time marks were supplied by a Tektronix time mark generator. The entire experiment was taped on a four channel analog tape recorder (Hewlett Packard 3960) and records were filmed both directly and from the tape at various voltage gains and sweep speeds for more defined measurements. A Tektronix 565 oscilloscope with both Polaroid® and 35 mm strip film was used for these procedures.

The experiments were performed under a dissecting microscope with a magnification of 12.5. Anatomic distance determinations were made with use of a graduated eyepiece.

Results

During application of the electrical blocking current a segment of block approximately 3 to 4 mm in length was produced by depolarization in the right chamber where the negative blocking electrode was located. The functional proximal boundary was located near the dividing partition. The exact delineation of the distal boundary was inherently difficult to determine, but would correspond to the site of the earliest regenerative response initiated by passive electrotonic transmission through the segment of block. Electrotonic potentials continued beyond the distal boundary as prepotentials preceding active responses. The transmembrane action potentials were usually normal in the more distal portions of the preparation. Differences of blocking effect in the various fibers of the preparation contributed to the problem of distal boundary localization.

Three sequential microelectrode recordings were obtained at 2, 3 and 4 mm locations from the dividing membrane producing a matrix of nine impalements (Fig. 1). By applying the appropriate amount of blocking current, Wenckebach cycles were produced and recorded at the various points. Figure 2 demonstrates an example of typical three cycle Wenckebach periods recorded from each of the nine positions dur-

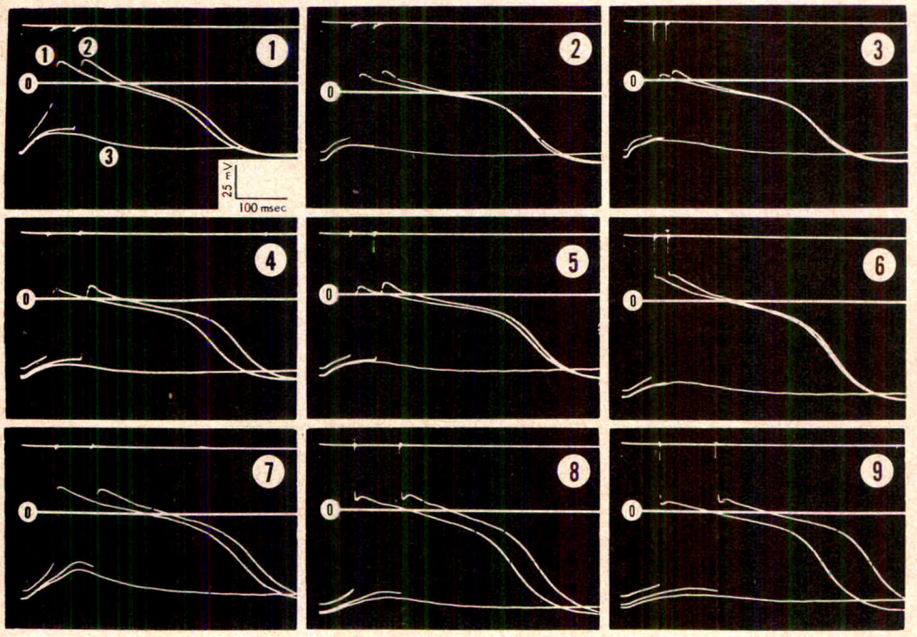

FIGURE 2. Experiment 6. Intracellular microelectrode recordings of three cycle Wenckebach periods taken from each of the nine sites labeled in Figure 1. Top tracing in each panel represents distal electrographic recordings. Zero millivolts is represented by 0 in each panel. In panel 1 the numbers 1 and 2 refer to the first and second responses with associated electrograms and 3 refers to the nonpropagated impulse.

ing a single experiment. Each cycle was photographed by superimposing successive sweeps of the oscilloscope. The superimposed stimulus artifacts initiating the three impulses are seen at the left edge of the top tracing in which the distal electrogram is displayed. The respective distal responses recorded by the microelectrode and corresponding electrogram are labeled 1 and 2 and the nonconducted impulse is labeled 3 without a corresponding electrogram. Variation in delay between the first and second impulses of the cycles resulted from separate applications of the blocking current at each site. Slight changes in the steady state of the preparation altered the effect of the blocking current requirement which was critical to produce the Wenckebach cycles. The first two complexes of each cycle, representing conducted impulses, exhibit a two component wave form. The initial deflection represents an electrotonic potential that originated from the proximal boundary of the blocked zone. The second delayed component represents a retrograde electrotonic potential originating from the regenerative response at the distal block boundary.[1,3] The third complex of each cycle that failed to attain threshold at the distal boundary is nonconducted and exhibits only an initial electrotonic component. The second component is absent because no regenerative response occurred. Some inhomogeneity of blocking effect in the various fibers is evident.

Phase 4 diastolic depolarization was always marked near the distal block boundary in the presence of the blocking current. The nonconducted electrotonic potential had relatively little effect upon the slope of phase 4 depolarization between the last conducted impulse and the first impulse of the succeeding cycle.

Figure 3 shows the variables measured in this experiment for the impulses of each Wenckebach cycle. An electrogram (EG) is displayed in the top tracing. The second tracing represents zero millivolt potential obtained by withdrawing the microelectrode from the fiber during application of the blocking current. The bottom tracing represents the recorded transmembrane potential. The various

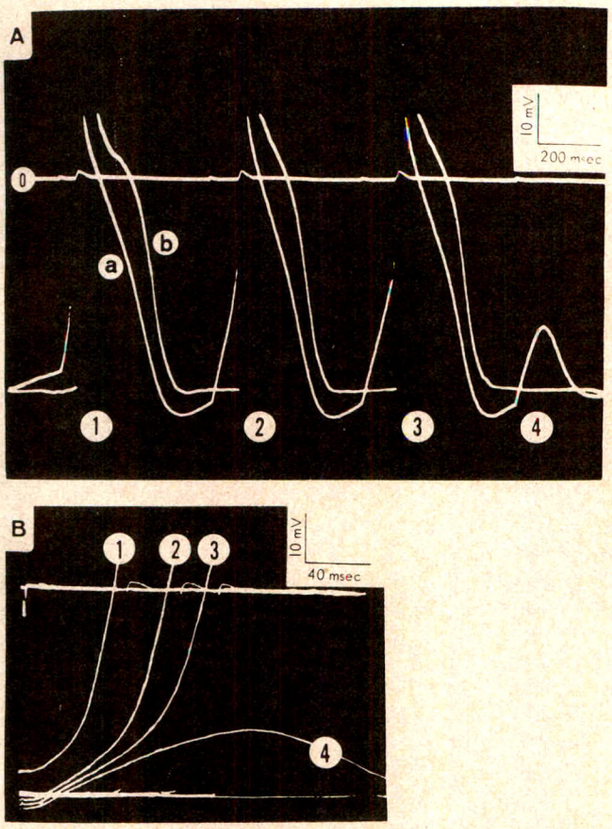

FIGURE 4. Experiment 12. Two fibers impaled in the vicinity of position 7 (see Fig. 1). Position b is 1 mm distal to position a. Zero millivolt potential (0) and distal electrogram are recorded in the top tracing. Numbers 1, 2, 3 and 4 represent four consecutive impulses of a four cycle Wenckebach period. **Panel A** displays the simultaneous microelectrode recordings of both positions. **Panel B** represents the superimposed initial components of recording positions a and b displayed at a greater sweep speed.

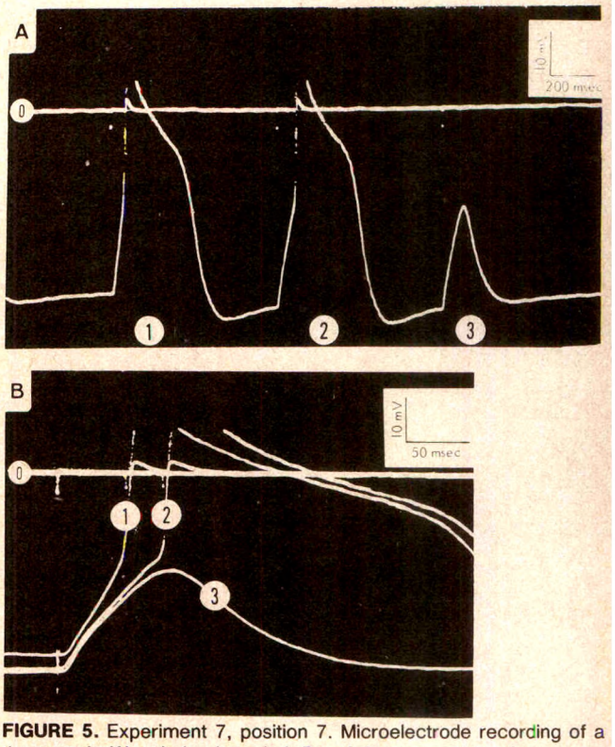

FIGURE 5. Experiment 7, position 7. Microelectrode recording of a three cycle Wenckebach period. **Panel A** represents a slow sweep speed used to visualize impulses 1, 2 and 3 of the Wenckebach cycle. Zero millivolt potential and distal electrogram are recorded in the top tracing. **Panel B** is a superimposition of the initial components of the three responses photographed at a more rapid sweep speed.

voltage and time variables measured are labeled and are as follows: The *minimal diastolic voltage* (mDV) represents the magnitude of the potential at the time the artificial stimulus was applied. The *maximal diastolic voltage* (MDV) represents the maximal negative voltage level attained after a response. The *peak prepotential voltage* (PPV) represents the negative voltage magnitude at the peak of the initial electrotonic potential. The *onset to peak prepotential voltage* (O–PPV) represents the onset to peak voltage of the initial electrotonic potential. The *transmembrane potential duration* (TMPD) represents the total time from the onset of the response to its recovery of maximal diastolic voltage. The *stimulus to electrogram response* (S–EG) represents the time delay between the stimulus and the electrogram. The *diastolic interval* (DI) represents the interval between the maximal diastolic voltage and the onset of the subsequent response. The slope of phase 4 diastolic depolarization was also examined.

Cycles containing up to 10 impulses were recorded, but 95 percent of the total number of cycles recorded contained fewer than 7 impulses. Three impulse Wenckebach cycles were the most easily produced and with few exceptions were recorded at each recording site in all experiments. The increment in delay with successive impulses was frequently inconsistent in the longer cycles, often not conforming to the classic Wenckebach structure. Because of inhomogeneity of block in the various fibers, one would not expect to see all significant determining voltage variables at every recording site in the complex, multifibered preparation. This is demonstrated in Figure 4, A and B, in which two areas of the preparation are simultaneously impaled. Fiber a is at a location equivalent to position 7 (Fig. 1). The second impalement, b, is recorded 1 mm distal to position 7. Figure 4A represents a slow sweep speed recording of a four impulse Wenckebach cycle and Figure 4B a superimposed fast sweep recording of each successive impulse in the cycle. Examination reveals that recording from position a demonstrates electrotonic prepotential activity and marked changes in slow phase 4 depolarization compared to findings in the recording from position b. A marked electrotonic response to the nonconducted impulse (4) is seen at position a, whereas position b demonstrated no electrotonic response. In this figure two microelectrode recording sites are separated by 1 mm and there is considerable variation in recorded activity. This finding suggests that the electrodes are in different fibers and demonstrates the dissociation that may occur under conditions of block even though the tissue acts as a functional syncytium in the normal state.

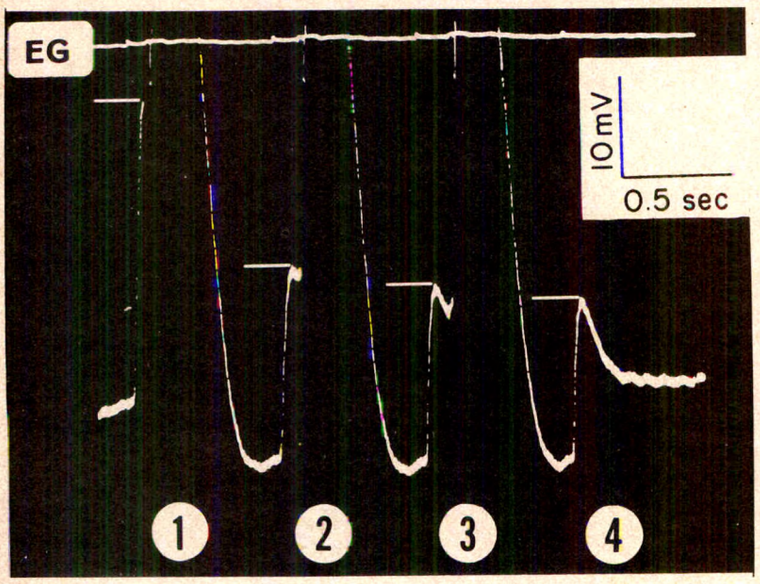

FIGURE 6. Experiment 9, position 3. Single fiber recording of a four cycle Wenckebach period recorded at high gain to demonstrate progressively increasing (more negative) peak prepotential voltages. Numbers 1, 2, 3 and 4 represent each successive response to artificial stimulation. EG represents the channel displaying the stimulus and distal electrogram. The voltage level at the peak of each prepotential is delineated by a small white line to the left of each peak.

Since three cycle Wenckebach periods were most commonly observed, a typical cycle is displayed in Figure 5, A and B. The data in Figure 5A were recorded at a slower sweep speed than those of Figure 5B. Two conducted responses are shown by the distal electrogram. The third impulse failed to conduct. The top tracing in each panel represents the zero millivolt potential as well as the distal electrogram. Examination of the first impulse of the cycle reveals a considerable increase in maximal compared to minimal diastolic voltage. Furthermore, the maximal diastolic voltage after the second impulse of the cycle exhibits slightly greater negativity than that after the first impulse. In the absence of a significant change in the slope of phase 4 diastolic depolarization this phenomenon would cause a progressive increase in minimal diastolic voltage with successive impulses of the cycle. This progressive change in maximal diastolic voltage with successive impulses was observed in many of the recorded Wenckebach cycles. Of particular importance was the marked increase in maximal compared to minimal diastolic voltage associated with the first impulse of the cycle. This consistently observed phenomenon was related to the marked increment of delay associated with the second impulse of the cycles.

Another frequently observed phenomenon may be seen in the four cycle recording (a) of Figure 4A and in Figure 6. A progressive decrease in diastolic interval with successive impulses of the cycle is apparent. This usually resulted from a progressive increase in transmembrane potential duration of each preceding impulse of the cycle caused by an increment in delay of the impulse which was manifested in the transmembrane recording as an increased duration of the initial electrotonic potential. In the presence of a relatively constant slope of phase 4 diastolic depolarization this would result in a progressive increase in minimal diastolic voltage with each impulse of the cycle. A decrease in diastolic interval was infrequently observed without a measurable increase in minimal diastolic voltage. This phenomenon appeared to be due to a slight change in the slope of phase 4 diastolic depolarization in some recordings. It could also have been due to the critical anatomic specificity for optimal recording of voltage variables at the distal block boundary in the multifibered preparation. Changes in the contour of the terminal portion of phase 3 at times made accurate evaluation difficult.

An almost constantly observed change throughout the recorded cycles was a progressive increase in minimal diastolic voltage with successive impulses of the cycle. This is apparent in Figures 4B and 5B and in some cycles in Figure 2. The greatest increase always occurred between the first and second impulses of the cycle. High gain recording was sometimes necessary to demonstrate the change in the later impulses of the cycle, and the phenomenon was usually more marked at several recording sites than in others in each preparation. Further examination of the figures reveals an equally constant feature consisting of a progressive decrease in the upstroke velocity of the initial electrotonic potential with successive impulses of the cycles. The greatest change was apparent between the first and second impulses.

A progressive increase in peak prepotential voltage with successive impulses of the Wenckebach cycle was observed in most recordings. This change is obvious in Figure 6 and to a lesser extent in Figure 5A. As with the previously mentioned observations, the change was often more marked at some recording sites than in others in each preparation. It was usually accompanied by a progressive decrease in onset to peak prepotential voltage, which was associated with the previously described changes in minimal diastolic voltage. This phenomenon appears to be related to

the voltage-dependent changes in membrane resistance described by Weidmann.[19]

Discussion

Concepts of Block Associated with Conduction Delay

An understanding of the electrophysiologic variables that appeared to be determinants of the Wenckebach structure in our study would be facilitated by some familiarity with our concepts of block associated with simple delay. These have previously been described in detail[1] and will be summarized.

Our initial studies[1] indicated that investigation of block mechanisms should be performed in a preparation with a segment of block limited in length so as to include a defined distal boundary. The presence of a distal boundary is necessary for wave form generation and for determination of block magnitude. The importance of such a preparation has recently been reemphasized by Cranefield et al.[11] Our data indicate that a blocked zone may be characterized as an inactivated fiber segment with proximal and distal active boundaries. Active propagation ceases at the proximal block boundary and transmission through the blocked zone is accomplished by a passive electrotonic potential that preserves continuity of conduction in simple delay. The transmitted electrotonic potential is the stimulus that initiates a regenerative response at the distal block boundary. Delay is incurred as a function of distance attenuation of upstroke velocity and voltage of the electrotonic potential dictated by the fiber cable properties. Severe attenuation so that the electrotonic potential fails to reach the threshold potential at the distal block boundary results in complete block. Stimulation of a regenerative response at the distal block boundary initiates a second electrotonic potential that is transmitted in a retrograde fashion back into the blocked zone to be superimposed upon the initial electrotonic potential. This potential also demonstrates distance attenuation of voltage and upstroke velocity. This phenomenon gives rise to a characteristic two component wave form of the transmembrane potential which is always recorded within a segment of simple block. Multiple components in the wave form suggest a more complex situation with fragmentation. The existence of this mechanism does not suggest that wave form components may not be caused by adjacent asynchronously excited fibers, which is almost surely the case when fragmentation occurs in a multifibered syncytial preparation; however, the two component wave form could be derived within a single fiber.[20]

Conduction abnormalities have often been ascribed to "decremental conduction."[10,11,16,21] This mechanism was hypothesized as a possible explanation for the "physiologic delay" found in the A–V node and was characterized as conduction in which the properties of the fiber change along its length in such a manner that the action potential becomes progressively less effective as a stimulus to the unexcited portion of the fiber even though the fiber is still excitable. Hoffman and Cranefield[16] further suggested that this type of conduction might be produced in other portions of the conduction system by a variety of pathologic conditions, although they did not restrict the possibilities to this mechanism. Hoffman et al.[21] made a distinction between "decremental conduction" and "slow conduction" per se. A third possibility would then be a predominantly electrotonic mechanism. Extensive microelectrode recordings throughout blocked segments in our series of experiments suggest the latter mechanism. Mendez and Moe previously described similar wave forms and emphasized their electrotonic origin between active and inactive regions of block in the A–V node[22] and Purkinje-papillary muscle preparations.[23]

We have never observed data that might be interpreted as "decremental conduction," as described, or "slow active conduction." The existence of delay between two recording points does not permit inference of the mechanism by which the delay was incurred. This requires extensive microelectrode recording throughout the area of block between the two recording points. In our opinion an actual documentation of "slow active propagation" would require demonstration of a progressive delay in *onset* of an active response as a distance function through an area of block.

Electrotonic wave form components: The electrotonic nature of the transmembrane potentials that we have always observed in blocked segments is indicated by the expected progressive distance attenuation of voltage and upstroke velocity and, of particular importance, a lack of delay in *onset* of the deflections throughout the blocked zone. A simultaneous onset of the initial electrotonic component throughout the blocked segment is somewhat distorted by a distance factor inherent in traveling wave theory which we have previously emphasized.[3] Early loss of high-frequency components results in a slight "apparent" delay in onset of the deflection with greater distances which may be particularly misleading with low gain recording.

We have accumulated conclusive evidence that the second electrotonic wave form component is derived from the regenerative response at the distal block boundary. This is indicated by the expected distance attenuation with retrograde transmission and the fact that the onset of the distal regenerative response precedes the onset of the attenuated signal in the more proximal portions of the blocked segment. The fact that this also is only an "apparent" delay in onset does not negate an inference as to the origin of the deflection. The second component is always present when a distal active response has been initiated and is always absent with nonconducted impulses. Furthermore, as the magnitude of delay is changed, which is easily accomplished by manipulation of the blocking current density, the onset of this component always maintains a temporal relation with the distal active response. The result of this phenomenon is that the observed duration of the initial electrotonic

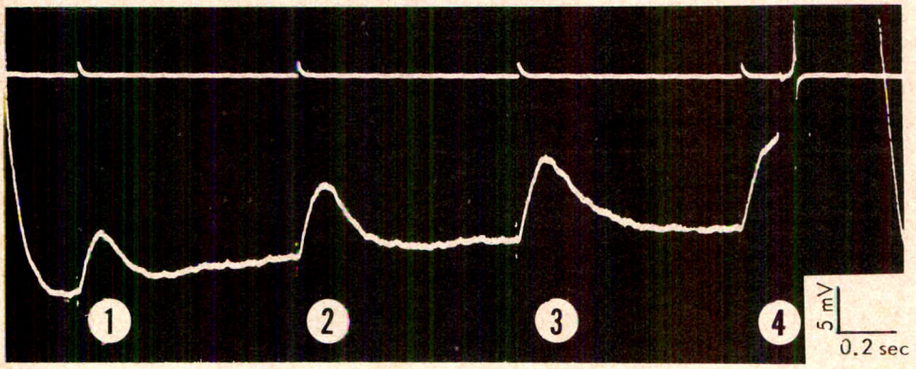

FIGURE 7. Experiment 2, position 9. Microelectrode recording of 4:1 block that occurred as a result of injury produced by prolonged exposure to the blocking current. The blocking current has been turned off. Numbers 1, 2, 3 and 4 represent successive electrotonic responses to artificial stimulation of a fiber showing slow depolarization. Response 4 is propagated and has an associated distal electrogram. See text for discussion.

component correlates well with the magnitude of delay.

Local responses: A considerable ambiguity exists in published reports concerning the nature and role in propagation of transmembrane potentials with low voltage and very slow upstroke velocities. A distinction is made between purely electrotonic potentials and graded or local responses. In our preparations, we frequently see evidence of local graded activity that distorts the voltage or contour of the electrotonic potential. This partial engagement of the active process, which does not progress to an all or nothing response, remains within the confines of passive transmission and has not been observed to be associated with active propagation. We object to the term "action potential" in reference to wave forms associated with block because "action" on the part of the fiber is usually not well defined.

Examination of the data obtained in our study reveals voltage and time variables that appear to be important determinants of the Wenckebach mechanism. Some of the electrophysiologic variables were not consistently observed in all cycles. Possible explanations for this, associated with the complex multifibered preparations, have been mentioned (see Results). The possibility of a spectrum of determinants operative in different cycles should also be considered.

Determinants of Wenckebach Mechanism

Changes in initial electrotonic potentials: An almost constant finding and the most direct determinant of Wenckebach periodicity was a progressive increase (more negative) in peak prepotential voltage with successive impulses in the cycle. The initial electrotonic potential that originated from the proximal boundary of the blocked zone became progressively less efficacious as a stimulus for the regenerative response at the distal block boundary with successive impulses of the cycle. A progressive voltage attenuation of the signal caused it to become progressively further removed from the threshold for stimulation of a regenerative response until the last impulse of the cycle failed to attain threshold, thus resulting in a nonconducted impulse. Phase 4 diastolic depolarization, relatively unaffected by the nonconducted electrotonic potential, allowed resetting for the next cycle by decreasing the base-line voltage toward threshold during the prolonged period between the last conducted impulse of the cycle and the first impulse of the next cycle. A progressive attenuation in rise time of the electrotonic potential resulted in a progressive delay of stimulation for the regenerative response at the distal block boundary with successive impulses of the cycle.

These observed changes in the initial electrotonic potentials resulted from two factors. The first was related to a progressive increase (more negative) in minimal diastolic voltage with successive impulses of the Wenckebach cycle. The base-line voltage level from which the transmitted electrotonic potential originated became further removed from threshold with successive impulses. This was an almost constantly recorded observation in all preparations and is apparent in Figures 4B and 5B. The second factor was a frequently observed progressive decrease in the onset to peak prepotential voltage occurring with successive impulses of the cycle. This decrease in absolute voltage of the electrotonic potential was secondary to the described increase in minimal diastolic voltage and was related to the voltage dependence of membrane resistance. An increase in membrane resistance associated with slow phase 4 diastolic depolarization was demonstrated in Purkinje fibers by Weidman.[19,24] Furthermore, the diastolic depolarization was not accompanied by significant changes in threshold potential so that later in diastole less stimulating current was required to initiate an all or nothing response.[24]

Figure 7 demonstrates this voltage dependence in an example of 4:1 block. Examination of the tracing reveals some slow depolarization. Superimposed are electrotonic potentials 1, 2, 3 and 4 in response to artificial stimulation. As the voltage decreases because of slow depolarization, the onset to peak voltage of the nonconducted electrotonic potentials becomes progressively greater. Finally, after three failures to elicit a propagated response, the fourth stimulus is associated with an electrotonic component sufficient to elicit a regenerative response that activates the distal tissue, as indicated by the electrogram in the top tracing.

The observed voltage changes of the onset to peak prepotential voltage during Wenckebach periods were the reverse of those seen in Figure 7. As the electrotonic potential originated from a greater (more negative) voltage, a decrease in membrane resistance resulted in a decreased fiber space constant that caused greater distance attenuation of the signal.

These phenomena are somewhat similar to those observed in 2:1 block,[3] in which the electrotonic potentials of alternate impulses fall below the threshold for stimulation, and are the opposite of those seen in 3:1 and higher grades of block, in which the electrotonic signals move progressively toward threshold with successive impulses resulting in a periodically conducted impulse (unpublished data).

Mechanisms producing alterations in the minimal diastolic voltage: A more basic problem related to the Wenckebach mechanism concerns the variables responsible for the observed progressive increase in minimal diastolic voltage. A constant finding in this regard was a marked increase in maximal as compared to minimal diastolic voltage associated with the first impulse of each cycle. Even in the presence of marked phase 4 depolarization this caused an increase in minimal diastolic voltage associated with the impulse of the second cycle compared to that of the first cycle. The fact that the electrotonic potential associated with the second cycle arose from a voltage markedly greater than that of the first cycle is the most likely explanation of the greatest increment of delay frequently observed in this portion of the cycle. A continued progressive increase in maximal diastolic voltage when observed with successive impulses of the cycle was thought to be an important determinant associated with progressive delay and, finally, nonconduction of the last impulse. This is seen in the three cycle recording of Figure 5A.

Another often observed finding which appeared to be an important determinant of minimal diastolic voltage was a progressive decrease in the diastolic interval (DI, Fig. 3) with successive impulses of the Wenckebach cycle. This change was usually due to a progressive encroachment upon the diastolic interval of each impulse by an increase in the total transmembrane potential duration (TMPD, Fig. 3) of the preceding impulse, which was in turn associated with an increased observed duration of the initial electrotonic component caused by a greater increment of delay. The effect of this change in the presence of slow phase 4 diastolic depolarization, which was always pronounced near the distal boundary of the blocked segment, would be to cause the transmitted electrotonic potential of the subsequent impulse to arise from a greater (more negative) diastolic voltage, thus, further removed from the threshold for stimulation of a regenerative response. This would cause a further increment of delay or nonconduction of an impulse. This mechanism is apparent in recording a of Figure 4A and in Figure 4B.

The mechanism for Wenckebach periodicity in terms of the transmembrane potential has not been adequately explained in published reports. We do not propose that the possibilities be restricted to a single mechanism for all cardiac tissues under all conditions of conduction disturbance; however, we have presented concepts derived from more extensive microelectrode exploration than has previously been performed. One might argue that block produced by an electrical blocking current may be unique. We do not believe so because identical wave forms were observed in segments of block produced by other methods, including localized iodine application used in our earliest studies and segmental block produced as an irreversible anodal effect from prolonged application of the blocking current.

Several factors should be emphasized concerning the interpretation of transmembrane potentials recorded in experimental block. High gain recording with our preparation indicated that the system is extremely sensitive to slight changes in voltage. Differences in the range of 1 to 2 mv appeared to be an important determining factor in the increment of delay or nonconduction of an electrotonic potential. In addition, the recording site for optimal demonstration of variables involved in the mechanism is found at the functional distal boundary, which may include a limited group of fibers in a multifibered preparation.

We cannot completely exclude the possibility that some other mode of conduction is occurring in one of the fibers of the multifibered preparation and that we are recording artifactual data; however, the syncytial nature of the fibers and the fact that we have never observed such phenomena in extensive microelectrode exploration of blocked segments, including fibers at various depths, argue against it.

Clinical implication: Although Wenckebach periodicity may occur clinically in the bundle branches,[25,26] the site of primary interest is in the junctional tissues proximal to the bundle of His in most cases.[18,27,28] We have no data specifically indicating that the mechanisms we have described are operative in the area of the A–V node; however, similar two component transmembrane wave forms have been recorded in the A–V node by many investigators,[7,10,15,16,29–34] thus suggesting that similarities in the mode of conduction under normal and abnormal conditions may exist.

The Four Horsemen of Stroke...

HYPERTENSION

HEART DISEASE

DIABETES

ELEVATED CHOLESTEROL

You have your own therapeutic regimen to reduce these risk factors—the "Big Four" accelerators of stroke.

...and TIA's-the Prophetic Fifth Horseman

Transient Ischemic Attacks (TIA's) are another signal of impending stroke that is particularly ominous. In fact, 33% of patients with TIA's will develop a severe neurological deficit within 5 years.*

For such patients, PAVABID® (papaverine HCl) vasodilatation helps to preserve cerebral circulation. By reducing arterial tone, Pavabid therapy helps block vasospasm that can result in neurological damage.

*Meyer, J. S., and Gilroy, J.: *Medical Neurology,*

PAVABID®
(papaverine HCl, 150 mg.) Plateau CAPS®

Pavabid® Plateau CAPS® (Papaverine HCl, 150 mg.)—Each capsule contains papaverine hydrochloride, 150 mg. in a special base for prolonged therapeutic effect. *Indications:* ischemia associated with arterial spasm and myocardial ischemia complicated by arrhythmias. *Dosage:* One capsule every 12 hours. In difficult cases, administration may be increased to one capsule every 8 hours, or two capsules every 12 hours. *Precaution:* Use with caution in patients with glaucoma. Hepatic hypersensitivity has been reported with gastrointestinal symptoms, jaundice, eosinophilia and altered liver function tests. Discontinue medication if these occur. *Side effects:* Infrequently reported side effects of papaverine include nausea, abdominal distress, anorexia, constipation, malaise, drowsiness, vertigo, sweating and headache, diarrhea and skin rash.

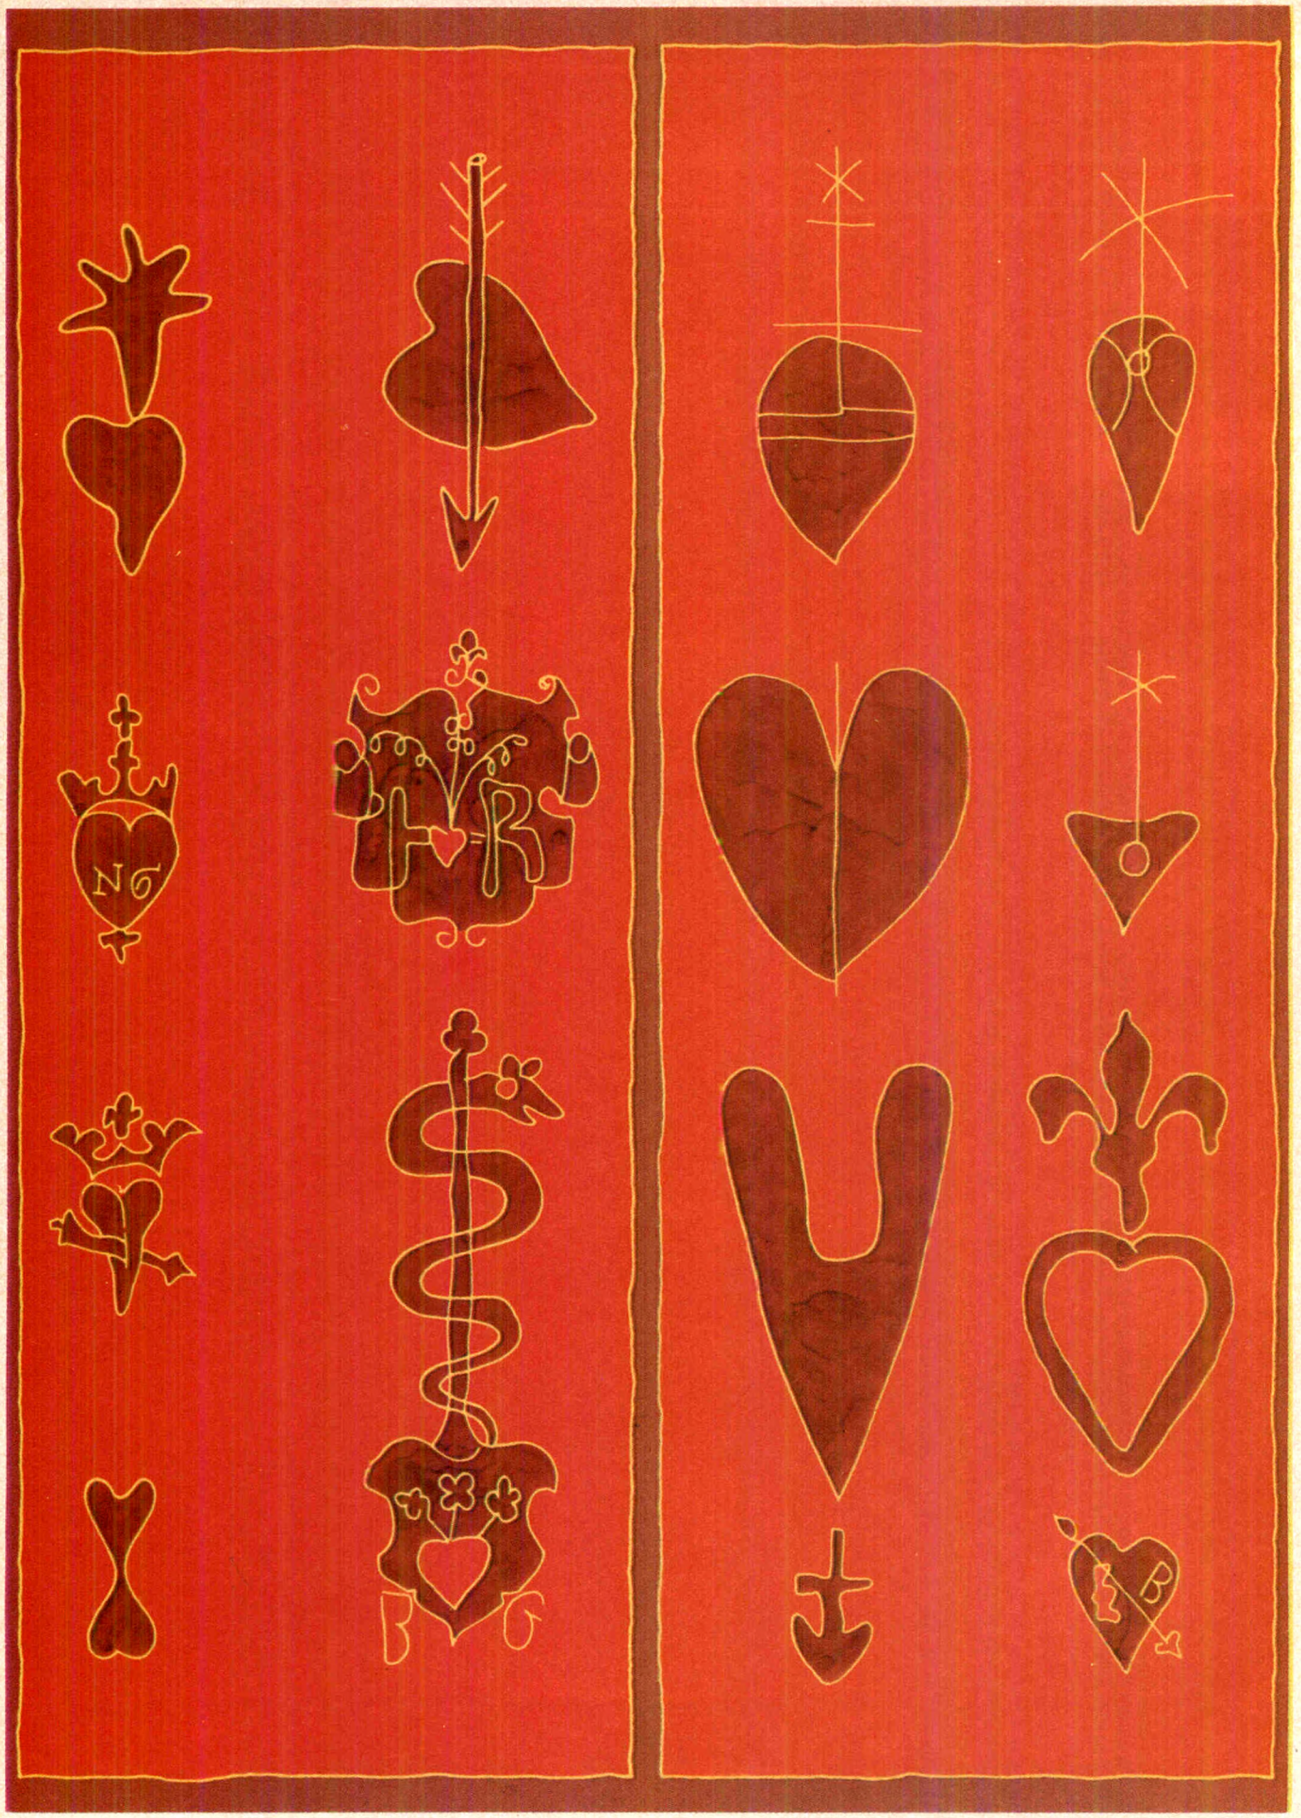
PHARMACEUTICAL DIVISION MARION



The art of antianginal therapy

For centuries, treating the heart's ills has been the subtlest of arts. Even today, evaluating a drug for chronic angina pectoris involves the art of medicine as well as its science.

Persantine — over a decade of use

During more than a decade of clinical experience, compounding both science and art, Persantine has often been found useful in the long-term management of chronic angina pectoris.* It may:

eliminate or reduce the frequency of anginal attacks

improve exercise tolerance

reduce nitroglycerin requirements

Persantine — give enough — long enough

The recommended dosage: 50 mg. t.i.d. at least one hour before meals. *Give enough, long enough* — several weeks or longer of continuous therapy may be needed to see response.

Persantine® Tablets of 25 mg.
dipyridamole

the non-nitrate
coronary vasodilator

Heart-Shaped Watermarks
14th to 16th Century, from C. M. Briquet "Les Filigrans," Leipzig, 1923.

It was believed during the middle ages that the earth was the center of the universe and the heart was the center of man; all other organs were inferior and grouped around it. The heart was believed to be the essence of man, his most essential and noble part. In art, the heart was depicted in a variety of symbols. These heart-shaped watermarks typify the symbology of the heart.

*INDICATIONS—Based on a review of this drug by the National Academy of Science-National Research Council and/or other information, FDA has classified the indication as follows:

"Possibly" effective: For long-term therapy of chronic angina pectoris. Prolonged therapy may reduce the frequency or eliminate anginal episodes, improve exercise tolerance, and reduce nitroglycerin requirements. The drug is not intended to abort the acute anginal attack.

Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS—No specific contraindications are known.

PRECAUTIONS—Since excessive doses can produce peripheral vasodilation, the drug should be used cautiously in patients with hypotension.

ADVERSE REACTIONS—Adverse reactions are minimal and transient at recommended dosages. Instances of headache, dizziness, nausea, flushing, weakness or syncope, mild gastrointestinal distress and skin rash have been noted during therapy. Rare cases of what appeared to be an aggravation of angina pectoris have been reported, usually at the initiation of therapy. On those uncommon occasions when adverse reactions have been persistent or intolerable, withdrawal of medication has been followed promptly by cessation of undesirable symptoms.

DOSAGE AND ADMINISTRATION—The recommended dosage is 50 mg. (2 tablets) three times a day, taken at least one hour before meals. In some cases higher doses may be necessary but a significantly increased incidence of side effects is associated with increased dosage. Clinical response may not be evident before the second or third month of continuous therapy.

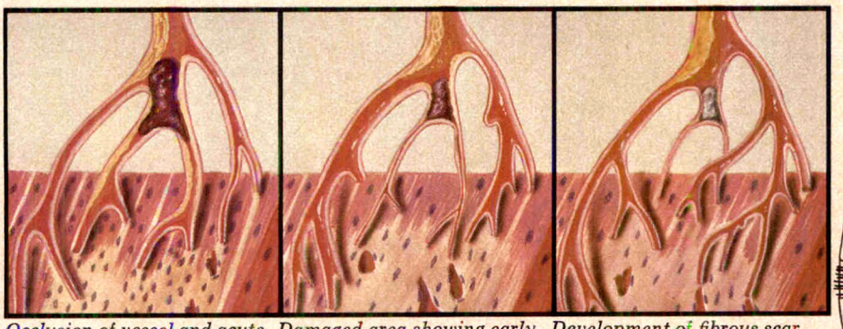
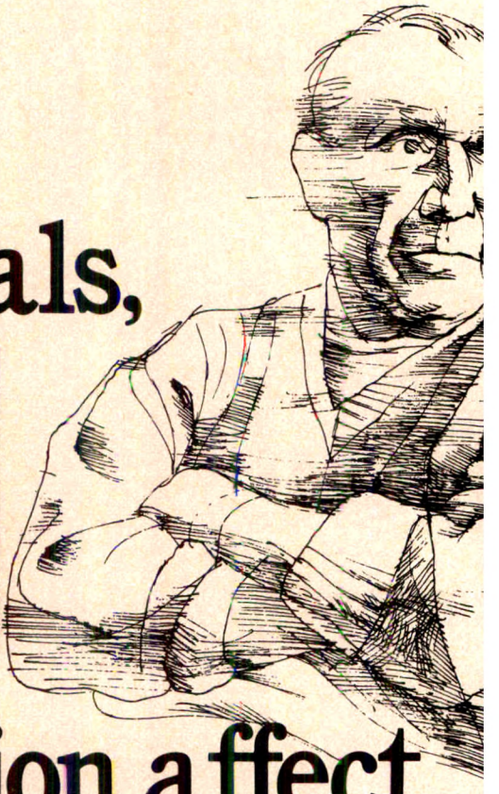
As the infarct heals,



Occlusion of vessel and acute infarct of the myocardium.

Damaged area showing early collateral vessel formation.

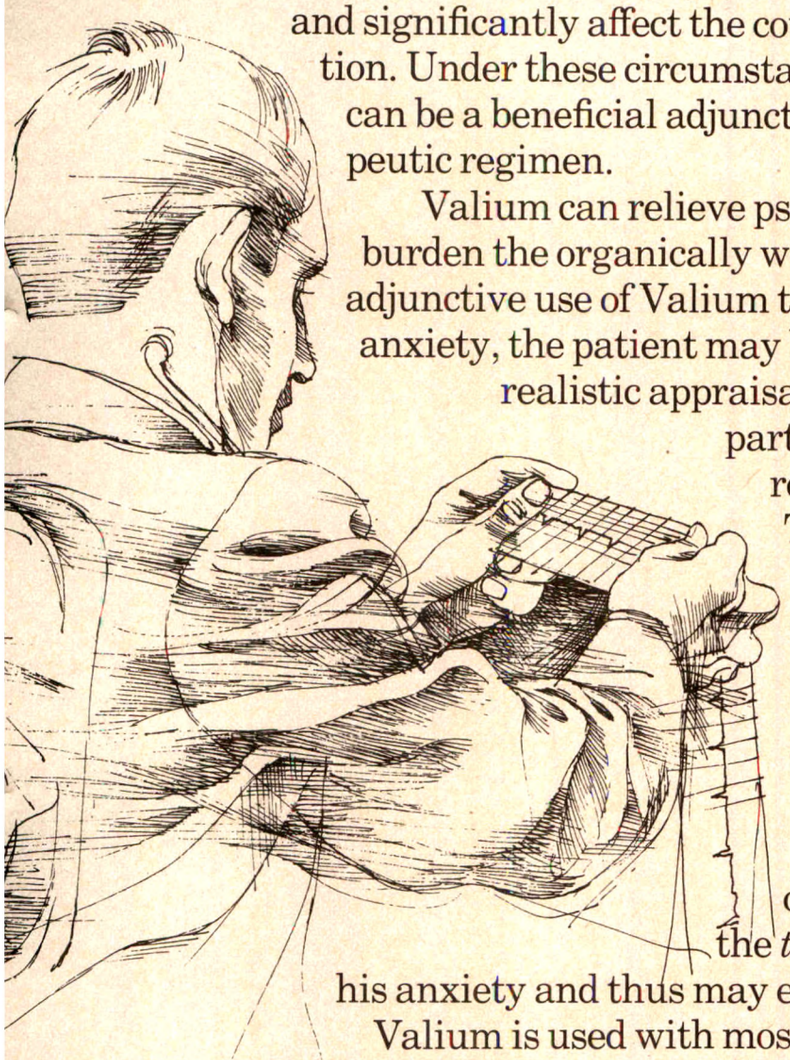
Development of fibrous scar and healing of infarcted area.



will psychic tension affect the patient's rehabilitation?

ROCHE

After the MI patient's acute episode has been successfully managed, a program of rehabilitation is begun. At times the overly tense cardiac patient may present a special problem. Although you continue to encourage a positive outlook through counseling and enlistment of support from the patient's family, psychic tension may remain, and significantly affect the course of rehabilitation. Under these circumstances, Valium (diazepam) can be a beneficial adjunct to the patient's therapeutic regimen.



Valium can relieve psychic tension that may burden the organically weak heart. As a result of adjunctive use of Valium to relieve unwarranted anxiety, the patient may be able to arrive at a more realistic appraisal of his situation and participate more fully with his rehabilitation program.

Therapy should normally be continued until the patient's anxiety has been reduced to tolerable levels.

Since the cardiac patient may be particularly prone to tension and anxiety at bedtime, the addition of an *h.s.* dose of Valium to the *t.i.d.* schedule can relieve his anxiety and thus may encourage sleep.

Valium is used with most classes of primary medications such as cardiac glycosides, diuretics, vasodilators, anticholinergics and antacids. The most commonly reported side effects have been drowsiness, fatigue and ataxia. Patients taking Valium should be cautioned against driving or operating dangerous machinery.

Valium®(diazepam)
2-mg, 5-mg, 10-mg tablets

when you consider it essential to keep the heart patient calm

Please turn page for a summary of product information.

When you consider it essential to keep the heart patient calm

- Valium (diazepam) can relieve psychic tension and anxiety that may burden the organically weak heart and interfere with the patient's course of rehabilitation.
- Valium works promptly in most patients. Significant improvement is usually noted during the first few days of therapy, although some patients may require more time to respond.
- Adjustments in dosage can alter clinical response. With appropriate titration, a regimen can be tailored to the patient's individual needs.
- Valium has a wide margin of safety in the usual oral dosage range and generally does not significantly affect respiration or pulse.

Valium® (diazepam) 2-mg, 5-mg, 10-mg tablets

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Tension and anxiety states, somatic complaints which are concomitants of emotional factors; psychoneurotic states manifested by tension, anxiety, apprehension, fatigue, depressive symptoms or agitation; symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology, spasticity caused by upper motor neuron disorders, athetosis, stiff-man syndrome, convulsive disorders (not for sole therapy).

Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.

Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms (similar to those with barbiturates and alcohol) have occurred following abrupt discontinuance (convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence. In pregnancy, lactation or women of childbearing age, weigh potential benefit against possible hazard.

Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.

Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.

Dosage: Individualize for maximum beneficial effect. *Adults:* Tension, anxiety and psychoneurotic states, 2 to 10 mg b.i.d. to q.i.d.; alcoholism, 10 mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. to q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).

Supplied: Valium® (diazepam) Tablets, 2 mg, 5 mg and 10 mg; bottles of 100 and 500. All strengths also available in Tel-E-Dose® packages of 1000.

tolerance to exercise improved for angina patients

INDICATIONS: For the prophylaxis and long-term management of patients with frequent or recurrent anginal pain and reduced exercise tolerance associated with angina pectoris, rather than for the treatment of the acute attack of angina pectoris, since its onset of action is somewhat slower than that of nitroglycerin.

PRECAUTIONS: As with other effective nitrites, some fall in blood pressure may occur with large doses. Caution should be observed in patients with a history of recent cerebral hemorrhage, because of the vasodilatation which occurs in the area. Although therapy permits more normal activity, the patient should not be allowed to misinterpret freedom from anginal attacks as a signal to drop all restrictions.

SIDE EFFECTS: No serious side effects have been reported. As with nitroglycerin or other effective nitrites, temporary vascular headache may occur during the first few days of therapy. This can be controlled by temporary dosage reduction in order to allow adjustment of the cerebral hemodynamics to the initial marked cerebral vasodilatation. These headaches usually disappear within one week of continuous therapy but may be minimized by the administration of analgesics such as Empirin® Compound.

Mild gastrointestinal disturbances occur occasionally with larger doses and may be controlled by reducing the dose temporarily.

SUPPLIED: 10 mg. chewable tablets. Bottles of 100. Also 5, 10 and 15 mg. scored tablets in bottles of 100. 10 mg. scored tablets also supplied in bottles of 1000.

Also available: Cardilate-P brand Erythrityl Tetranitrate with Phenobarbital (Warning: may be habit-forming).

Cardilate®

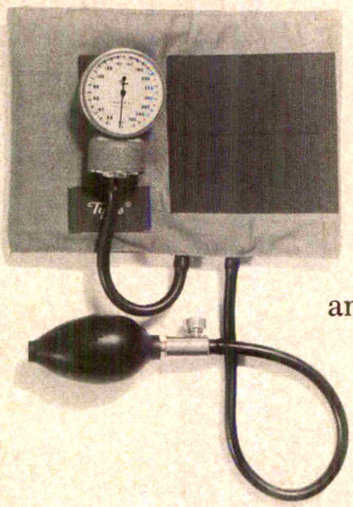
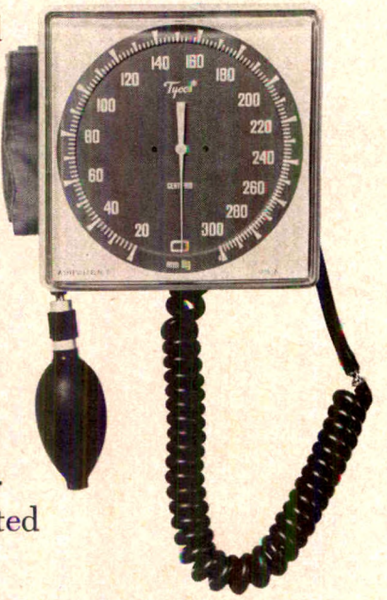
Three Sphygs for perfectionists.



For over 65 years Tycos® has set the standard for excellence in precision aneroids. The fact that there are over three million Tycos sphygs in use today attests to their unsurpassed accuracy, design and reliability.

The big wall sphyg, featuring a large 6¼" dial, is ideal for mounting between two beds anywhere in the hospital. The swivel bracket and large white numerals assure easy reading from anywhere in the room.



The hand and pocket aneroids are recognized everywhere as fine diagnostic instruments. Their compactness and light weight make them easy and comfortable to carry either in pocket or bag.

All three sphygs have the exclusive Tycos visual check for accuracy and are backed by the famous Tycos 10-year warranty. For the practitioner who demands perfection, they can be counted upon to give top performance for many, many years.

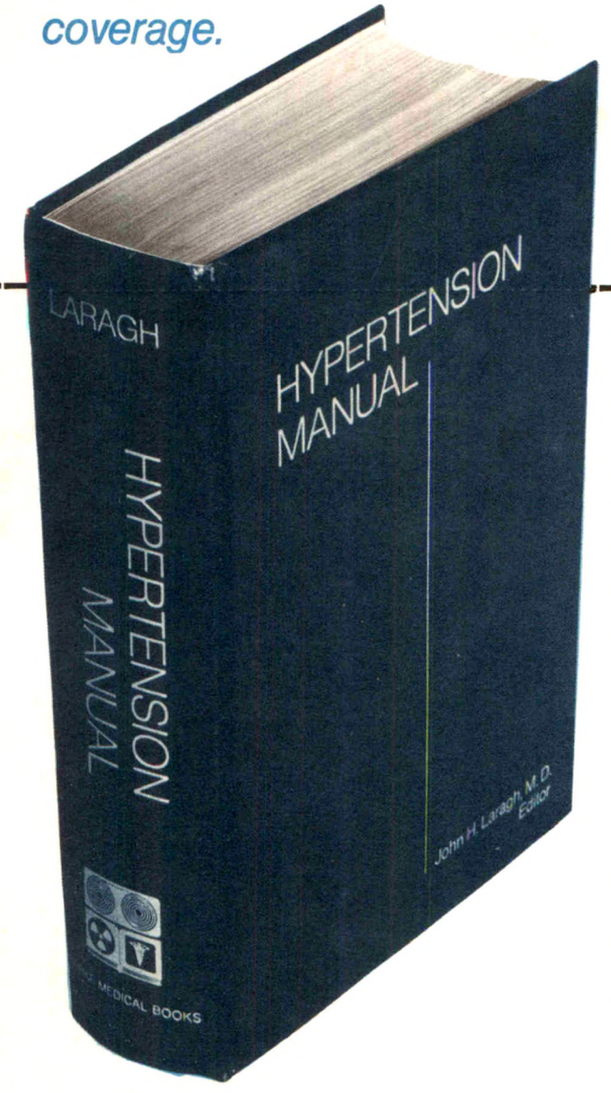
Medicine's continuing concern is hypertension.

We have just released *Hypertension Manual*, edited by John H. Laragh, M.D., of the College of Physicians and Surgeons, Columbia-Presbyterian in New York City.

Now, available in one new book, is the latest, in-depth, clinical coverage.



Across its 900 pages and within its 150 illustrations is all of the up-to-the-hour information needed by the physician who must diagnose and treat hypertension. The Manual features mechanisms, methods and management of this widespread syndrome, and will doubtless become the standard reference work on the subject.

Other contributors to *Hypertension Manual* include specialists whose names appear at the frontiers of hypertension research and clinical progress.

Model 5000 Dyna-Gram® Recorder

The Model 5000 Dyna-Gram® Recorder for Holter Electrocardiography.

The Model 5000 is a new 24-hour cassette recorder with electronic timing and a digital patient clock for precise correlation of the ECG with patient activities and symptoms. The advanced design of the Model 5000 includes an exclusive circuit to minimize electrode artifact. The rechargeable Dyna-Gram® Power-Pack provides continuous 24-hour recording capability *without* turning the cassette. Compact and light weight, the Model 5000 Dyna-Gram® Recorder can be worn with a waist belt or a shoulder strap.

No purchase of costly processing equipment is required. Your recorded Dyna-Gram® cassettes will receive Cardio-Dynamics comprehensive analysis using the unique Dyna-Gram® III Analyzer System.

A quality line of cassettes, disposable electrodes, and related patient hookup supplies is available.

Let's face it. Conventional nitroglycerin is a notably unstable compound. It migrates from tablet to tablet, from tablet to cotton, from cotton to cap. Result: a wide variance in potency and therapeutic effect.

But with Nitrostat your angina patient gets a stabilized nitroglycerin. *Stabilized for uniform potency retention.* Thus, Nitrostat does the job that sublingual nitroglycerin is *supposed* to do. And does it *consistently*—providing the same pain-relieving potency, tablet after tablet. That's why more and more physicians are turning to Nitrostat.

Important facts to know whenever you're prescribing for a patient with a history of angina.

think nitroglycerin…write

Detection of Ventricular Arrhythmias in Real-Time with a Portable Analog Computer

DAVID S. CANNOM, MD
DONALD C. HARRISON, MD, FACC

Stanford, California

Recent studies on the occurrence of sudden death emphasize that many patients have ventricular premature contractions as prodromes of lethal arrhyhmias. A portable, 6 ounce analog computer has been developed to detect tachycardias (heart rate 150 to 190 beats/min), bradycardias (heart rate less than 50 beats/min) and ventricular premature contractions. When preset limits are exceeded, acoustic warnings are sounded, and the patient may transmit his electrocardiogram by telephone, without additional equipment, to a receiving device that graphically reproduces the electrocardiogram in real-time. Hospital studies in 26 ambulatory patients with a variety of arrhythmias have been completed. Tachycardias and bradycardias were detected in every instance during 30 observation periods in six patients. Reproducible warnings were triggered in 19 of the 20 patients with ventricular premature contractions of various configurations during each of 5 observation periods (100 observations). In one patient, the electrical vector of the ventricular premature contraction closely resembled the normal QRS vector and was not detected. Appropriate electrode placement is essential to avoid initial Q waves and to maximize the difference between the vector of ventricular premature contraction and that of the normal QRS complex. No false positive acoustic alarms were sounded. Our results demonstrate that it is possible to detect ventricular premature contractions readily and reproducibly in ambulatory patients. Use of this detector may permit large scale monitoring of patients with a high risk of sudden death.

During the 1960's the establishment of coronary care units for the treatment of serious ventricular arrhythmias considered premonitory of cardiac arrest significantly reduced the in-hospital mortality rate of acute myocardial infarction.[1] It seems likely that further reduction of the in-hospital mortality rate will be limited, since most of these deaths are due to massive myocardial necrosis with severe pump failure.

A major reduction in the mortality rate of myocardial infarction may be possible in the group of patients who die outside the hospital. Recent studies have shown that 50 to 70 percent of all deaths from infarction occur in nonhospitalized patients.[2] Many of these occur suddenly, and pathologic examination of the heart reveals extensive coronary artery disease and myocardial ischemia but no evidence of massive myocardial necrosis.[3] It is probable that these deaths are caused by ventricular arrhythmia, since many occur instantaneously. In many patients, perhaps 30 to 35 percent, sudden death may be the first clinical sign of coronary artery disease.[2] There are several indications that these patients may be identified as being at high risk for sudden death: (1) As many as 23 to 33 percent of patients dying suddenly have visited their physician within 2 weeks of death.[4,5] (2) Ventricular arrhythmias occur as premonitory signs of cardiac arrest in

From the Cardiology Division, Stanford University School of Medicine, Stanford, Calif. This work was supported in part by Grants HE-5866 and HE-5709 from the National Institutes of Health, Bethesda, Md. Manuscript accepted July 5, 1973.

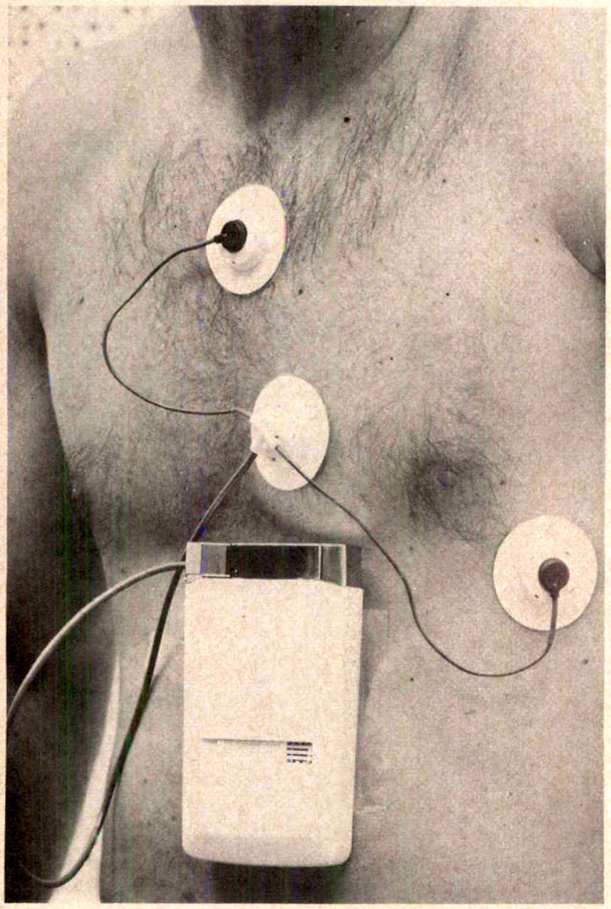

FIGURE 1. Analog computer attached to a patient during a study, showing the R wave-sensing electrodes positioned in the regions most commonly used, one applied apically and one midsternally. A common electrode is placed between these two, and the electrodes are connected by a cable to the computer.

outpatients who have been monitored.[6] (3) Patients with prior episodes of coronary artery disease are at higher risk for sudden death than the general population.[2]

By detecting prelethal arrhythmias that herald sudden death it may be possible to identify and treat patients at high risk. Accordingly, we have evaluated a device that permits continuous real-time monitoring of cardiac rhythm and the initiation of alarms when preset conditions are exceeded. Such a device will allow monitoring of outpatients who are suspected to be at high risk for sudden death.

This study outlines our preliminary experience with a small analog computer attached to the patient by electrodes. The instrument detects tachycardias, bradycardias and ventricular ectopic beats. When preset limits are exceeded, acoustic alarms are sounded and the patient can transmit his electrocardiogram in real-time by ordinary telephone to a receiving unit, where the electrocardiogram can be printed on a strip chart and analyzed. This preliminary study describes the use of this device in detecting arrhythmias in a controlled in-hospital setting. Ongoing studies are evaluating its usefulness in ambulatory hospital patients and outpatients.

Materials and Methods

Twenty-six patients hospitalized in the Cardiology Service at Stanford University Hospital were selected for study because their standard electrocardiograms showed either premature ventricular contractions, supraventricular tachycardias or sinus bradycardias. An additional 14 patients with electrocardiograms whose QRS complex had an unusual configuration, such as a bundle branch block pattern or marked ST–T wave changes, were studied to determine the potential for false positive alarms caused by such electrocardiographic changes when the analog computer detector was used.

The Instrument

The instrument evaluated in these experiments (VIDA, Cardiodynamics-Vida Medical Systems, Dublin, Calif.) is shown in Figure 1. It is a 6 ounce analog computer that can be operated for 30 days without replacement of its self-contained battery. It looks like a small transistor radio and can be worn in a coat pocket, special belt holder or shirt pocket. The computer contains electronic circuitry that performs the following primary functions: (1) electrocardiographic signal amplification; (2) nonlinear analog wave form processing; (3) ventricular ectopic beat identification; (4) ectopic interval evaluation; and (5) signaling of audio alarms to the patient when preset limits are exceeded.

The electrical signal from the electrodes is amplified to an appropriate level by the input amplifier. This signal is processed by a nonlinear circuit that is sensitive to the sharpness of initial slope of ectopic beats but ignores normal QRS configurations. When the processed signal exceeds a specific value, a binary signal is generated to indicate that an ectopic beat is occurring. If two such occurrences are separated by less than a preprogrammed interval, the unit produces an 8 second audible tone. This signals the patient that the criteria for ectopic activity established by the physician have been exceeded and, depending upon the clinical situation, specific actions should be taken.

Several secondary functions are performed by the instrument: (1) detection of tachycardia; (2) detection of bradycardia; and (3) telephone transmission of an audio signal that can be converted to an electrocardiogram.

The rate at which normal QRS complexes occur is converted to a voltage and compared against preprogrammed limits. If the voltage exceeds the limit for tachycardia (set between 150 and 190 beats/min) or falls short of the limit for bradycardia (less than 50 beats/min), the audio tone sounds a different alarm, a short, high-pitched "beep," corresponding to each heart beat.

The instrument also has the capacity to transmit the electrocardiogram wave form in real-time to a central receiving point with use of regular telephone service. To transmit the low frequency electrocardiographic signal over a telephone line intended for voice frequencies, an FM (frequency modulation) modulator is used. The analog computer emits a constant frequency tone (about 2,000 cycles/sec) when the electrocardiographic wave form is at its base-line value. This tone varies in pitch as the electrocardiogram varies from its base line: An upward or positive variation of the electrocardiogram results in a higher pitch, and a downward variation results in a lower pitch.

At the receiving station, a complementary instrument converts this varying period signal back to an ordinary low frequency electrocardiogram and records it on a strip chart

recorder. The overall system maintains the 0.05 to 100 Hz standard suggested by the American Heart Association for recording of electrocardiograms.

Method of Study

Each patient was studied in a similar fashion. Since the instrument recognizes only pure or predominant R waves, irrespective of their precise configuration, the position for placing the electrodes on the chest is important. The patient lay supine and his precordium was initially explored with use of two suction cups attached to the right and left arm leads of a standard electrocardiogram until bipolar lead I showed a predominant R wave. An initial Q wave or large S wave, as part of an RS complex, was always eliminated by continued precordial mapping. Typically, placement of one electrode apically and one midsternally was the most favorable electrode position.

The skin in the area was shaved, and commercial electrodes (NDM disposable electrodes, Bionetics, Inc., Dayton, Ohio) were applied to the sites previously shown to provide the largest R wave. The electrodes were attached to the computer by a short insulated wire (Fig. 1).

Each patient was monitored simultaneously by either an electrocardiogram or an oscilloscope attached to a separate pair of electrodes placed near those of the computer. The study in each patient was personally observed by one of us.

Five different computer units were used in succession during the study of each patient. Each patient studied with a single unit was considered to comprise an individual observation, so that each patient studied with five different units in succession comprised five observations. Comparison between the response of the unit and the simultaneously recorded electrocardiogram forms the basis of our results. In each case, when an alarm sounded, telephone transmission to the receiving unit was made by the patient to test this modality of the device.

Results

Six patients with tachycardias or bradycardias were studied. In each case, the unit responded with the appropriate repetitive acoustic signal when the rate was either faster than 150 or slower than 50 beats/min, the limits chosen for this study. Figure 2 shows an example of the unit's response to a tachycardia and a bradycardia. Thus, for this group of patients, there were 30 accurate observations, with no false positive or false negative alarms.

A total of 20 consecutive patients with more than five ventricular premature contractions per minute were studied. Although any number of ventricular premature contractions per minute could have been chosen, five per minute was the criterion selected for this study. An additional 14 patients with bundle branch block configurations, deeply depressed S–T segments or inverted T waves were studied to determine whether such changes would affect the unit's capability to detect ventricular premature contractions. No variations in QRS or ST–T configurations triggered false positive alarms in these 14 patients.

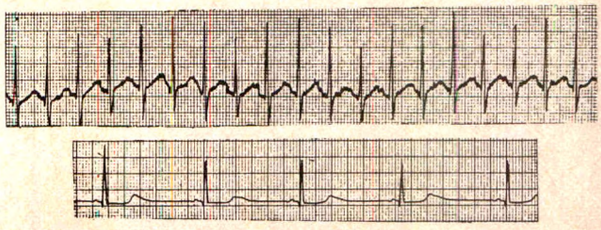

FIGURE 2. Examples of a tachycardia **(above)** and bradycardia **(below)** detected by the device, showing strip-chart printouts of the arrhythmias as transmitted over ordinary telephone lines. A short, high-pitched acoustic "beep" sounded with the occurrence of each QRS complex, alerting the patient to an arrhythmia. Paper speed 25 mm/sec.

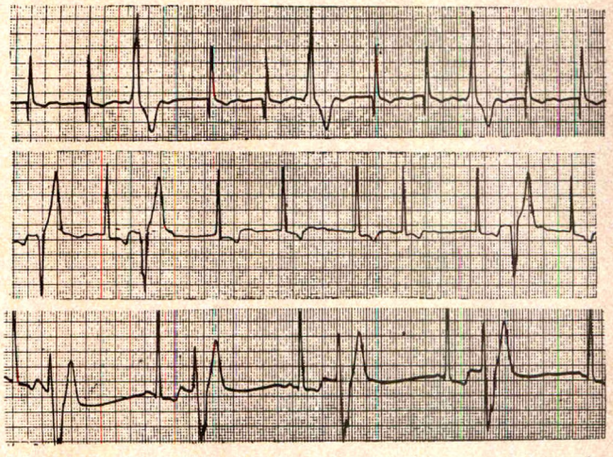

FIGURE 3. Three panels showing representative premature ventricular contraction configurations detected by the computer. If two premature contractions occurred within 12 seconds, an 8 second acoustic alarm sounded and continued to sound if the arrhythmia was repetitive. Paper speed 25 mm/sec.

In 19 of the 20 patients with ventricular premature contractions, the device correctly identified the contraction if two occurred within 12 seconds of each other (that is, at a rate of five per minute). The acoustic alarm, lasting 8 seconds, sounded each time two ventricular premature contractions occurred in this interval; it continued to sound if these contractions were frequent or persistent. Examples of the various wave forms detected are shown in Figure 3. Each of these arrhythmias was tested with all five units, and there were no differences in response of the units studied. Although many of the alarms were repetitive in these 19 patients, in the 95 observations

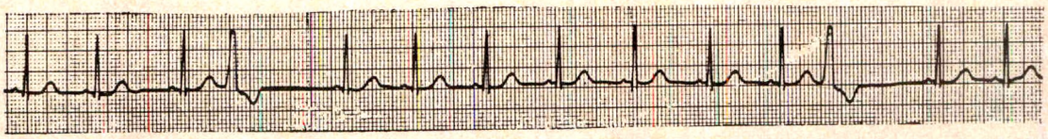

FIGURE 4. Transmitted recording of the patient whose premature ventricular contractions were not detected by the device. The initial vector of the premature contraction is similar to that of the normal sinus QRS complex. Paper speed 25 mm/sec.

made, there were no false positive or false negative alarms.

In one patient, ventricular premature contractions (Fig. 4) were not detected by any of the five units. The probable explanation for this failure is that the slope of the initial R wave of these contractions was very similar to the slope of the sinus R waves. In this patient, it was not possible to change electrode position so that the vector of the ventricular premature contractions differed significantly from the sinus QRS vector. These five observations represent the only false negative results in the study. It should be emphasized, however, that all patients had preexisting ventricular premature contractions, so that appropriate electrode placement on the chest could be made to detect the arrhythmia.

Discussion

The 26 patients studied in this carefully controlled manner to evaluate the sensitivity and specificity of the design model arrhythmia detector demonstrate the capabilities of this analog computer. The behavior of the five units in detecting tachycardias and bradycardias was uniformly satisfactory. Premature ventricular contractions of various configurations were successfully detected in 19 of 20 patients. The failure to detect ventricular premature contractions in one patient (Fig. 4) was probably related to the logic of the computer, which requires recognition of a change in the slope of the initial R wave of the QRS complex. The slope of the R wave of this patient's ventricular premature contractions was virtually identical to that of the base-line QRS complex, representing those ectopic beats that are beyond the capability of this unit to recognize and detect.

We do not expect the capability of the device to detect premature ventricular contractions to approach 95 percent in a randomly selected outpatient population. Knowledge of the vector of the ventricular premature beats in our controlled population permitted electrode placement that enhanced the arrhythmia detection capabilities of the device in our study. In randomly selected patients without previously existing ectopic beats of known vector, the frequency of failure to detect ventricular premature contractions would be greater. Studies are currently underway to document this point; however, the circuitry of this equipment is designed to avoid a high prevalence of false positive signals.

The transmission capability of the unit was tested in each case. Patients had no difficulty with the mechanics of telephone transmission. The electrocardiograms graphically reproduced by the receiving device during telephone transmission are of high quality, as can be appreciated from the illustrations.

Clinical implications: Our studies suggest that this device has important implications for the patient who has, or who can be expected to have, arrhythmias. A unit potentially suitable for outpatient use is now available for monitoring arrhythmias in real-time and alerting the patient and his physician to arrhythmias when they occur. The unit will permit assessment of therapy and treatment of the patients while they are experiencing the arrhythmia. The effect of such real-time monitoring of patients at high risk for sudden death remains unknown. Clearly, the study of such patients by detecting premonitory lethal rhythms is now possible using the analog computer described. A unit of this kind would appear ideal for surveying these patients clinically and for research purposes.

Our studies were performed under carefully controlled circumstances to evaluate the capabilities of the computer itself. Careful mapping of the chest for the vector of ventricular premature contractions is essential; good electrode contact and maintenance is necessary; educating the patient to understand the alarms is required; and psychological support for the patient using the system is mandatory. Our findings suggest that controlled outpatient studies should now be attempted both to define the problems of long-term electode placement and patient acceptance and tolerance of the concept of continuous monitoring and to establish mechanisms for telephone transmission to a coronary care unit or central hospital facility. Resolution of these potential problems must be achieved before widespread outpatient use of this device can be undertaken.

Ventricular Septal Defect with Increased Pulmonary Vascular Resistance

Late Results of Surgical Closure

BEAT FRIEDLI, MD
B. S. LANGFORD KIDD, MD, FACC
WILLIAM T. MUSTARD, MD, FRCS(C)
JOHN D. KEITH, MD, FACC

Toronto, Ontario, Canada

The fate of 57 children who underwent surgical closure of ventricular septal defect in the presence of increased pulmonary vascular resistance was analyzed. Eighteen (32 percent) died at or immediately after operation. Seven late deaths, due to the Eisenmenger syndrome, occurred 1 to 7 years after operation. Follow-up studies, including cardiac catheterization, were performed in 25 survivors, 1 to 11 years (mean 5 years) after operation. In patients operated on after age 2 years, the degree of preoperative elevation of pulmonary vascular resistance largely determined the prognosis: The condition of patients with mild elevation (pulmonary vascular resistance less than one third the systemic level) returned to normal after operation, with one exception. Patients with more severe elevation (pulmonary vascular resistance more than one third the systemic level) most often showed progressive pulmonary vascular disease; the condition of a few remained unchanged and that of only one returned to normal after operation.

Operative mortality rate was high in children with elevated pulmonary vascular resistance during the second year of life who were operated on before age 2 years, but pulmonary vascular resistance returned to normal in the three survivors. When pulmonary vascular resistance was increased in the first year of life, it generally decreased spontaneously (independently of operation); the early increase in these cases is believed to represent delayed maturation of the pulmonary vascular bed rather than pulmonary vascular disease.

The overall results of surgery in ventricular septal defect associated with a high level of pulmonary vascular resistance are unfavorable and call for interruption of the natural history before significant pulmonary vascular obstructive changes have taken place; this can be achieved by surgical closure before age 2 years or pulmonary artery banding in infancy.

Pulmonary vascular disease is a serious complication in a significant number of patients with a large ventricular septal defect.[1–5] It is generally agreed that the advanced stage with right to left or bidirectional shunting, known as the Eisenmenger syndrome, constitutes a contraindication to surgery. However, controversy exists about the fate of patients whose ventricular septal defect is closed in the presence of a mild or moderate increase in pulmonary vascular resistance. Although some investigators[6–9] have indicated a marked postoperative reduction in pulmonary vascular resistance, to normal in many cases, others[10,11] have found little change. Concern has been repeatedly expressed that pulmonary vascular disease may progress further after closure of the defect. Although severely increased pulmonary vascular

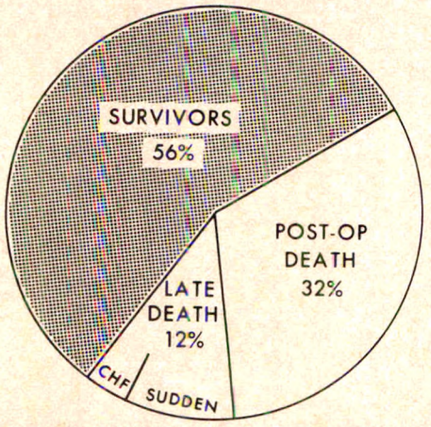

FIGURE 1. Fate of 57 patients operated on for ventricular septal defect and pulmonary vascular disease, including early postoperative and late deaths. Late fatalities were due more often to sudden death (five cases) than to congestive heart failure (CHF) (two cases).

resistance has long been considered a contraindication to surgery in this hospital, 57 patients with mild to moderately severe elevation of resistance underwent surgical repair of ventricular septal defect between 1955 and 1971. In this paper, we present their postoperative course, including results of long-term follow-up catheterization studies in the survivors.

Material and Methods

Patients were selected for study whose pulmonary vascular resistance was more than 25 percent of the systemic vascular resistance and in excess of 400 dynes sec cm^{-5} per m^2. At operation their ages ranged from 11 months to 17 years (mean 4.8 years).

Postoperative catheterization was performed in 25 of the survivors and repeated in 2. All catheterization studies were carried out with the patient under light sedation induced by a mixture of meperidine, 25 mg, chlorpromazine, 6.25 mg, and promethazine, 6.25 mg/ml (0.1 ml/kg). Pressures were recorded on an Electronics for Medicine DR8 recorder and transmitted from Statham transducers. Oxygen content of venous, systemic arterial and pulmonary arterial blood was measured using a Waters cuvette oximeter.

Flow measurements were calculated[2] using an assumed value for oxygen consumption of 180 cc/min per m^2. Because this procedure may introduce an error of unknown magnitude into calculations of absolute flow and resistance levels, we have elected to report our results in terms of flow ratios (pulmonary blood flow over systemic blood flow) and resistance ratios (total pulmonary vascular resistance over systemic vascular resistance) expressed as a percentage. Both of these measurements are independent of oxygen consumption, and we believe that they are the most reliable in a primarily retrospective study of this kind. Patients with a residual ventricular septal defect were included in the study only when the oxygen saturation data indicated an insignificant left to right shunt (pulmonary/systemic flow ratio between 1 and 1.5), and the pulmonary vascular resistance had returned to normal.

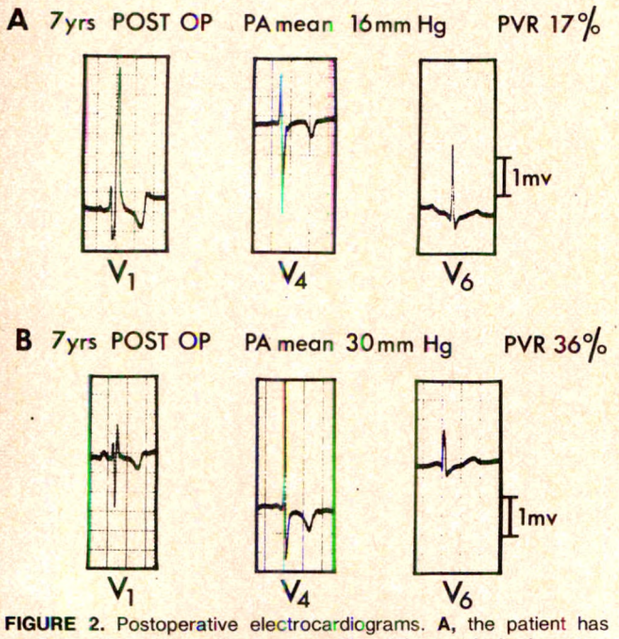

FIGURE 2. Postoperative electrocardiograms. **A,** the patient has electrocardiographic evidence suggesting right ventricular hypertrophy, although normal pulmonary arterial (PA) pressure and resistance (PVR) values were found. In another patient **(B),** no signs of right ventricular hypertrophy exist despite moderately elevated pulmonary arterial pressure and resistance values.

Results

Mortality

There was a high operative mortality rate (Fig. 1). Twelve of the 18 postoperative deaths occurred in patients who were operated on in the first, second or third year of life for increasing pulmonary vascular resistance. In many of these cases the operation had been performed between 1955 and 1961. There were, in addition, seven instances of late death (12 percent). These occurred 1 to 7 years postoperatively and were all due to the Eisenmenger syndrome; the patients' ages at death ranged from 7 to 16 years. Sudden death was characteristic of this subgroup (five of seven); one occurred during right ventricular angiography, the other four while the children were at school or at play. The remaining two children died with congestive heart failure. Postmortem examination, performed in 17 patients, revealed grade II to IV pulmonary vascular changes according to the classification of Heath and Edwards.[12] There were 32 long-term survivors (56 percent of the total group).

Follow-Up Study

In assessing the state of the pulmonary vascular bed after operation, one must rely heavily on the hemodynamic data. Although advanced pulmonary vascular disease can be diagnosed clinically by use of auscultation and chest roentgenogram, we have found it difficult to recognize persistence of mildly or moderately increased pulmonary vascular resistance without a catheterization study. The most sensitive preoperative indicator of pulmonary hypertension, the electrocardiogram, can be misleading postoperatively (Fig. 2). Very tall R waves in lead V_1 may be seen in the presence of normal pulmonary arterial

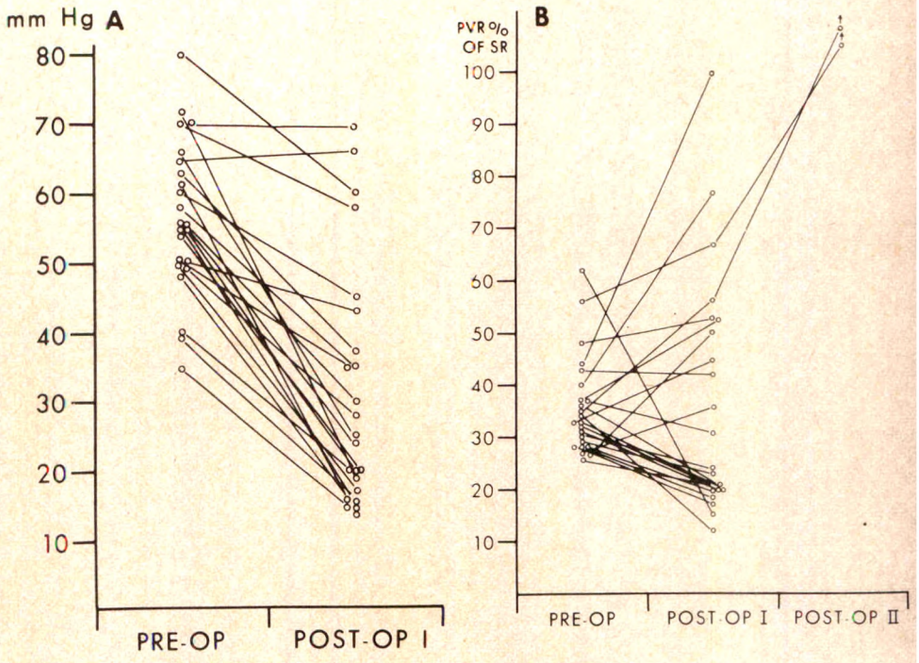

FIGURE 3. Pre- and postoperative values for pulmonary arterial pressure **(A)** and resistance **(B).** There is a tendency toward decreasing pulmonary arterial pressure, but resistance values show a wide scatter. Post-op I and II = first and second postoperative catheter studies, respectively; pre-op = preoperative data; pulmonary vascular resistance is presented as a percentage of systemic resistance (PVR % OF SR).

pressure; more rarely, patients with increased pulmonary vascular resistance may have no evidence of right ventricular hypertrophy on the electrocardiogram. This phenomenon may be caused by the postoperative intraventricular conduction disturbance; it has been suggested[13] that, in some cases, persistent signs of right ventricular hypertrophy indicate abnormal reactivity of the pulmonary vascular bed.

Hemodynamic Data

Twenty-five of the survivors were submitted to cardiac catheterization 1 to 11 years after operation, whether or not persistent pulmonary hypertension was suspected on clinical grounds. Four patients had a small residual ventricular septal defect that was hemodynamically insignificant (pulmonary to systemic flow ratio between 1.0 and 1.5). In the 21 other patients the defect was completely closed.

As shown in Figure 3A, pulmonary arterial pressure was reduced to some degree in all but two patients, although seldom to normal values. Because all patients had a sizable left to right shunt before operation, this reduction can be expected to occur independently of any change in pulmonary vascular resistance simply because of decreased pulmonary blood flow. Indeed, pulmonary vascular resistance did not show a uniform tendency to decrease (Fig. 3B). A large scatter in resistance values was found at follow-up catheterization: In some patients, values had returned to normal or near normal levels, whereas in others they had remained unchanged or had definitely increased, in some instances to systemic levels or higher.

The patient population was classified according to age and degree of preoperative elevation of pulmonary vascular resistance. Findings in the three main groups follow.

Patients operated on after age 2 years: In this group of patients, the degree of elevation of pulmonary vascular resistance before operation seemed to be the critical factor determining the prognosis. Figure 4A shows the outcome in patients with mild to moderate elevation, as defined by a value for pulmonary vascular resistance between one fourth and one third the systemic value. Of the eight patients in this group, six manifested a return to normal levels after operation. One showed a mild increase 7 years after operation, but he is well clinically 11 years postoperatively, and another catheterization study has not been considered warranted. The only patient in this subgroup with a clear-cut increase in pulmonary vascular resistance suggesting progressive pulmonary vascular disease happens to be our oldest patient, who was operated on at age 17 years.

Data from patients with a moderately severe increase in pulmonary vascular resistance, defined as a resistance value more than one third the systemic value (Fig. 4B), suggest that the prognosis in this subgroup is much worse. The level of pulmonary vascular resistance returned to normal in only one patient, and this subject had a preoperative value close to one third the systemic value. The other patients either had no significant changes in resistance or, more often, showed clear-cut progression of pulmonary vascular disease. Seven patients demonstrated clinical features of the Eisenmenger syndrome: loud pulmonic second sound, pulmonary regurgitation and signs of pulmonary vascular disease on the chest roentgenogram. Two of these patients underwent a second postoperative catheterization and were found

to have above systemic levels of pulmonary vascular resistance, with a value for peak pulmonary arterial pressure of 180 mm Hg in one and twice the systemic value in the other. Three patients in this subgroup were among those who experienced a late death.

Two additional children had progressive pulmonary vascular disease after operation, one of whom has died. They are not included in the graph because they did not have preoperative catheterization studies. However, both had clear-cut clinical evidence of increased pulmonary vascular resistance before surgery and were operated on for this reason, in the third and fourth years of life, respectively. Both were found to have pulmonary vascular resistance at systemic level at catheterization, 2 and 5 years postoperatively.

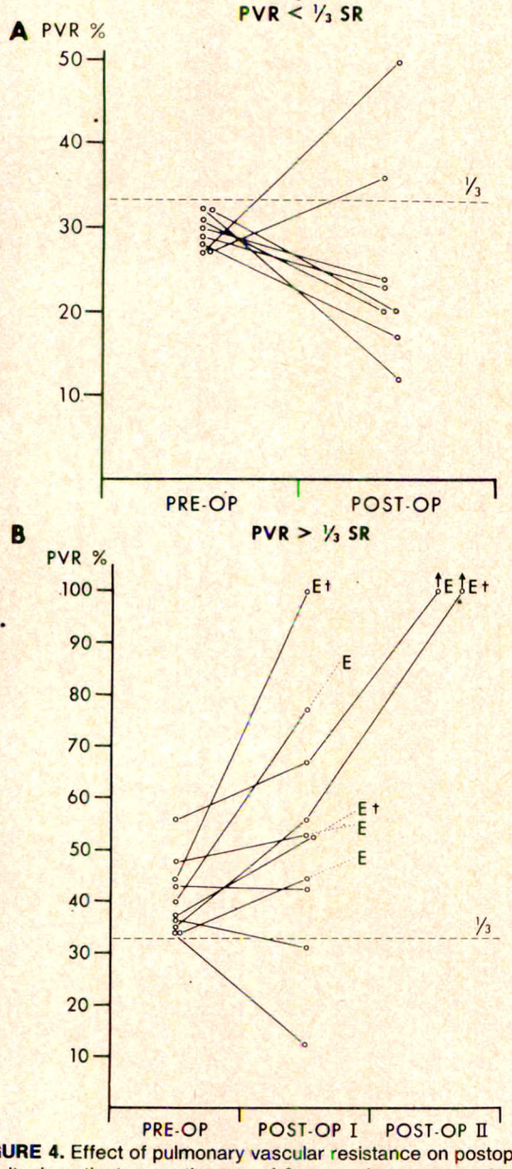

FIGURE 4. Effect of pulmonary vascular resistance on postoperative results. In patients over the age of 2 years, the postoperative evolution is related to the degree of preoperative elevation of pulmonary vascular resistance (PVR). The prognosis is favorable if this value is less than one third the systemic value (SR) **(A).** Progressive pulmonary vascular disease most often occurs when the preoperative level of pulmonary vascular resistance is more than one third the systemic level **(B).** E = clinical evidence of Eisenmenger syndrome.

Patients operated on before age 2 years: Nine patients who had increased pulmonary vascular resistance in the second year of life were operated on before age 2 years. Figure 5A shows their preoperative and postoperative course plotted against the normal maturation line for pulmonary vascular resistance.

All those whose catheterization had been performed in infancy had at that time reduced pulmonary vascular resistance, well below the normal maturation level, but all had a high level of pulmonary blood flow, more than three times the systemic level. When their pulmonary vascular resistance increased markedly in the second year of life, surgical closure of the ventricular septal defect was attempted. Six did not survive the operation; all were found at autopsy to have intimal changes in their pulmonary arterioles (grade II, some even grade III). All three survivors had normal or near normal resistance at follow-up catheterization, although one had moderately severe elevation of pulmonary vascular resistance preoperatively.

Patients with a high level of pulmonary vascular resistance in infancy operated on later: Figure 5B shows the course of five patients with a high level of pulmonary vascular resistance in the first year of life. Three of these patients are not included in the group of 57 who form the basis of this report because they had normal pulmonary vascular resistance immediately before operation. Two patients were included because at the time of their only preoperative catheterization study they had elevated resistance levels. Both patients had normal pulmonary vascular resistance at follow-up catheterization, even though one had markedly increased resistance in infancy.

Discussion

The aim of surgical treatment of ventricular septal defect, as of congenital heart disease in general, is the interruption of the natural history of the disease. This implies, therefore, that when pulmonary vascular disease is already present, surgery can be justified only when it can be demonstrated that the vascular changes regress, or at least no longer progress. What actually happens is still in dispute. Some workers[6–8] have shown a decrease in pulmonary vascular resistance—although not usually to normal levels—in every case, irrespective of the degree of preoperative elevation. One exceptional case has been reported[9] of a 4 year old boy with severe pulmonary hypertension and a bidirectional shunt through a ventricular septal defect who had normal pulmonary arterial pressure and resistance 8 months after successful surgery. Other workers[10,11] have found that although pulmonary arterial pressure decreased postoperatively, there was no significant change in resistance. Furthermore, as data based on longer postoperative fol-

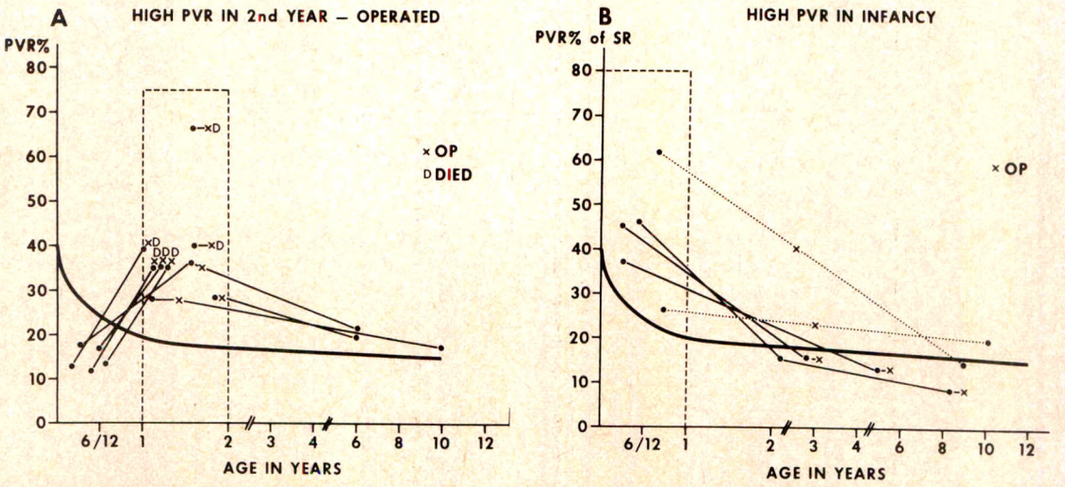

FIGURE 5. Natural and postoperative history of patients with increased pulmonary vascular resistance (PVR). **A,** patients with increased pulmonary vascular resistance in the second year of life, operated on before age 2 years. The heavy line represents the normal maturational line for pulmonary vascular resistance. There was a high mortality rate, but in the three survivors pulmonary vascular resistance returned to normal. **B,** patients with increased pulmonary vascular resistance in infancy, operated on later. All were found to have normal resistance later. In three **(solid lines),** a spontaneous decrease (before operation) was documented by preoperative catheterization study (see text).

low-up periods become available, it is clear that some patients have progressive pulmonary vascular disease in spite of closure of the ventricular septal defect.[4,14,15]

Factors influencing prognosis and mortality: In our series with follow-up periods as long as 11 years (mean 5 years), a change in resistance occurred in the majority of patients, in one direction or the other. Thus, a wide scatter in data has been found at follow-up catheterization. If one disregards the infant group and those operated on before age 2 years, the prognosis seems clearly related to the degree of preoperative elevation of pulmonary vascular resistance. The outcome is much more benign when the preoperative level is less than one third the systemic level. However, even in this group, an occasional patient will still experience progressive pulmonary vascular disease, a finding previously reported by DuShane et al.[4] A progressive increase in pulmonary vascular resistance and in clinical signs of pulmonary vascular disease seems to be the rule in patients whose preoperative pulmonary vascular resistance is more than one third the systemic level. Because of the clear-cut directional changes in pulmonary vascular resistance at follow-up study, the ultimate outcome seems clear in the majority of our cases. Only a few patients have shown little change in pulmonary vascular resistance. The two patients in this latter group who have been followed up for a very long time (6 and 11 years, respectively) are both doing very well clinically. Postoperative catheterization data indicate moderately increased pulmonary vascular resistance (35 and 42 percent, respectively), and these values are only slightly different from those obtained before operation (28 and 44 percent). One can speculate whether these patients truly had "arrested pulmonary vascular disease" and will lead normal lives with some degree of pulmonary hypertension.

That the presence of increased pulmonary vascular resistance results in a higher immediate postoperative mortality rate for closure of a ventricular septal defect has long been recognized. In our series it has been 32 percent; this is in striking contrast to the 7 percent mortality rate in our hospital for closure of a ventricular septal defect without associated increased resistance. Others[8,14,15] have reported a mortality rate for this procedure ranging from 15 to 50 percent depending on the degree of preoperative elevation of pulmonary vascular resistance. Castaneda et al.[6] found that the rate was reduced considerably when the defect was closed through the atrium, thus avoiding ventriculotomy (7 percent mortality in their series). Since the ventricular approach was used routinely in our series, we cannot comment on this issue.

Two thirds of the postoperative deaths occurred in the very young children (first to third years). Typically, these were children with a large ventricular septal defect and severe heart failure in infancy who underwent operation after manifesting pulmonary vascular disease very early in life. The combination of young age and increased pulmonary vascular resistance seemed to result in a very high operative mortality rate. We cannot comment on whether the rate would be lower for infants with increased pulmonary blood flow but normal resistance since in this hospital few such infants have undergone repair of the defect. Pulmonary artery banding has usually been preferred in this situation and has prevented the occurrence of early pulmonary vascular disease and permitted correction at a later time.

Increased pulmonary vascular resistance in the first and second year of life: Our data on patients operated on before age 2 years reveal several interesting facts. First, pulmonary vascular resistance returned to normal in the three survivors. Although this group is too small to permit definite con-

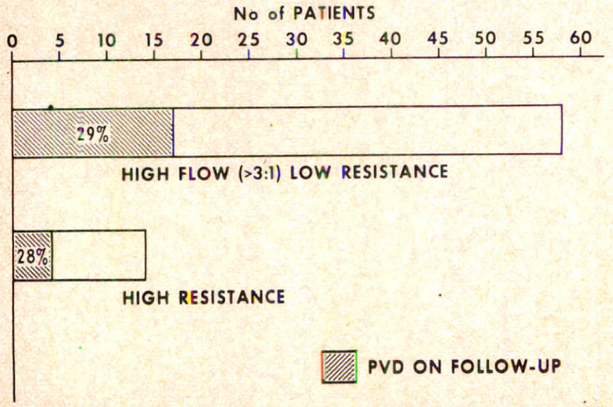

FIGURE 6. Prevalence of pulmonary vascular disease (PVD) in early childhood in patients who had increased pulmonary blood flow in infancy (more than three times systemic blood flow) and patients who had increased pulmonary vascular resistance in infancy (see text).

clusions, it is interesting that one of the three had a pulmonary vascular resistance of 38 percent before operation. Equivalent values in older children did not regress to normal postoperatively. This finding is in accord with recent data from the Mayo Clinic,[4] in which 13 patients with increased pulmonary vascular resistance operated on before age 2 years were later found to have normal pulmonary vascular resistance. Such data indicate that a large ventricular septal defect should be approached surgically very early in life, when pulmonary vascular disease is still reversible or has not yet developed. Primary closure is ideal if it can be performed with an acceptable mortality rate; the alternative is pulmonary artery banding to protect the pulmonary vascular bed and permit total correction later in life.

Increased pulmonary vascular resistance in early childhood was most often preceded in infancy by a phase of reduced resistance associated with a very high level of pulmonary blood flow. In these patients, the hemodynamic situation changed from one of increased pulmonary blood flow with reduced resistance in infancy to one of increased resistance and reduced blood flow in the second year of life. In contrast, of five patients with a high level of resistance in the first year of life, three had normal resistance on repeat preoperative catheterization; the two others were operated on without a repeat catheterization but had normal resistance values in the postoperative study. Whether closure of the ventricular septal defect was responsible for the decrease in resistance in these two cases is disputable. Indeed, all five cases could well represent instances of delayed pulmonary vascular maturation.

Two questions were raised by these patterns of evolution from infancy: (1) Does increased pulmonary vascular resistance in the first year of life invariably decrease spontaneously? (2) What percentage of infants with a ventricular septal defect, a very high flow ratio (pulmonary blood flow/systemic blood flow >3:1) and reduced pulmonary vascular resistance will have increased resistance in early childhood? These questions can be answered only by follow-up catheterization studies of patients who had these hemodynamic patterns in infancy but did not undergo surgery. In our patient material, we found 82 such cases (Fig. 6), of which 58 had a flow ratio of more than 3:1 and a resistance level below normal for age. In 29 percent of these, pulmonary vascular disease developed in early childhood. Since this prevalence is greater than that found in any other hemodynamic group,[16] these patients are clearly at high risk. Increased resistance in infancy (pulmonary vascular resistance above the normal maturational line) is uncommon at sea level: We found only 14 such cases. In 10 of these, resistance spontaneously returned to normal with an increase in pulmonary blood flow, but pulmonary vascular disease developed in 4, as determined by further increases in resistance values. Thus, although most of these patients will have a favorable course, this is another group that requires careful follow-up study.

Clinical Conclusions

The overall postoperative prognosis in ventricular septal defect with increased pulmonary vascular resistance, as found in our study, is obviously not good. In addition to the 18 operative deaths, there have been 7 late deaths, all almost certainly related to pulmonary vascular disease, as confirmed at autopsy in 5.

Fatalities occurred 1 to 7 years after operation and the patient's ages at death ranged from 7 to 16 years. This finding does not compare favorably with data on the natural history of nonsurgically treated Eisenmenger syndrome,[17,18] indicating that death is uncommon in the first and second decades, even with severe pulmonary vascular disease. Thus, in some patients, life expectancy is apparently shortened by the operation, even if they survive the procedure. On theoretical grounds, this finding is not unexpected; indeed, when pulmonary vascular resistance exceeds the systemic level, right to left shunting cannot occur after the defect is closed and the cardiac output becomes limited by the pulmonary vascular obstruction; suprasystemic pressures are then found in the pulmonary artery, as observed in two of our cases.

Finally, of the 32 long-term survivors (56 percent), 5 have evidence of progressive pulmonary vascular disease by both clinical and hemodynamic criteria, and 3 more have increased pulmonary vascular resistance not suspected clinically. Our data do not encourage operation in cases of moderately marked elevation of pulmonary vascular resistance, but rather call for interruption of the natural history before vascular obstructive changes of a significant degree are present. To be watched particularly closely are the high risk groups cited. Either pulmonary artery banding in the first year, or early surgical closure between the ages of 6 months and 2 years, should prevent irreversible pulmonary vascular damage from taking place. As results of open heart surgery in infants improve,[19,20] preference will probably be given to the latter procedure in many centers.

Effect of Red Cell Volume Reduction on Pulmonary Blood Flow in Polycythemia of Cyanotic Congenital Heart Disease

AMNON ROSENTHAL, MD
DONALD C. FYLER, MD

Boston, Massachusetts

The acute effects of red cell volume reduction (erythropheresis) on pulmonary blood flow and pulmonary vascular resistance were measured in 16 patients with severe shunt-induced polycythemia. In subjects with D-transposition of the great arteries and no significant pulmonary stenosis (Group A) erythropheresis was associated with a decrease in pulmonary vascular resistance and an increase in pulmonary blood flow and in mixing between the systemic and pulmonary circulations. Systemic arterial saturation decreased slightly. By contrast, erythropheresis in patients with severe pulmonary stenosis or atresia and a ventricular septal defect (Group B) was associated with a decrease in pulmonary blood flow and left to right shunt and an increase in right to left shunt. These alterations resulted in a significant reduction in systemic arterial oxygen saturation despite relatively little change in effective pulmonary blood flow. The acute hemodynamic effects of packed red cell transfusion in five patients with D-transposition of the great arteries, no significant pulmonary stenosis and relative anemia were more variable.

The observations in patients with shunt-induced polycythemia are probably related to a reduction in blood viscosity produced by a lowering of hematocrit concentration. The reduced viscosity decreases the impedance to flow in the systemic and pulmonary circulations. When pulmonary blood flow is largely derived from the systemic circuit, erythropheresis will diminish pulmonary flow and reduce systemic oxygen saturation. If the pulmonary blood flow is largely independent of the systemic circuit (as in D-transposition of the great arteries without pulmonary stenosis), an increase in total and effective pulmonary flow occurs.

Hypervolemia and an increase in red cell mass occurs in patients with congenital cardiac malformations as a compensatory response to the decreased arterial oxygen saturation.[1] The polycythemia is proportional to the severity of the hypoxemia which in turn is determined by the degree of right to left shunt, pulmonary blood flow and in some malformations (for example, D-transposition of the great arteries) by the systemic blood flow as well. Marked increases in hematocrit, which accompany severe polycythemia, lead to increased viscosity and shear stress and alterations in flow rate.[2] We have previously demonstrated that acute reduction in red cell volume with replacement of the blood withdrawn by plasma or albumin results in a decrease of blood viscosity, increased systemic blood flow, and an increase in the total amount of oxygen delivered to the tissues.[3] The purpose of this study was to determine the acute effect of red cell vol-

ume reduction on pulmonary vascular resistance and flow in patients with severe shunt-induced polycythemia.

Methods

Twenty-one patients with cyanotic congenital heart disease, 16 with severe polycythemia and 5 with relative anemia, were studied in the catheterization laboratory. Demerol® compound (meperidine 25 mg, promethazine 6.25 mg, and chlorpromazine 6.25 mg/1 ml of mixture) in a dose of 1 ml/30 lb (maximal dose 2 ml) was administered before the study. The desired venous hematocrit value was achieved in the 16 polycythemic patients by replacement (erythropheresis) of whole blood with fresh plasma or 5 percent human albumin in physiologic saline solution and in the 5 anemic patients by transfusion with packed red blood cells. Details of the technique and method used in carrying out the reduction in red cell volume have been previously reported.[3] For transfusion, 8 to 11 ml/kg of packed red cells (hematocrit of blood 85 to 91 percent) was used.

Hemodynamic measurements were made with patients in the supine position after a 12 hour fast and before and approximately 1/2 to 1 hour after erythropheresis or packed cell transfusion. The hematocrit was determined on central venous blood and oxygen carrying capacity measured by the cyanmethemoglobin method. Blood oxygen saturation was determined by an oximeter (American Optical Corporation model 10840). Oxygen consumption was measured (Kipp method in 7 patients and Douglas bag collection in 14 patients) and systemic and pulmonary blood flow determinations were made in duplicate by the direct Fick principle. Mixed systemic venous (superior vena caval or right atrial) and arterial blood oxygen saturation and mixed pulmonary arterial and venous (pulmonary venous or left atrial in the absence of an atrial septal defect) blood were used for the calculation of systemic blood flow and pulmonary blood flow, respectively. In six patients blood oxygen contents were directly measured by the Lex-O_2-Con apparatus (Lexington Instrument Co., Waltham, Mass.). In the six patients with pulmonary atresia the saturation level of mixed pulmonary arterial blood was assumed to equal the systemic arterial oxygen saturation level, and in three patients the value for pulmonary venous blood saturation was assumed to be 96 percent. Arterial and venous pressures were obtained using strain gauge transducers, and the heart rate was monitored.

Effective pulmonary flow (EPF) and total right to left shunt were derived and calculated as follows:

$$\text{EPF} = \frac{\text{oxygen consumption (ml } O_2\text{/min per m}^2)}{\text{pulmonary venous oxygen content (ml } O_2\text{/liter) minus mixed systemic oxygen content (ml } O_2\text{/liter)}} \quad (1)$$

$$\text{Total left to right shunt} = \text{pulmonary blood flow (liters/min per m}^2\text{) minus effective pulmonary flow (liters/min per m}^2\text{)} \quad (2)$$

$$\text{Total right to left shunt} = \text{systemic blood flow minus effective pulmonary flow} \quad (3)$$

The effective pulmonary flow may be defined as the flow necessary to carry metabolic oxygen requirements if systemic mixed venous blood alone were perfusing the lung.[4] In patients with D-transposition of the great arteries and absence of severe pulmonary stenosis, effective pulmonary flow = left to right shunt = right to left shunt. The data on 8 of the 21 patients have been previously published in part.[3]

The results were analyzed using standard statistical equations. All tests for significance were based on paired *t* statistics.

Results

Effects of Red Cell Volume Reduction

The acute effects of red cell volume reduction on pulmonary blood flow and systemic blood flow in patients with severe polycythemia due to cyanotic congenital heart disease are summarized in Table I. The 16 patients with polycythemia were classified into two groups on the basis of their response patterns. Group A comprised 5 patients with D-transposition of the great arteries with intact ventricular septum (or small septal defect) and no significant pulmonary stenosis, and Group B comprised 11 patients with se-

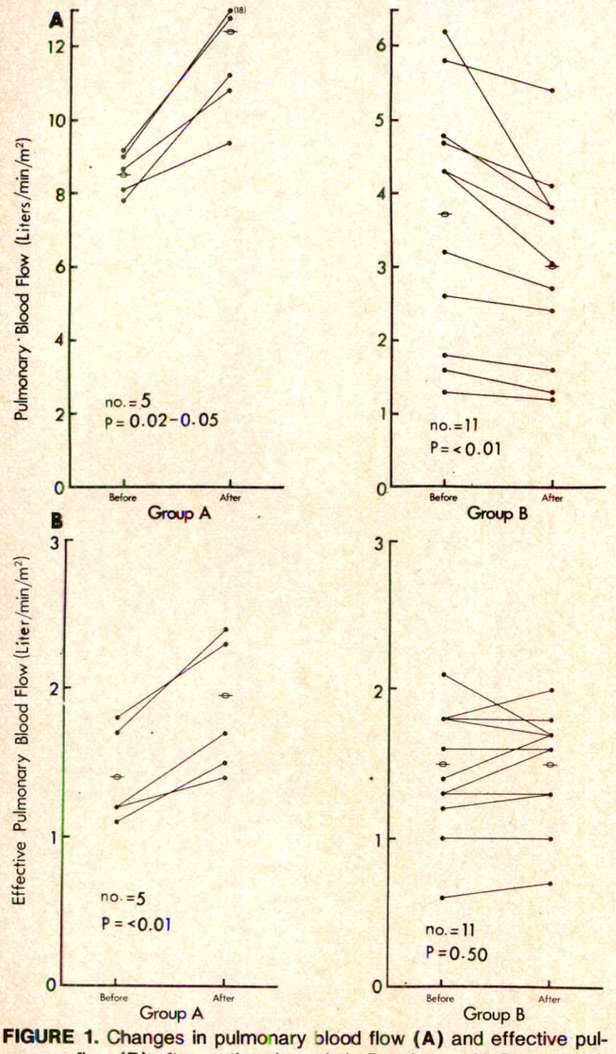

FIGURE 1. Changes in pulmonary blood flow **(A)** and effective pulmonary flow **(B)** after erythropheresis in 5 patients with D-transposition of the great arteries (D-TGA) and no pulmonary stenosis (Group A), and 11 patients with severe pulmonary stenosis or atresia and normally or abnormally related great arteries (Group B). The **hatched oval** symbols denote mean values before and after the procedure.

vere pulmonary stenosis or pulmonary atresia, ventricular septal defect and normally or abnormally related great arteries.

The presence of a steady state during the study was suggested by the lack of significant changes in heart rate, oxygen consumption, respiratory rate, temperature or level of activity. The mean initial venous hematocrit in patients in Group A was reduced from 76 percent (range 66 to 84) to 66 percent (range 61 to 76) and in Group B from 74 percent (range 65 to 80) to 63 percent (range 53 to 69). The mean oxygen carrying capacity in patients in Group A was reduced from 28.7 vol. percent (range 25.5 to 32.1) to 23.2 vol. percent (range 20.9 to 25.0) and in Group B from 30.6 vol. percent (range 28.5 to 33.7) to 26.1 vol. percent (range 21.9 to 28.4). Reduction of the red cell volume by replacement with fresh frozen plasma or 5 percent albumin has been previously demonstrated to result in only a minimal decrease in total blood volume.[3]

Group A (D-transposition of the great arteries without significant pulmonary stenosis): Three of the five patients had pulmonary arterial hypertension and two had normal pulmonary arterial pressure. The reduction in hematocrit was associated with a decrease in systemic vascular resistance in all patients (P <0.02) from an initial mean of 19.6 ± 6.7 to 11.7 ± 5.8 mm Hg/liter per min per m^2. The mean systemic blood flow increased in all patients (P = 0.10 to 0.05) from 4.2 ± 1.8 to 7.1 ± 3.0 liters/min per m^2. Changes in the pulmonary circulation paralleled those in the systemic circuit. Pulmonary blood flow increased in all patients (P = 0.05 to 0.02) from a mean of 8.5 ± 0.6 to 12.5 ± 3.3 liters/min per m^2 (Fig. 1A) and pulmonary vascular resistance decreased in all patients (P = 0.05 to 0.10) from a mean of 4.0 ± 3.3 to 2.7 ± 2.3 mm Hg/liter per min per m^2. The reduction in red cell volume was also accompanied by an increase in shunting between the pulmonary and systemic circulations (P <0.01). The right to left shunt (equal to left to right shunt or effective pulmonary flow) increased from a mean of 1.4 ± 0.3 to 1.9 ± 0.5 liters/min per m^2 (Fig. 1B). However, systemic arterial saturation decreased slightly (P = 0.1) from an initial mean of 70.2 ± 3.6 to 67.7 ± 5.0 percent.

Group B (pulmonary stenosis or pulmonary atresia and a ventricular septal defect with normally or abnormally related great arteries): All 11 patients in Group B had very severe pulmonary stenosis or atresia with a large right to left shunt through a ventricular septal defect. Reduction in hematocrit resulted in a decrease in systemic vascular resistance in all patients (P <0.01), from a mean of 29.4 ± 12.5 to 19.3 ± 8.5 mm Hg/liter per min per m^2 and an increase in systemic blood flow (P <0.01) from a mean of 3.1 ± 1.1 to 4.7 ± 1.9 liters/min per m^2. However, in contrast to results in patients in Group A, pulmonary blood flow decreased in all patients (P <0.01) from a mean of 3.7 ± 1.7 to 3.0 ± 1.3 liters/min per m^2 (Fig. 1A). The decrease in pulmonary blood flow was associated with a decrease in left to right shunted blood from a mean of 2.2 ± 1.5 to 1.5 ± 1.1 liters/min per m^2 (P <0.01). Since most of the patients had pulmonary atresia, pulmonary arterial pressure could not be measured and resistance was therefore not calculated. The increase in systemic blood flow was accomplished by an increase in intracardiac right to left shunting in all patients (P <0.01) from a mean of 1.6 ± 0.9 to 2.7 ± 1.6 liters/min per m^2. In two patients with D-transposition of the great arteries, ventricular septal defect and severe pulmonary stenosis, the right to left shunt was assumed to equal systemic flow minus effective pulmonary flow. The overall results for Group B, however, would not be significantly altered if right to left shunt were assumed to equal effective pulmonary flow. Calculation of pulmonary blood flow in these patients may be somewhat inaccurate because of the probability of increased collateral pulmonary circulation and the difficulty in obtaining an accurate mixed pulmonary arterial blood sample.

The decrease in pulmonary flow and increase in right to left shunt resulted in a reduction in arterial oxygen saturation from 78.1 ± 7.4 to 72.1 ± 8.0 percent (P <0.01). The effective pulmonary blood flow remained essentially unchanged (P = 0.50) (Fig. 1B), possibly because of insignificant changes in mean mixed venous saturation from 61.6 ± 7.7 to 59.6 ± 6.7 percent. Erythropheresis did not alter the pulmonary venous blood oxygen saturation in either group.

The procedure was not associated with any serious complications and was well tolerated by the patients.

Effects of Transfusion with Packed Red Cells

The acute effects of red cell transfusion on systemic and pulmonary flow in five patients with D-transposition of the great arteries are summarized in Table II. The mean hematocrit was increased from 44.6 ± 6.1 to 49.2 ± 5.9 percent (P <0.01) and mean oxygen carrying capacity from 17.1 ± 3.5 to 19.2 ± 3.0 vol. percent (P <0.01). The increase in the venous hematocrit and carrying capacity was accompanied by an increase in systemic vascular resistance and reduction in systemic flow in all patients. Mean systemic vascular resistance increased from 11.1 ± 1.6 to 15.3 ± 3.2 mm Hg/liter per min per m^2 (P = 0.01 to 0.02) and systemic flow decreased from 5.8 ± 1.2 to 4.6 ± 0.7 liters/min per m^2 (P = 0.01 to 0.02). The acute effects on pulmonary flow and vascular resistance were not marked and were more variable. Pulmonary blood flow increased slightly (P = 0.4) and pulmonary resistance decreased slightly (P = 0.5) in four of five patients. The acute transfusion resulted in less mixing between the systemic and pulmonary circulations. Mean effective pulmonary flow decreased from 2.9 ± 1.1 to 2.4 ± 0.6 liters/min per m^2 (P = 0.05 to 0.1). Systemic arterial oxygen saturation was essentially unchanged by the procedure, but when measured (by an air oximeter) 24 to 48 hours later had increased by 2 to 7 percent (mean 5).

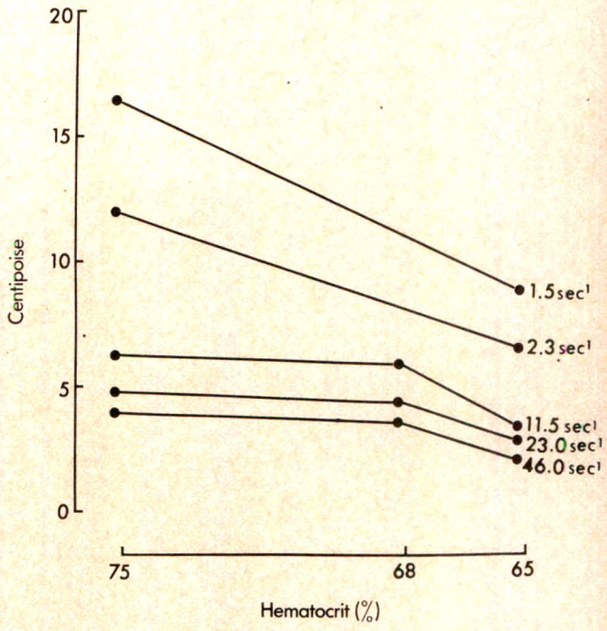

FIGURE 2. Changes in blood viscosity at various shear rates associated with erythropheresis in a patient with polycythemia and D-transposition of the great arteries.

Discussion

Red cell pheresis: Polycythemia in some patients with cyanotic congenital heart disease may become so severe that the advantages of increased oxygen carrying capacity are offset by adverse physiologic effects, the development of hyperviscosity, with consequent thromboses or infarctions in vital organs, and frequently a bleeding diathesis.[5–8] In a previous study[3] we have shown that red cell volume reduction in these patients results in decreased blood viscosity, reduced systemic vascular resistance, increased systemic flow and improved systemic oxygen transport. The present study indicates that acute red cell volume reduction in polycythemic patients with D-transposition of the great arteries without a large ventricular septal defect or significant pulmonary stenosis results in a decrease in pulmonary vascular resistance and an increase in pulmonary blood flow. The de-

TABLE II

The Effects of Red Cell Transfusion on Blood in Five Patients With D-Transposition of the Great Arteries

	Mean ± Standard Deviation		
	Before	After	*P* Value
Hematocrit (%)	45 ± 6	49 ± 6	...
Oxygen capacity (vol. %)	17.1 ± 3.5	19.2 ± 3.0	0.01
Systemic oxygen saturation (%)	75.8 ± 4.9	76.0 ± 4.4	0.3–0.4
Oxygen consumption (ml/min per m^2)	175 ± 37	178 ± 24	0.7
Heart rate (beats/min)	126 ± 21	126 ± 20	0.8
Systemic blood flow (liters/min per m^2)	5.8 ± 1.2	4.6 ± 0.7	0.01–0.02
Pulmonary blood flow (liters/min per m^2)	15.3 ± 7.3	13.9 ± 4.1	0.5
Effective pulmonary flow (liters/min per m^2)	2.9 ± 1.1	2.4 ± 0.6	0.05–0.10
Right to left shunt (liters/min per m^2)	2.9 ± 1.1	2.4 ± 0.6	0.05–0.10
Systemic vascular resistance (mm Hg/liters per min per m^2)	11.1 ± 1.6	15.2 ± 3.1	0.01–0.02
Pulmonary vascular resistance (mm Hg/liters per min per m^2)	1.9 ± 1.7	2.0 ± 2.2	0.5

creased resistance is probably secondary to the reduced blood viscosity that accompanies the reduction in hematocrit. The decrease in viscosity is greatest at low shear rates, that is, those present at the level of the small arterioles and venules,[2] where it might be expected to have the greatest influence on reducing the resistance to flow. The effect of erythropheresis on reducing viscosity at various shear rates is illustrated in Figure 2.

There was also a significant increase in effective pulmonary flow or mixing between the systemic and pulmonary circulations. Despite the improved mixing, systemic arterial oxygen saturation decreased slightly because of the increase in systemic blood flow and reduction in oxygen carrying capacity. The systemic arterial saturation in patients with D-transposition of the great arteries depends not only on the degree of mixing between the pulmonary and systemic circulations, but also on the systemic blood flow and hemoglobin concentration.[4] The effect of an increase in the rate of recirculated systemic flow (systemic venous return) and reduction of hemoglobin concentration thus results in a slightly lower level of systemic arterial saturation despite the improved mixing.

In contrast to polycythemic patients with transposition of the great arteries without pulmonary stenosis (Group A), patients with pulmonary atresia or severe pulmonary stenosis and ventricular septal defect (Group B) manifested a reduction in pulmonary blood flow after red cell pheresis. Because pulmonary blood flow in these patients is supplied totally or predominantly from the systemic circulation, a reduction in the systemic vascular resistance results in a decrease of the left to right shunt through a surgically created anastomosis or the extensive aortopulmonary collateral circulation. The decrease in systemic vascular resistance must be relatively greater than that of the already reduced resistance of the pulmonary circuit. The increase in systemic blood flow is accomplished by an increased right to left shunt through the ventricular septal defect. Despite the reduced pulmonary blood flow, effective pulmonary blood flow is essentially unchanged, but because of the greater right to left shunt there is a significant decrease in the systemic arterial oxygen saturation. The ability to increase the total amount of oxygen delivered to the tissues per unit of time, or systemic oxygen transport, will then be totally dependent on the ability to increase cardiac output.[3] Excessive reduction in the hematocrit in these patients may lead to severe hypoxemia, and erythropheresis should therefore be performed with great care.

Red cell transfusion: In patients with D-transposition of the great arteries, a relatively small increase in hematocrit and oxygen carrying capacity after red cell transfusion resulted in a significant increase in systemic vascular resistance and decrease in systemic flow (Table II). The effect of the transfusion on pulmonary flow, effective pulmonary flow and systemic arterial oxygen saturation was more variable. Effective pulmonary flow showed a tendency to decrease and systemic arterial saturation remained essentially unchanged by the procedure. However, our data are from a small group of patients and do not exclude the possibility of an effect on pulmonary flow and systemic saturation. Clinical follow-up studies of patients with D-transposition of the great arteries who have been given transfusion suggest that the procedure does increase systemic saturation and reduce congestive heart failure. An increase in systemic oxygen saturation was seen in our patients within 24 hours after the transfusion.

Clinical implications: The hemodynamic effects reported here are acute in nature, and after a period of adjustment and fluid equilibrium between the vascular and extravascular compartments a different hemodynamic state may exist. Erythropheresis in our experience is helpful in reducing complications during the operative and postoperative periods[9] and in treating some of the more serious complications of severe polycythemia.[10] Since the calculated ratio of systemic to pulmonary vascular resistance can be significantly altered by changes in the hematocrit and hemoglobin, criteria for operability based on these variables should take into consideration the hemodynamic state at the time the resistance levels were measured. The transfusion of packed red cells in a patient with D-transposition of the great arteries and relative anemia may not immediately improve the arterial saturation, but a benefit may be apparent a few days later. We believe the procedure is indicated in all patients who have lost a considerable amount of blood (at catheterization, for example) or are relatively anemic.

Bypass Graft Surgery Versus Medical Therapy of Angina Pectoris

WILBERT S. ARONOW, MD, FACC*
EDWARD A. STEMMER, MD, FACC

Long Beach and Irvine, California

Forty patients with angina pectoris (New York Heart Association functional class III) despite medical therapy were studied. Twenty who underwent coronary bypass graft surgery and 20 comparable patients treated only medically underwent exercise tests during the control period and 3, 6, 9 and 12 months later. One of 20 surgically treated patients (5 percent) died at operation. One year mortality rates were 10 percent (2 of 20 surgically treated patients) and 5 percent (1 of 20 medically treated patients). Three of 20 patients (15 percent) had a myocardial infarction at operation. By 1 year, 4 of 20 surgically treated patients (20 percent) and 1 of 20 medically treated patients (5 percent) had had a myocardial infarction. At 1 year, 18 of 27 grafts (67 percent) were patent. Three and 6 months after the control period, no angina after exercise, a more than 25 percent increase in exercise performance until angina, and an increase in the value for product of systolic blood pressure times heart rate occurred in significantly more surgically than medically treated patients. One year after the control period, 14 of 18 surgically treated patients (78 percent) and 10 of 19 medically treated patients (53 percent) had no angina after exercise or a more than 25 percent increase in exercise performance until angina. One year after the control period, 4 of 16 medical patients (25 percent) and 6 of 15 surgical patients (40 percent) not receiving digitalis had no postexercise ischemic S–T segment depression. These data suggest that the coronary artery bypass operation should be considered only if medical therapy fails to relieve disabling angina.

The advent of aortocoronary saphenous vein bypass graft surgery has been welcomed by the medical profession. However, the indications for this procedure are not firmly agreed upon. Until results of controlled clinical trials[1,2] provide the data needed to formulate these indications properly, recommendations for this operation must be made with caution.[3]

We performed saphenous vein coronary artery bypass graft surgery in 20 of 40 patients who had angina pectoris (functional class III, New York Heart Association) despite medical management. The other 20 patients continued to receive medical therapy. The medical and surgical groups were comparable in angiographic evidence of significant coronary artery disease, myocardial function and risk factors for coronary artery disease. Physiologic studies were performed in both groups during the control period and 3, 6, 9 and 12 months later. Coronary angiography, left ventricular cineangiography and left heart catheterization were also performed in all surviving surgically treated patients 1 year postoperatively. This paper presents the data from this study.

Subjects and Methods

Case Material

The surgical group consisted of 19 men and 1 woman with a mean age of 50 ± 4 years (standard deviation). The medical group consisted of 20 men with a mean age of 50 ± 5 years. The surgically treated patients and the patients chosen for continued medical management were matched case by case to provide comparability. All 40 patients had functional class III angina pectoris despite medical management (including administration of nitroglycerin, sublingually and at least 120 mg daily of propranolol, orally). All had at least one bypassable significant coronary arterial lesion with good patent distal runoff. Significant single vessel disease (greater than 50 percent luminal narrowing) was present in 4 of the 20 patients (20 percent) in each group. Significant multivessel disease was present in the other 32 patients. The mean ejection fraction was 52 percent in both the medical and surgical groups.

Eleven of the 20 surgically treated patients (55 percent) and 12 of the 20 medically treated patients (60 percent) had documented old healed myocardial infarction. Mild hypertension (blood pressure between 140/90 and 160/100 mm Hg) was present in 2 surgically treated patients (10 percent) and in 3 medically treated patients (15 percent). One patient (5 percent) in each group was a cigarette smoker on entering the study. Twelve surgically treated patients (60 percent) and 14 medically treated patients (70 percent) had a serum cholesterol level above 250 mg/100 ml. Twelve surgically treated patients (60 percent) and 10 medically treated patients (50 percent) had an elevated serum triglyceride level (above 150 mg/100 ml). A type IV lipoprotein pattern was present in 8 surgically treated patients (40 percent) and 7 medically treated patients (35 percent). A type II lipoprotein pattern was present in 3 patients (15 percent) in each group. Only 1 of the 40 patients (in the medical group) was receiving medication (phenformin) for diabetes mellitus.

All 40 patients selected for this study demonstrated ischemic S–T segment depression greater than or equal to 1 mm below the resting level after exercise-induced angina. Three patients in each group received digitalis during the control and study periods.

Protocol

Exercise testing: Before the study, the patients were taken to the laboratory where they were familiarized with the equipment and the procedure and practiced upright exercise on a constant-load Collins bicycle ergometer with a progressive work load.[4]

During the control period and 3, 6, 9 and 12 months after operation or continued medical management, all surviving patients performed the following exercise protocol at 8 AM in the fasting state. Leads V_5, aVF and I were recorded in that order with an electrocardiograph with the subject in the supine position. An electrocardiogram with a modified lead V_5 was then recorded with the patient sitting upright on the Collins bicycle ergometer, and the resting heart rate was obtained from this electrocardiogram. The resting blood pressure was then measured with a mercury sphygmomanometer with the patient sitting upright on the bicycle ergometer.

Each patient then exercised upright on the constant-load bicycle ergometer with a progressive work load[4] until the onset of angina, and the duration of exercise was recorded with a stopwatch. If angina did not develop, the patient exercised until the onset of marked fatigue. Blood pressure and heart rate at the onset of angina or marked fatigue were recorded with the patient sitting upright on the bicycle ergometer. An electrocardiogram with a modified lead V_5 was recorded immediately after angina or marked fatigue with the patient in the upright position. Leads V_5, aVF and I in that order were then recorded while the patient was in the supine position immediately after angina or marked fatigue and 1, 2, 3, 4, 5 and 6 minutes later.

No patient smoked or took antianginal medication on the morning of the exercise tests. The electrocardiograms were coded and analyzed after the study was completed by an investigator who did not know from whom or when the tracings were obtained.

Coronary arteriography and ventriculography: One year after operation, coronary arteriography was performed by either the Judkins[5] or the Sones[6] method in all surviving surgical patients. Three views of each coronary vessel (including the right and left anterior oblique views) were obtained. Selective opacification of the bypass graft was performed in at least 2 views (right and left anterior oblique) in all surviving surgical patients. These films were reviewed at weekly cardiac catheterization conferences by cardiology staff members, cardiac surgeons and a cardiac radiologist. The interpretation of these films was based on group consensus.

One year after operation, all surviving surgical patients also underwent left heart catheterization and left ventricular cineangiography. Left ventriculography was performed in the 45° right anterior oblique projection. Left ventricular end-diastolic and end-systolic volumes were computed from angiographic films exposed in the right anterior oblique projection. Frames showing premature ventricular beats or short runs of tachycardia or frames within two beats after the premature ventricular beats were excluded. In all patients, both the left ventricular margin and a clearly defined left ventricular apex and aortic valve plane were clearly delineated.

The ejection fraction was calculated from the formula:

$$EF = (EDV - ESV)/EDV$$

where EF = ejection fraction, EDV = end-diastolic volume and ESV = end-systolic volume.[7] The ejection fractions were calculated by fellows in cardiology.

Results

Mortality: One of the 20 surgically treated patients (5 percent) died at operation. One patient each (5 percent) in the medical and surgical groups died of myocardial infarction during the 1 year follow-up period. The 1 year surgical mortality rate of 10 percent (2 of 20 patients) was not significantly different from the 1 year medical mortality rate of 5 percent (1 of 20 patients((chi-square = 0.36; $P > 0.05$).

Myocardial infarction: Three of 20 surgically treated patients (15 percent) had a transmural myocardial infarction at the time of operation, with new pathologic Q waves that persisted. In these three patients an area of asynergy due to postoperative myocardial infarction was noted on the left ventriculogram obtained 1 year postoperatively. These myocardial infarctions occurred in the region supplied by the bypassed artery. The 20 percent rate of myocardial infarction at 1 year in the surgical group (4 of 20 patients) was not significantly different from the 5 percent rate of myocardial infarction at 1 year in the medical group (1 of 20 patients) (chi-square = 2.06; $P > 0.05$).

Exercise performance until angina: Table I shows the data on exercise performance until angina for the 19 survivors in the surgical group and the 20 medically treated patients during the control period and during repeat testing performed 3, 6, 9 and 12 months later.

At 3 months, 11 of 19 surgically treated patients (58 percent) were angina-free after exercise compared with none of 20 medically treated patients (chi-square = 16.13; $P < 0.001$). At 3 months, 16 of 19 surgically treated patients (84 percent) had no angina after exercise or a more than 25 percent increase in exercise performance until angina compared with 5 of 20 medically treated patients (25 percent) (chi-square = 13.75; $P < 0.001$).

At 6 months, 8 of 19 surgically treated patients (42 percent) had no angina after exercise compared with 1 of 19 medically treated patients (5 percent) (chi-square = 7.13; $P < 0.01$). At 6 months, 15 of 19 surgically treated patients (79 percent) had no angina

after exercise or a more than 25 percent increase in exercise performance until angina compared with 7 of 19 medically treated patients (37 percent) (chi-square = 6.91; $P < 0.01$).

At 9 months, 8 of 18 surgically treated patients (44 percent) had no angina after exercise compared with 2 of 19 medically treated patients (11 percent) (chi-square = 5.39; $P < 0.05$). At 9 months, 14 of 18 surgically treated patients (78 percent) had no angina after exercise or a more than 25 percent increase in exercise performance until angina compared with 10 of 19 medically treated patients (53 percent) (chi-square = 2.56; $P > 0.05$).

At 1 year, 8 of 18 surgically treated patients (44 percent) had no angina after exercise compared with 3 of 19 medically treated patients (16 percent) (chi-square = 3.63; $P > 0.05$). At 1 year, 14 of 18 surgically treated patients (78 percent) had no angina after exercise or a more than 25 percent increase in exercise performance until angina compared with 10 of 19 medically treated patients (53 percent) (chi-square = 2.56; $P > 0.05$).

Excluding digitalized patients, at 1 year, 4 of 16 medical patients (25 percent) and 6 of 15 surgical patients (40 percent) had less than 1 mm of ischemic S–T segment depression after exercise (chi-square = 0.80; $P > 0.05$).

Systolic blood pressure-heart rate product: Table II shows the mean product of systolic blood pressure times heart rate ± 1 standard deviation/100 after exercise for the 18 one-year survivors in the surgical group and the 19 one-year survivors in the medical group during the control period and 3, 6, 9 and 12 months later. This table also shows the percent increase in mean product of systolic blood pressure times heart rate after exercise for the 1 year survivors in the surgical and medical groups 3, 6, 9 and 12 months from the control period.

In the surgical group, the product of systolic blood pressure times heart rate after exercise showed a mean increase of 25 percent at 3 months ($t = 4.75$; $P < 0.001$), 25 percent at 6 months ($t = 5.05$; $P < 0.001$), 23 percent at 9 months ($t = 4.66$; $P < 0.001$) and 21 percent at 12 months ($t = 4.25$; $P < 0.001$).

In the medical group, a significant increase in mean product of systolic blood pressure times heart rate after exercise occurred after the control period; this increase was 4 percent at 3 months ($t = 2.43$; $P < 0.05$), 6 percent at 6 months ($t = 2.44$; $P < 0.05$), 10 percent at 9 months ($t = 3.17$; $P < 0.01$) and 11 percent at 12 months ($t = 3.10$; $P < 0.01$). The mean product of systolic blood pressure times heart rate after exercise was significantly greater in the surgical group than in the medical group at 3 months ($t = 3.67$; $P < 0.001$) and at 6 months ($t = 3.11$; $P < 0.01$) but not at 9 or 12 months.

The mean ejection fraction for the 18 surviving surgical patients at 1 year was 54.8 ± 6.7 percent compared with 52.2 ± 6.3 percent before operation ($t = 2.06$; $P > 0.05$).

Eighteen of the 27 grafts (67 percent) were patent at 1 year. Sixteen of 18 patients (89 percent) who survived 1 year after operation had at least one patent graft. Surgical Patient 5 (Table I) had two of two grafts occluded, and the 1 year follow-up coronary arteriograms demonstrated occlusion of the single graft of Patient 9. Patient 3 had two of two grafts patent 3 months postoperatively, and one of these grafts was patent 1 year after operation. Patient 4, who died 8.5 months after operation, had patency of his single graft 6 months after operation.

Discussion

Postoperative Myocardial Infarction

Myocardial infarction documented by the appearance of significantly abnormal Q waves on the electrocardiogram or by autopsy has been reported to occur at the time of coronary artery bypass graft surgery by several investigators. The finding was noted in 3 of their last 30 patients (10 percent) by Hultgren et al.,[8] in 23 of 100 patients (23 percent) by Williams et al.,[9] in 15 of 151 patients (10 percent) by Kansal et al.,[10] in 11 of 37 patients (30 percent) by Espinoza et al.,[11] in 7 of 102 patients (7 percent) by Alderman et al.,[12] in 53 of 480 patients (11 percent) by Morris et al.,[13] in 11 of 38 patients (29 percent) by Guiney et al.,[14] in 8 of 46 patients (17 percent) by Anderson et al.[15] and in 3 of our 20 patients (15 percent). Anderson et al.[15] reported that the postoperative vectorcardiogram showed new myocardial infarction in 6 of 17 patients (35 percent). Hultgren et al.[8] also found elevation of serum glutamic oxaloacetic transaminase levels above 90 units in 12 of their last 30 patients (40

percent) and lactic dehydrogenase levels exceeding 900 units in 10 of these 30 patients (33 percent) after saphenous vein coronary bypass graft surgery. They considered serum enzyme elevations of this degree to be diagnostic of acute myocardial infarction.

Brewer et al.[16] reported that 27 of 252 patients (11 percent) undergoing saphenous vein coronary artery bypass graft surgery died. Ten of the 17 patients (57 percent) who underwent autopsy after operation were found to have acute myocardial infarction. One patient who died but did not undergo autopsy had electrocardiographic evidence of acute myocardial infarction. Forty-nine of their 243 patients (20 percent) had a new myocardial infarction documented by autopsy or by postoperative electrocardiography.

In light of the high rate of postoperative myocardial infarction in these reported series,[8–16] the evidence does not justify performance of coronary artery bypass graft surgery to prevent myocardial infarction in patients with stable angina.

Objective Improvement with Surgical or Medical Therapy

Our data show absence of angina after exercise in significantly more surgically than medically treated patients at 3, 6, and 9 months but not at 12 months after the control period. Our data also show absence of angina or a greater than 25 percent increase in exercise performance until angina in significantly more surgically than medically treated patients at 3 and 6 months but not at 9 or 12 months after the control period. One year after the control period, absence of angina after exercise or a greater than 25 percent increase in exercise performance until angina occurred in 14 of 18 surgically treated patients (78 percent) and in 10 of 19 patients (53 percent) who continued to receive the same medical management. The trend toward alleviation of angina by medical therapy alone shown by these data indicates the importance of conducting controlled clinical trials in evaluating therapeutic regimens.

An increase in the product of systolic blood pressure times heart rate, presumptively indicating increased oxygen delivery to the ischemic myocardium, was also significantly higher in our surgical group than in our medical group at 3 and 6 months but not at 9 or 12 months after the control period. One year after the control period, an increase of 21 percent in mean product of systolic blood pressure times heart rate occurred in the surgical group compared to an 11 percent increase in the medical group.

Six of the 15 surgically treated patients (40 percent) and 4 of the 16 medically treated patients (25 percent) not receiving digitalis had ischemic S–T segment depression greater than or equal to 1 mm during the control period but no evidence of ischemic S–T segment depression 1 year later. These data also indicate the need to conduct controlled clinical trials in evaluating therapeutic regimens.

Amsterdam et al.[17] found that 6 to 10 weeks after coronary artery saphenous vein bypass graft surgery, angina could not be provoked by exercise in 20 of 20 patients with severe angina pectoris. The mean product of the systemic intraarterial pressure times heart rate increased from 144 to 179 (24 percent) in these 20 patients. These investigators also stated that electrocardiographic ischemic ST–T changes of exercise cleared or decreased.

Bartel et al.[18] found in 92 patients tested with maximal graded treadmill exercise tests 2 to 20 months after aortocoronary bypass surgery that 64 percent exercised longer and that 49 percent achieved higher maximal heart rates. Twenty-eight of their 62 patients (45 percent) who preoperatively had ischemic S–T segment depression of 1 mm after exercise had normal exercise electrocardiograms in the postoperative follow-up study.

Miller et al.[19] restudied 12 to 28 months postoperatively 78 survivors from a group of 96 surgical patients treated by saphenous vein coronary artery bypass graft surgery. In all 25 patients who were studied by bicycle ergometry, exercise performances increased, but the increase was smaller in patients with closed grafts.

Guiney et al.[14] described 38 survivors among 40 surgically treated patients who performed maximal exercise tests on a bicycle ergometer preoperatively and 3 to 8 months after coronary bypass graft surgery. In 20 of these 38 patients (53 percent), neither angina nor ischemic S–T segment depression greater than or equal to 1 mm occurred when they exercised to fatigue. Another 10 patients (26 percent) experienced angina or greater than 1 mm ischemic S–T segment depression at a higher value for product of systolic blood pressure times heart rate.

Follow-Up Coronary Arteriography in Surgical Patients

Griffith et al.[20] pointed out that although 86 percent of their 71 patients had symptomatic relief of angina and 60 percent of these 71 patients had no angina after coronary artery saphenous vein bypass graft surgery, 50 of these 71 patients (70 percent) had occlusive changes in the intrinsic coronary arterial circulation 6.1 ± 0.8 months after operation.

Lespérance et al.[21] demonstrated that 133 of 154 (86 percent) coronary artery saphenous vein grafts were patent at 2 weeks after operation and that 103 of these 154 grafts (67 percent) were patent at 1 year. Alderman et al.[12] evaluated graft patency in 63 of their 93 one-year survivors at an average period of 11.5 months after operation. Eighty of the 106 grafts (75 percent) in these 63 patients were patent.

From a group of 96 patients with angina treated by saphenous vein coronary artery bypass graft surgery, 78 survivors were restudied 12 to 28 months postoperatively by Miller et al.[19] They found that in these 78 patients all grafts were patent in 52 (67 percent), all grafts were closed in 6 (8 percent) and one or more grafts were closed in 20 (25 percent). Griffith et al.[20] found that 79 of 120 saphenous vein coronary artery bypass grafts (66 percent) placed in 71 patients were patent 6.1 ± 0.8 months after operation. We found in our study that 18 of 27 grafts (67 percent) in 18 patients were patent 1 year after operation.

Mechanisms for Postoperative Improvement

Improvement in exercise performance and reduction of postexercise ischemic S–T segment depression after coronary artery bypass graft surgery has been attributed to improved coronary blood flow. However, all three of our patients who had operative myocardial infarction had no anginal pain or electrocardiographic evidence of myocardial ischemia after exercise in their postoperative studies. We agree with Brewer et al.[16] that one must consider at least four possible mechanisms causing alleviation of angina after coronary artery bypass graft surgery. These are (1) increased coronary blood flow to ischemic areas of myocardium, (2) placebo effect, (3) necrosis of ischemic areas of myocardium, and (4) interruption of afferent nerve fibers for pain.

Clinical Implications

In conclusion, there is no good evidence that coronary artery bypass graft surgery favorably alters the natural history of stable angina pectoris due to coronary artery disease in comparison with medical therapy by reducing mortality or preventing myocardial infarction. The operation may, however, improve the quality of life in many surviving patients with angina. On the basis of a critical review of the literature and our data, we believe that coronary artery bypass graft surgery should be considered in patients with disabling stable angina despite appropriate medical therapy who have coronary angiographic evidence of a significant bypassable lesion with good patent distal runoff. This operation should not be performed in asymptomatic persons or in patients with stable angina who respond well to medical management.

Acknowledgment

We gratefully acknowledge the many physicians, especially John C. Kern, MD, who assisted in performing this study, the technical assistance of Michael W. Isbell, CPT, and the help of Reed Boswell, PhD, for biostatistical analysis of the data.

Symposium on the Effects of Surgical Treatment on the Natural History of Acquired Heart Disease. Part I. Coronary Artery Disease

JOHN ROSS, Jr., MD, FACC, *Guest Editor*

Introduction

JOHN ROSS, Jr., MD, FACC

La Jolla, California

This Symposium grew directly out of a session of the same title held at the Annual Meeting of the American College of Cardiology on February 16, 1973. The theme was simple: What are the immediate and late risks to life of nonoperative treatment versus operative intervention in patients with cardiac disease, and what are the chances of significantly altering the quality of life or arresting progression of disease? To answer these two questions in a rational manner, both the natural history of disease and the early and late effects of operative treatment must be known. The key problem has been to have such information in matched groups of patients whose condition has been carefully characterized by cardiac catheterization, angiography and other objective methods. Only in recent years have some prospective studies of natural history in such patients become available, and even after many years of technically sound operative treatment there continues to be inadequate prospective information on postoperative history.[1] The Symposium was designed to focus attention on these problems, with Dr. T. Joseph Reeves discussing the natural history of patients with coronary heart disease for comparison with results of coronary revascularization procedures, reviewed by Dr. Vincent L. Gott (Part I of the Symposium). Dr. Elliot Rapaport then analyzed the natural history of patients with various forms of valvular heart disease, and Dr. Dwight C. McGoon compared these findings with the course after surgical treatment by prosthetic valve replacement (Part II of the Symposium, to be published).

In discussing the natural history of patients with coronary heart disease, Reeves and co-workers provide a comprehensive historical review and a contemporary analysis of risk factors that has considerable pertinence to studies on the natural history of all types of heart disease. They point out the serious problems in early studies of patients who died from heart disease, emphasizing that unless an entire cohort of subjects is followed up until death the term "average survival" means little. They further point out the need to make comparisons in similar populations; for instance, differences in survival statistics in two populations that are not age-matched may disappear if the data are adjusted for survival rates of the normal population at the same age. Reeves et al. then focus on the prognostic implications of specific risk factors. Thus, whereas the Framingham Study indicates that the annual mortality rate is about 4 percent in an unselected population with angina pectoris,[2] when both hypertension and electrocardiographic changes are also present the risk is many times greater. Perhaps even more important is the extent of coronary artery involvement. Recent studies demonstrating a relation between the extent of coronary artery disease (as revealed by coronary arteriographic findings) and prognosis are reviewed. Data available so far in such prospective studies show an average annual mortality rate of 2.2 percent in patients with single vessel coronary artery disease, 6.8 percent in those with double vessel disease and 11.4 percent in patients with triple vessel disease. These average figures accord remarkably well with those recently reported by Bruschke et al.[3] in patients who were not treated surgically at the Cleveland Clinic.

Reeves and co-workers also analyze an additional important risk factor in the prognosis of such patients: the degree of myocardial involvement. In their data, mortality was increased threefold if clinical symptoms of left ventricular failure were present in patients with two or three vessel coronary artery disease, and if heart volume (calculated by plain roentgenography) was enlarged, patients with two vessel disease had six times the mortality rate of those with a normal heart volume. These data conform to our recent finding[4] that patients followed up prospectively after acute myocardial infarction have approximately a fivefold increase in mortality if left ventricular size is increased. The need for this type of information in studies on natural history and postoperative course in patients with valvular heart disease seems clear.

In analyzing the outlook for patients after coronary artery revascularization, Gott reviews surgical results from various centers, focusing on survival statistics as well as on relief of symptoms. It seems evident that

myocardial revascularization in the patient with uncomplicated stable angina pectoris can now be accomplished with a relatively low operative mortality rate (average less than 6 percent). Perhaps the most promising preliminary study so far is that of Sheldon et al.,[5] which suggests that overall annual mortality rates in patients after operation are lower than in patients treated medically. They report an average annual mortality rate of only 4.1 percent (including hospital mortality) over a relatively short average follow-up period (22 to 60 months), which is clearly lower than that in patients with multivessel disease who have not been treated surgically. However, more data in this area are necessary. Gott's analysis also draws attention to the fact that more than 80 percent of patients manifest symptomatic improvement after bypass operations, and that objective measures of improvement (coronary arteriography, treadmill testing, for example) generally correlate with and corroborate such symptomatic improvement.

The special problem of unstable angina pectoris is now the object of at least two prospective, randomized studies (Veterans Administration Cooperative and Myocardial Infarction Research Unit studies). As Gott points out, problems in defining this entity and in follow-up have resulted in reported first year mortality rates ranging between 3 and 43 percent. He also briefly discusses the experimental nature of coronary revascularization early after acute myocardial infarction and in the treatment of patients with cardiogenic shock. Recent experimental studies indicate the feasibility of salvaging myocardial tissue by revascularization within a few hours of an acute coronary occlusion,[6] and it has been shown that experimental infarct size can be reduced by pharmacologic and other therapeutic means.[7] Thus, in the future, reduction of infarct size may also become an important consideration in assessing the effects of emergency medical and surgical interventions in man.

It may be hoped that placing the natural history side by side with the course of disease after cardiac surgical treatment in patients whose condition has been objectively characterized will lead to increased appreciation of the need for more prospective analyses of this type. Ultimately, such information will allow the decision of whether or not, or when, to operate on the individual patient with cardiac disease to be made on a more rational basis. Such objective data also may eventually elucidate such unknown factors as the rate of progression of coronary atherosclerosis both with and without surgical intervention and the question of whether chronic myocardial dysfunction can be reversed after cardiac operations. Although some studies in patients with valvular[8] or coronary heart disease[9] suggest that it cannot be reversed, additional prospective investigations may allow a definite answer to this important question.

Natural History of Angina Pectoris

T. JOSEPH REEVES, MD, FACC
ALBERT OBERMAN, MD
WILLIAM B. JONES, MD, FACC
L. THOMAS SHEFFIELD, MD, FACC

Birmingham, Alabama

An understanding of the natural history of angina pectoris is crucial to decision making in the management of patients with this disease. Early investigations suggested a highly variable annual mortality rate, ranging from 2.5 to 9 percent. These studies clearly pointed to the association of certain electrocardiographic changes, hypertension, cardiac enlargement and congestive heart failure with increased mortality. Several recent studies based on findings at coronary arteriography indicate a high degree of correlation between the extent of coronary atherosclerotic occlusive disease and the likelihood of early death. A combination of data from several laboratories indicates that if only one of the three major coronary arterial branches (left anterior descending, left circumflex or right) is significantly stenosed, the annual mortality rate will be approximately 2 percent of the cohort. If two of the three major arteries are stenosed, the rate will be approximately 7 percent, and if all three arteries are stenosed, it will be approximately 11 percent. Some data suggest that these mortality figures based on the extent of atherosclerotic occlusive disease are importantly modulated by the extent of ventricular myocardial impairment as reflected by cardiac enlargement or symptoms of congestive heart failure.

According to William Heberden's original description of angina pectoris in the 18th century, "The termination of the angina pectoris is remarkable. For if no accident intervenes but the disease goes on to its height, the patients all suddenly fall down and perish almost immediately."[1] Fear of this sudden and premature death now provides the great impetus for coronary arteriography and bypass surgery that characterizes the practice of cardiology in 1974. In this review we examine the basis for this fear in a consideration of what is known of the natural history of the disease.

Survival Studies in the Pre-Coronary Arteriography Era

The early pessimism of Heberden was shared and augmented by the great cardiologists of the early 20th century whose estimates of the prognosis of the disease were based on duration of life of relatively small numbers of patients followed up until death (Table I).[2–7] Herrick and Nuzum[2] in 1918 reported an average survival period of only 3 years in 50 fatal cases from a total series of 200 patients with angina pectoris. In 1923 Sir James Mackenzie[3] reported an average survival period of 5.4 years in 214 fatal cases in a cohort of 380 patients with angina pectoris. In 1926 Paul Dudley White[4] reported his observations on a series of 200 patients studied from 1920 to 1926, noting an average survival of 3.4 years in the 66 patients who had died. Importantly, he also paid attention to the survival period of the 134 patients still alive, which was then 4.6 years. Subsequently, White with Bland[5] added 300 more patients, making a total of 500 patients entered into the study between 1920 and 1931. No other new

patients were added and all 500 patients were followed up until death or for 25 years; the completed study was reported by Richards, Bland and White in 1956[7] after an interim report issued in 1943.[6] As would be expected, the average survival period (onset of angina to death) in the fatal cases gradually increased to 9.4 years as the study continued. On its completion in 1956, 445 of the patients were dead, 6 were living and 5 lost to follow-up study. The other 47 patients had been reclassified because of associated valvular or aortic disease. Among the six living patients, the average survival was 31.7 years after diagnosis. It is now generally appreciated that unless the entire cohort of subjects is followed up until death the term "average survival" is without significance.

Figure 1 shows the survival curves for the 451 patients in White's study who were completely followed up. For both male and female subjects the curves are almost linear for the first 20 years. Thus, at 5.5 years, 25 percent of the male and 17 percent of the female subjects were dead, and at 10.5 years, 41 percent of the male and 39 percent of the female subjects were dead. The annual mortality rate of the entire cohort was slightly more than 4 percent.

Table II presents the survival rates of patients in several long-term follow-up studies.[6,8–11] These data indicate a variable prognosis, ranging from a 10 percent 10 year survival rate in a study reported by Sigler[8] in 1951 to a 75 percent 10 year survival rate in a study of young army men by Zukel et al.[9] Block et al.[9] of the Mayo Clinic reported a massive study involving 6,882 patients in which survivors were followed up for a minimum of 5 years. Their 5 year survival rate was 58 percent and the 10 year survival rate 33 percent. The findings of White et al.[6] have already been discussed. Zukel et al.[10] reported a 2.5 percent annual mortality rate in a study of younger army men. Kannel and Feinleib[11] in the Framingham study reported statistics very similar to those of White and his colleagues, indicating an overall annual mortality rate of approximately 4 percent, with 62 percent surviving at 10 years.

The great variation in these studies has caused considerable confusion. Many of the differences are clearly related to differences in the populations studied. Sigler[8] included patients with acute myocardial infarction, and more than half (891 of 1,700) of his patients had a myocardial infarction as the first clinical manifestation of disease. The patients described by Block et al.[9] had been referred to a large diagnostic clinic; thus, their study clearly represents some measure of selectivity. The patients of Zukel et al.[10] not only were younger than those of the other investigators, but also were generally free of other major complicating diseases. The community study by Kannel and Feinleib[11] is perhaps more representative of the total population of patients with angina pectoris. In these early studies coronary arteriography was not performed, and the data reflect entire cohorts of patients with angina pectoris; that is, all potential subclasses have been grouped together.

Identification of high risk factors: It should not be inferred that these early investigators were not aware of the differences in survival rates of subclasses of patients with different characteristics. White and his colleagues[7] noted that women had a better prognosis than men and that patients with hypertension, cardiomegaly, congestive heart failure and certain electrocardiographic abnormalities had a much greater likelihood of early death than patients without such findings. Block et al.[9] also studied survival with respect to age and sex, hypertension, electrocardiographic abnormalities, cardiomegaly and congestive failure. As can be seen in Table III, ventricular

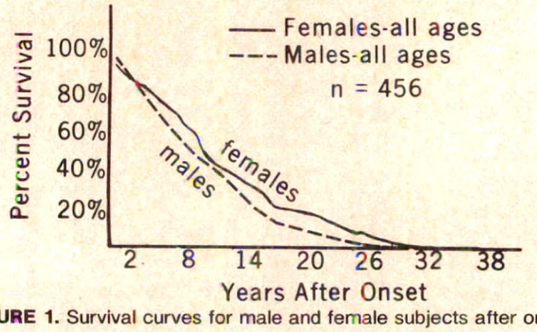

FIGURE 1. Survival curves for male and female subjects after onset of angina pectoris. (Redrawn by permission from Fig. 3, Richards et al.[7])

hypertrophy, even mild hypertension, congestive heart failure and electrocardiographic abnormalities all markedly diminished the survival rate of persons with coronary heart disease.

Block et al.[9] presented the survival curves as determined by an actuarial method for the male and female subjects of the study as contrasted to a normal population matched for age (Fig. 2). The better survival rates of female subjects are consistent with the earlier data of White et al.[7] and the recent findings of Kannel and Feinleib[11] in Framingham. Angiographic studies of patients with chest pain have consistently shown that a higher proportion of women than men have normal coronary arteriograms. This finding implies that woman may have a higher percentage of "false positive" clinical diagnoses of angina pectoris, a possibility that may explain this apparent sex difference. The question merits further study. In the study of Block et al.,[19] the 5 year survival rate of the age-matched normal population was 86.9 percent and the 10 year survival rate of their normal group was 70.4 percent. The older subjects with angina had a higher mortality rate than the younger ones. However, this difference was completely eliminated when survival rates were adjusted for the survival rates of normal subjects of the same age, thus indicating that increased age is not a specific added risk for patients with angina as compared to a normal population.

Weinblatt et al.[12] made an important study of angina in a defined population of white men between the ages of 25 and 64 years enrolled in a prepaid comprehensive group practice, The Health Insurance Plan of New York (HIP). This study, reported in 1968, differed from most others in that a defined population was studied prospectively, the subjects were all men under age 65 (mean age 55 years) and none had prior myocardial infarction or associated valvular heart disease. Particular attention was paid to the possibility of classifying these men with angina into high and low risk groups. There were 275 men with angina in the total cohort having a 10.5 percent mortality rate in 30 months of follow-up study, four times the rate of the age-matched persons in the total population at risk. A casual blood pressure determination at initial examination greater than 160 mm Hg systolic or greater than 95 diastolic was associated with a 30 month mortality rate of 18.6 percent compared to a 7.8 percent mortality rate in normotensive persons. In the 98 men whose electrocardiogram revealed a specified abnormality—usually a horizontal depression of the S–T segment of 0.5 mm or greater—the 30 month mortality rate was 20.8 percent as contrasted with 5.0 percent in 17 men with a normal electrocardiogram. In 30 men with both hypertension and electrocardiographic abnormalities, the mortality rate was 31.8 percent as contrasted to a 3.5 percent 30 month mortality rate in men with normal blood pressure and a normal electrocardiogram. The great significance of this study is its demonstration that with use of very simple and noninvasive measurements, persons with angina and at high risk of death can be separated from those with angina and a very low risk of death.

Survival of Patients Studied by Coronary Arteriography

Johns Hopkins Study

In 1970 Friesinger et al.[13] of Johns Hopkins reported a very important investigation. Their study population consisted of 224 persons with chest pain studied by coronary arteriography and then followed for an average period of 50 months. The coronary arteriograms were scored as follows: For each of three major arterial branches—the right, left anterior descending and left circumflex arteries—a score of zero was assigned if no disease was recognized, 1 if trivial disease was present, 2 if the extent of stenosis was between 50 and 90 percent, 3 if multiple narrowings between 50 and 90 percent were present in a single artery, 4 if the stenosis was greater than 90 percent but there was less than complete obstruction, and 5 if the artery was completely occluded. If the arteriographic score was greater than 10, implying significant obstruction in at least two arteries, the mortality rate at 50 months was 53 percent, contrasted to 5 percent in those with a score greater than 3 but less than 10. Only 1 of 32 patients with single vessel disease died

within the 50 month follow-up period, that patient dying in an automobile accident. Twenty-four of these patients had disease of the left anterior descending coronary artery, and in most the lesion was proximal to the first septal perforating branch.

University of Alabama Study

Oberman et al.[14] at the University of Alabama have also reported a follow-up study of persons with chest pain undergoing coronary arteriography. These investigators analyzed data from 246 patients studied by arteriography from July 1965 through June 1970. During that period coronary arteriograms were obtained in 437 patients. Associated cardiovascular disease such as aortic or mitral valve disease, overt cardiomyopathy, serious noncardiovascular disease or technically unsatisfactory arteriograms constituted causes for exclusion from the study. Of the remaining 304 patients, 55 underwent some form of cardiovascular surgical procedure, 2 were lost to follow-up study and 1 died immediately after coronary arteriography. The remaining 246 patients constitute the *study population*. It is relevant that this study was initiated before the advent of coronary artery bypass grafting at the University of Alabama; that is, the study population does not reflect preselection on the basis of current indications or contraindications for such surgery. The coronary arteriograms were scored according to the percent occlusion of each of the three major branches of the coronary arterial tree—the right coronary, the left anterior descending and left circumflex arteries. A vessel was considered "diseased" if the maximal obstruction was 50 percent or more of its lumen. Stenosis of the left main coronary artery was considered to represent two vessel disease.

As shown in Table IV, age at the time of the arteriogram ranged from 18 to 72 years (mean age 46.8 years) for 246 patients; 79 percent of all the patients were men. Ninety-eight patients had no diseased vessel; that is, no vessel was narrowed by 50 percent or more. Three of these patients died within the first 22 months of the follow-up study. Only one of these deaths—in a man with suspected cardiomyopathy—was cardiac in origin. Forty-six patients had single vessel disease, and two of these patients died in the follow-up period. Both had complete obstruction of the proximal left anterior descending coronary artery at the time of arteriography. Thirteen of 50 patients and 15 of 52 patients with two and three vessel disease, respectively, died in this period of 22 months. These data are in substantial agreement with those of Friesinger and co-workers[13] indicating that prognosis is closely related to the extent of arterial involvement, but additional important prognostic information was obtained from several of the other variables coded.

Electrocardiographic evidence of old transmural myocardial infarction was present in 64 patients with a 22 month mortality rate of 31 percent. In the 182 patients without this electrocardiographic abnormality, the mortality rate was only 7 percent. The difference in the mortality rate between those with and those without myocardial infarction is evident in all four classes of vessel disease (Table V).

A history of congestive heart failure, defined as dyspnea on effort plus either orthopnea or paroxysmal nocturnal dyspnea, was clearly related to prognosis. The 22 month mortality rate for the 45 patients with definite symptoms of pulmonary venous hypertension was 40 percent compared to 8 percent in the 201 patients without such symptoms. Of particular interest was the higher than 50 percent mortality rate in the 30 patients with either two or three vessel disease and congestive heart failure compared to the 16 percent mortality rate in similar patients without failure (Table VI).

Heart volume, as determined by measurements of standard posteroanterior and lateral chest X-ray films, was also significantly related to mortality in all classes of vascular involvement (Table VII). Thus, in patients with two vessel disease and a heart volume

LAD = left anterior descending coronary artery; LCA = le circumflex coronary artery; RCA = right coronary artery.

in excess of 396 ml/m², the 22 month mortality rate was 41 percent; in those with two vessel disease and a heart volume of less than 396 ml/m², the mortality rate was only 7 percent. Overall, the mortality rate for patients with a larger heart was 23 percent compared to only 3 percent in those with a smaller heart. The great majority of patients with two or three vessel disease had a heart volume greater than 396 ml/m² body surface area, which was the experimentally determined volume providing greatest separation between patients living and dying in the follow-up period. Several other factors, including S–T segment abnormalities, positive exercise tests and high resting heart rates, all had a significant association with prognosis.

Predictors of mortality: Many of the factors that correlated highly with mortality were strongly interrelated. Therefore, the important variables were considered simultaneously by means of discriminant function analysis to ascertain the best individual predictors of subsequent mortality. This analysis also allowed an adjustment for age and certain other variables. Seven factors contributed significantly to the prediction of mortality. Overall, the coefficient of determination was highly significant ($P < 0.0001$) with an r value of 0.6. In order of independent contribution, the variables were (1) heart size, (2) stenosis of the left anterior descending coronary artery, (3) dyspnea on effort and either paroxysmal nocturnal dyspnea or orthopnea, (4) heart rate, (5) stenosis of the left main coronary artery, (6) stenosis of the left circumflex artery, and (7) stenosis of the right coronary artery. Thus, increased heart size, symptoms of heart failure and tachycardia at rest all contributed independently to prognosis as did disease of each of the coronary arteries. The number of patients with stenosis of the left main coronary artery was small with respect to those with stenosis of the other arteries, possibly leading to an underestimate of its significance. Other measurements that by themselves had a strong association with subsequent mortalit —including electrocardiographic evidence of prio transmural infarction, the presence of classic angin pectoris, increased cholesterol concentrations an blood pressure—did not make independent contribu tions according to this discriminant function analy sis. It is possible that these variables exerted their in fluence on survival by affecting either the number o vessels involved, heart size, heart failure or hear rate.

It is also possible that other factors will becom significant as independent determinants of surviva as the study is extended in time. But at an averag follow-up period of 22 months, these are not eviden as independent determinants.

Other Studies Correlating Mortality and Coronary Arteriographic Data

Other investigators have reported powerful associ ations between prognosis of angina pectoris and the

number of coronary vessels involved. At the 1972 meeting of the American College of Cardiology, Moberg et al.[15] presented information on 200 patients studied by coronary arteriography and then followed up for 7 years or until death (Table VIII). Seventeen of 84 patients with one vessel disease were dead within 7 years, yielding an average mortality rate for the total group of 3 percent per year. However, the mortality rate of those patients with disease of the left anterior descending coronary artery was almost twice that of patients with disease of the right or left circumflex arteries. The mortality rate of the group with two vessel disease was 6 percent per year and that of patients with three vessel disease was 10 percent per year.

Lichtlen and Moccetti[16] of Zurich reported at the 1972 annual meeting of the American Heart Association a very similar experience in a series of 231 patients followed up for an average of 32.5 months (Table IX). Ten percent of their patients with one vessel disease and 18 percent and 34 percent, respectively, of those with two and three vessel disease died within the follow-up period. Again, patients with disease limited to the left anterior descending coronary artery had a higher mortality rate, 20 percent in 32.5 months. At the same meeting, Slagle et al.[17] of Duke University reported their experience with 94 patients followed up for an average period of 15 months after coronary arteriography (Table X). A more recent report[18] on 590 consecutive nonsurgical patients with coronary artery disease revealed a 5 year mortality rate of 17 percent for those with one vessel disease, whereas the rates of the patients with two and three vessel disease were 38 percent and 55 percent, respectively. These data are consistent with those of the other reports.

Summary of Combined Studies

Recognizing the heterogeneity of the population groups resulting from differing referral patterns, variations in techniques and different periods of follow-up study, we have combined data from these several studies to provide a crude idea of the fate of a large number of patients studied at various centers. The variations are compensated for in part by providing the range of values and by deriving a weighted average mortality rate in which the mortality rate of each of the studies is weighted by the reciprocal of the variance. The standard error is also shown. Despite the inherent problems in such analysis, the pooled results are remarkably similar and provide additional insight into the likely survival rates of the several subgroups.

Single vs. multiple vessel involvement: This combination of studies provided a total of 265 patients with one vessel disease having an average follow-up period of approximately 47 months. The weighted average annual mortality rate of this combined group was 2.2 ± 0.4 percent (Table XIA). This value assumes a linear relation between the rate of death and the duration of follow-up study. The death rate applies only to the original cohort, not to the survivors at the start of each new year of the follow-up period.

A similar combination of reports (excluding the data of Friesinger et al.,[13] which provide no information on the number of patients with two or three vessel disease) yielded 220 patients with two vessel disease. Sixty-five (29.5 percent) were dead in an average follow-up period of 38 months. The weighted average mortality rate per year of the original cohort was 6.8 ± 0.7 percent (Table XIB). Seventy-nine of 220 (35.9 percent) of persons with three vessel disease were dead in an average 33 month follow-up period, yielding a weighted average annual mortality rate of 11.4 ± 0.9 percent of the original cohort (Table XIC).

These data from several centers show a clearly recognizable trend; that is, the mortality rate of patients with angina is strongly associated with the number of arteries involved. But there is one area of important disagreement. Moberg and his colleagues[15] and Lichtlen and Moccetti[16] found that patients with "single vessel" disease involving the left anterior descending coronary artery have a relatively serious prognosis,

the annual mortality rate being 4 percent and 7.4 percent in their respective series. In contrast, Ross et al.[19] reported only one death (possibly cardiac in origin) in 24 patients with disease of the left anterior descending artery in a follow-up period of 55 months. The reports of Oberman et al.[14] and Slagle et al.[17] did not provide a similar breakdown of data, although the gross mortality rate of the patients with single vessel disease in both studies was low. This question obviously requires further study. It seems clear from all reports that patients with disease limited to the circumflex or to the right coronary artery have an excellent prognosis over a period of 2 to 7 years. It is also clear that patients with all three major vessels involved have a high mortality rate, approximately 10 to 15 percent per year. In all classes of patients cardiac enlargement or congestive heart failure, or both, grossly diminishes the likelihood of survival.

Clinical and Surgical Implications

These considerations indicate that if meaningful comparisons are to be made between medically and surgically treated patients, a number of subgroups must be identified, even if a randomized trial can be completed successfully. At a minimum these subgroups should be based on the extent of obstructive disease of the coronary arteries, the presence or absence of cardiomegaly, and the presence or absence of congestive heart failure. A more sophisticated analysis of the coronary arteriograms would almost certainly increase the precision of delineation of subgroups. It is also likely that more elegant descriptors of the condition of the ventricles than cardiomegaly or symptoms of congestive heart failure would further increase the refinement of these subgroups, as indicated in a very recent report by Scanlon et al.[20] on accelerated angina pectoris. A direct comparison of the survival and clinical course of patients in such subgroups assigned at random to medical or surgical treatment is required if clear answers relative to the respective merits of medical and surgical interventions are to be provided. In the absence of such data, the physician must be guided by the information available to him. In view of the low annual mortality rate of patients with disease limited to the right or left circumflex artery, it is difficult to justify an operation that, while providing symptomatic relief, may accelerate the disease process in the native coronary circulation as recently reported by Griffith et al.[21] and Levine et al.[22] and has the other

* Average follow-up = total patient months/total number of patients in combined series.

† Weighted average of annual mortality rate and standard error of combined studies, where the mortality rate of each study is weighted by the reciprocal of the variance. The calculations used are: Mortality rate (r) = d/NT; variance of rate (V_r) = d (N − d)/N^3T^2; and weight (W) = $1/V_r$ where d = no. dead; N = no. exposed to death; and T = time interval in years. Weighted average mortality rate = Σ Wr/ΣW and standard error of rate = $1/\sqrt{\Sigma W}$.

disadvantages of surgery. These disadvantages include a significant risk of infarction at operation, a definite if small surgical mortality rate, considerable pain and discomfort and a substantial cost both in dollars and in medical manpower.

By contrast, patients with three vessel disease, having a very high annual mortality rate with medical treatment alone, might well benefit from a more aggressive attitude on the part of physicians. At present it is our policy to offer surgery to essentially all of these patients who are without contraindications, recognizing that surgical intervention has not been shown to prevent premature death. Patients with two vessel disease or with very proximal disease of the left anterior descending coronary artery constitute the most difficult problems with respect to surgical intervention. If there is evidence of ventricular dysfunction or cardiomegaly, either condition of mild or moderate degree, especially if there is significant limitation of ordinary activity because of angina, then surgery is advised. Unfortunately, the patients with a very large heart and severe congestive heart failure who are at great risk of death with medical treatment alone are also those with the greatest hazard at surgery. Thus, in many centers these patients are not considered to be surgical candidates unless the dysfunction is explained by focal disease of the myocardium, with other areas of the ventricle exhibiting vigorous contraction.

Outlook for Patients After Coronary Artery Revascularization

VINCENT L. GOTT, MD,

Baltimore, Maryland

Data are now available from many centers on the results of the coronary artery bypass operation. Approximately 85 percent of the patients who survive the procedure experience relief of angina and 60 percent have no further chest pain. Similarly, 70 to 85 percent of the patients have improved results on objective testing, and this improvement seems to correlate fairly well with the patency of the bypass grafts. Data from various institutions on effects on ventricular function have not been consistent, but there is some evidence that myocardial contractility for segments with a patent graft can be improved, particularly when there is no infarction and the preoperative ventricular wall motion is moderately depressed.

The operative mortality rate for patients with stable angina is less than 6 percent in most centers and appears to be related to the quality of ventricular function. The mortality rate in patients with unstable angina is considerably higher in most institutions. Although vein patency is reduced to between 65 and 75 percent 1 year postoperatively, the occlusion rate over the next 2 years appears to be only 5 to 6 percent.

It is too early to state definitively whether surgery can prevent infarction in patients with stable or unstable angina. However, there is fairly good evidence that bypass surgery can prevent infarction if it is carried out within 4 hours after the onset of coronary occlusion.

The results from several centers suggest that bypass surgery may favorably influence the annual survival rate in patients with stable angina. There are not enough controlled data to say whether the procedure can extend life in patients with unstable angina, which is a highly lethal disease, particularly for individuals with continuing severe angina. Bypass surgery would appear to be of value for this group of patients.

During the past 6 years, the coronary artery bypass operation has been widely used as a myocardial revascularization procedure in many cardiac centers. Thousands of patients have been subjected to this operation, and it is important at this time to determine how beneficial the procedure has been. Has it been of value in eliminating the symptoms of angina? Has there been demonstrated improvement in ventricular function? More important, has it reduced the frequency of infarction and extended life in these patients? There is now a considerable amount of data to help formulate answers to these questions.

Vein Patency Rate and Mortality Rate After the Bypass Operation

Before considering the possible benefits of the newer bypass procedures, it is important to consider: (1) the percentage of bypass grafts that will remain open over a prolonged period of time, and (2) the mortality rate of the operative procedure.

Vein Patency Rate

Several institutions have reported early patency rates of 85 to 92 percent 2 to 3 weeks after operation, and reports by Achuff et al.[1] at our institution and Walker[2] and Grondin[3] and their co-workers have demonstrated late patency rates of 65 to 75 percent 4 to 12 months after operation. One of the best studies on the late patency rate was recently reported by Grondin et al.[4] from the Montreal Heart Clinic. They demonstrated, in a serial angiographic evaluation of vein bypass grafts in 60 patients, patency rates of 89 percent 2 weeks after operation and 68 and 63 percent 1 year and 3 years, respectively, after operation. It is gratifying that the reduction in patency between the first and third years was only 5 percent.

Several factors appear to affect the patency rate. Possibly the most important is the severity of obstructive disease in the distal arterial bed and the amount of blood flow or "runoff" that can be accepted by this bed after the graft placement. Grafts with flow rates of less than 20 cc/min have a very high frequency of early closure. Grafts with flow rates of more than 40 cc/ min have an excellent late patency rate.[2,5]

The results with the internal mammary artery as a bypass conduit have been more encouraging, demonstrating a 90 to 95 percent patency rate 1 year postoperatively.[6] This high patency rate has increased interest in use of the internal mammary artery as a bypass conduit for the left anterior descending and the circumflex coronary arteries. Ordinarily, the internal mammary artery is not of adequate length to reach the distal right coronary arterial tree.

Mortality

The risk of operation in patients with stable angina pectoris appears to be less than 6 percent. Table I[1–10] presents the mortality rate for several large series of patients with stable angina. Probably the most important factor in determining the mortality rate in patients with stable angina is the degree of left ventricular malfunction. This is well illustrated by the data reported by Kay et al.[11] (Table II). In their study, mortality rate was related to left ventricular ejection fraction, and very acceptable mortality rates were achieved even with only fair ventricular function. When the ejection fraction was under 20 percent, however, the mortality rate increased to 31 percent.

Clinical Results of Bypass Operation

Symptomatic Improvement

Probably the most significant benefit of the coronary bypass operation at this time is the symptomatic relief of angina pectoris. Table III shows the close relation of the data reported from seven different institutions.[1,7,12–16] Eighty to 95 percent of the patients had symptomatic improvement after the bypass operation, and 60 to 72 percent were angina-free. Therefore, for approximately 65 to 85 percent of the patients who survived this operation, the "quality of life" has improved significantly. Most of these patients have been able to return to work and, from the standpoint of the patient, the operation has been highly successful.

Objective Improvement by Stress Testing

Results of the data becoming available on the objective improvement in patients who have survived the bypass operation are quite encouraging. Table IV presents data from several studies[1,15,17–19] on the objective improvement as determined by stress testing, with right atrial pacing-induced tachycardia or exercise. It is apparent that 64 to 86 percent of these patients showed improved performance after the bypass operation.

Thus, approximately 85 percent of patients appear to have symptomatic improvement after the bypass operation, and approximately 80 percent improvement by objective measurements. Physicians tend to

be skeptical of these data because very similar benefits were reported after internal mammary artery implantation (Vineberg procedure), even when it was demonstrated that there was an occluded internal mammary artery implant. Several studies have shown that approximately 35 percent of patients who had an occluded internal mammary artery had symptomatic improvement and that many of these patients also demonstrated objective improvement. There is a real placebo effect, therefore, from any of the so-called revascularization operations, and physicians must remain cautious in interpreting these new data on symptomatic and objective improvement after the bypass operation.

It has been encouraging to note that there appears to be a fairly good correlation between the presence of a patent bypass graft and the degree of postoperative symptomatic and objective improvement. Also, several groups have noted a good correlation between the return of symptoms and occlusion of the grafts. Experiences of this type indicate that increased myocardial perfusion is very likely responsible for the reduction in symptoms in many patients undergoing the bypass operation. Alleviation of the symptomatic complaints of angina can, of course, also be related to postoperative infarction. This was well documented in a study by Griffith et al.[20] in which 56 of 71 patients undergoing vein bypass surgery reported symptomatic improvement, and in at least 9 of these 56 patients, improvement was apparently the result of a postoperative infarction.

Improvement in Ventricular Function

A more critical assessment of the value of the vein bypass procedure can be obtained by actually determining the improvement in left ventricular function after surgery. However, current data are inconclusive. The majority of patients undergo vein bypass operation for incapacitating angina, and if they have essentially normal left ventricular function, it will not be improved by the bypass procedure. In other words, one cannot expect "supercontraction" of a normal ventricle with the placement of a vein bypass graft. Also, in patients who have had a myocardial infarction, one cannot expect improvement in the contraction of scar tissue. The hope is that the patient with poor left ventricular function on the basis of ischemia will demonstrate improved function after the bypass operation.

Data presented in Table V have been abstracted from several reports and are not uniform or consistent with regard to the improvement in left ventricular function after the bypass operation. Achuff et al.[21] at our institution, in evaluating 71 patients after vein bypass surgery, found essentially no improvement in ventricular function as determined by left ventricular ejection fraction. It made very little difference if the veins were open or occluded. They did find that 26 percent of the ventricular segments demonstrated improved wall motion when bypass grafts to these segments were patent, but the improvement was not impressive when they evaluated changes in all myocardial segments.

Arbogast et al.[22] reported that the ejection fraction in 23 patients with all grafts patent was unchanged, whereas it was definitely worse in 19 patients with all grafts occluded. Rees and associates[23] similarly found poor ventricular wall motion in six patients with occlusion of all grafts. They indicated, however, that in eight patients with patency of all grafts, the ejection fraction and ventricular wall motion were better. They concluded that patients with severe depression of ventricular performance manifested improved ventricular function when the operation was a success and that a deterioration of ventricular function accompanied graft occlusion.

Chatterjee and associates[24] obtained results somewhat similar to those of Rees et al., in that they observed improvement in ejection fraction in 17 of 18 patients with moderate preoperative depression of left ventricular function and postoperative patency of all grafts. In three patients with occlusion of all grafts, ventricular function was further depressed. These latter two studies were somewhat selective with regard to the patients evaluated and the first

two groups (Achuff et al. and Arbogast et al.) were completely unselective. Thus, there is some evidence that, with moderate preoperative depression of ventricular function and postoperative graft patency, ventricular function in some patients can be improved, although this finding has not been uniform.

Extension of Life and Prevention of Myocardial Infarction

Reeves and associates[25] have provided an excellent discussion on the natural history of coronary disease, and it is important now to see if the bypass operation can alter this natural history. Figure 1 depicts in a highly schematic way the various interrelations among the clinical presentations of ischemic heart disease. This diagram simply depicts three categories of patients whose clinical course is characterized by development of myocardial infarction or by progression to death as a result of infarction or electrical instability. These three categories include asymptomatic patients and patients with stable or unstable angina. There is an additional subset of patients who do not undergo sudden death but are admitted to a coronary care unit with a potentially lethal myocardial infarction for which there is an interval of time for treatment.

Surgery has no current role in preventing infarction or sudden death in the asymptomatic patient without documented coronary artery disease. We are primarily concerned, therefore, about the possible role that surgery may have in altering the natural history pathways for patients with stable and unstable angina.

Patients with Stable Angina

Annual mortality rate: In studies made 10 to 15 years ago, the annual mortality rate in patients with stable angina was reported to be 8 to 9 percent.[26,27] More recently, there have been some excellent prospective studies on the yearly attrition rate in patients with stable angina. Two very good clinical studies are those generated by the Framingham group[28] and the Health Insurance Plan of New York (HIP).[29] In the HIP study, as reported by Frank,[29] there was a 4 percent annual attrition rate in men who had survived their initial coronary attack. Data from the Framingham study[28] demonstrated a comparable yearly attrition rate. It is important to note that Frank and his associates have reported an annual mortality rate of 8 percent in a high-risk group of men with an abnormal electrocardiogram and hypertension. In this same study, the annual attrition rate in a low-risk group of men with stable angina (normal electrocardiogram and normal blood pressure) was only 1.8 percent a year.

The two studies cited provide excellent clinical information on the natural history of patients with stable angina, but angiographic documentation of the severity of coronary artery disease was not obtained. Three important studies published in the last 2 years do provide excellent data on angiographic correlation with the annual mortality rate in patients with one, two and three vessel disease (Fig. 2). Friesinger et al.[30] of our institution reported in 1971 the results of a natural history study in which the severity of coronary disease had been initially documented by arteriography in 224 patients. All of these patients were then followed up for at least 5 years. It was found that patients with severe disease in at least two coronary arteries had an annual mortality rate of 10 percent (Fig. 2), and patients with less severe disease had an annual attrition rate of only 1 percent. This study was the first to show that the major determinant of survival in patients with angina pectoris was the severity of the coronary artery disease. A subsequent report by Jones et al.[31] has confirmed the important relation between the severity of the disease and patient survival. These investigators reported a

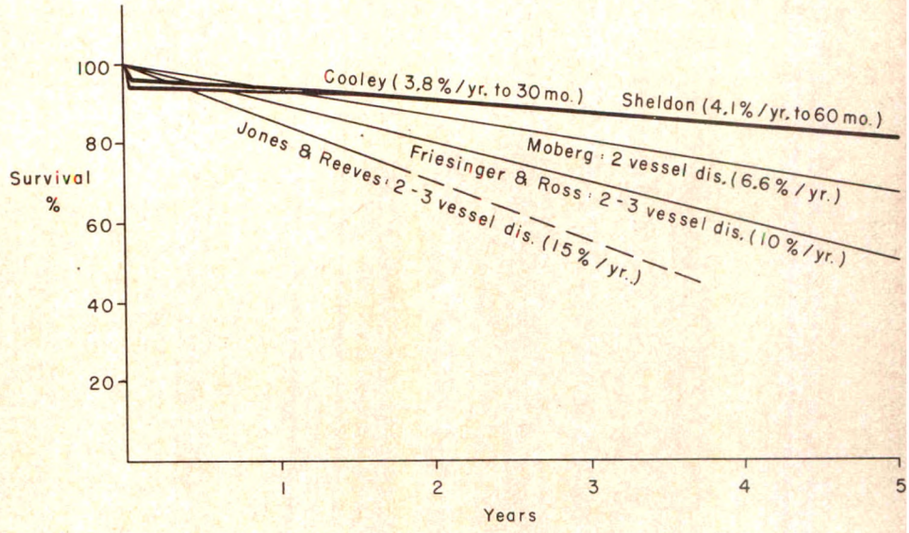

FIGURE 2. The annual attrition rate for patients with coronary disease documented by arteriography. The top line depicts data for patients undergoing coronary artery bypass in two different institutions. The lower three lines depict data from three studies in which revascularization was not carried out. Copyright © 1973 by Year Book Medical Publishers.

15 percent annual attrition rate in patients with severe disease in at least two coronary arteries. These data have now been further amplified by Reeves and associates[25] in their current presentation on the natural history of coronary artery disease. Moberg et al.[32] at the Cleveland Clinic more recently reported a 6.6 percent yearly attrition rate in patients with two vessel disease and a 4 percent yearly attrition rate in patients with single vessel disease.

Recent data based on evaluation of patients undergoing coronary artery bypass suggest that operation may favorably influence mortality in patients with stable angina (Fig. 1 and 2). In two groups of patients who underwent coronary artery bypass,[9,13] the annual attrition rates (including hospital mortality) were, respectively, 3.8 and 4.1 percent. Although all of the patients cited in Figure 2 had the severity of their coronary disease documented angiographically and the majority in the surgical series had severe two vessel disease, comparison of the survival rates of patients treated medically and surgically may be misleading. The results in the three groups of patients who received medical treatment were obtained during a period when some forms of current medical therapy were not available. In addition, it is not possible to determine how many patients in the group receiving only medical therapy would be suitable candidates for bypass graft surgery. Because patients with diffuse coronary disease and poor left ventricular function are often not selected for surgery, the medical group may include a significant number of patients with more advanced disease. In spite of these reservations, the data do suggest that the annual attrition rate of patients with stable angina can be favorably altered by the bypass operation.

Prevention of future myocardial infarction: Can the coronary artery bypass operation prevent future myocardial infarction? Unfortunately, there are not enough firm data to answer this major question. One problem has been obtaining accurate data on the annual incidence of nonfatal infarction in patients with stable angina on medical therapy. There is not much information in this area, but the Framingham study[28] indicated that 2 to 3 percent of patients with stable angina experience a nonfatal infarction each year. There are no comparable data for a group of patients with stable angina who have undergone bypass surgery. It can be said that the frequency of perioperative myocardial infarction, as defined by the appearance of new Q waves on the postoperative electrocardiogram, ranges from 2 to 22 percent in various reported series.[33–36] Although this is a relatively high rate, most infarctions occurred in the early postoperative period when appropriate therapy could be immediately employed. Perhaps the availability of immediate therapy explains why most of these early postoperative infarcts are not fatal. The incidence of late infarction (after hospital discharge) in patients undergoing successful coronary artery bypass operations appears to be low. In our first 141 patients discharged from the hospital and followed up for an average of 8.3 months, there were only six myocardial infarctions, one fatal and five nonfatal.

Currently, the Veterans Administration Hospitals (V. A. Cooperative Study of Surgery for Coronary Arterial Disease) are conducting an important prospective study to determine the effect of coronary artery bypass on the natural history of patients with ischemic heart disease. In that study, patients with disabling angina who are suitable candidates for bypass surgery are randomly assigned to either medical or surgical therapy. It is hoped that the data will provide some of the answers currently being sought. It is apparent that it will be several more years before we will know with certainty whether bypass surgery can reduce the incidence of myocardial infarction and improve the survival rate in patients with stable angina.

Patients with Unstable Angina

At the present time, probably no group of patients with coronary artery disease poses more of a therapeutic dilemma than the group with unstable or "preinfarction" angina. Evaluation of this problem is complicated by the fact that the terminology related to this clinical state has not been well defined, and frequently physicians, in comparing their experience with unstable angina, have not been describing comparable patient populations. As indicated in Figure 1, the reported first year mortality rate for patients with unstable angina has varied greatly (3 to 43 percent). Fulton et al.,[37] in reporting a 3 percent mortality rate within the first year after the onset of unstable angina, probably obtained this low rate because of the inclusion of a large number of patients with the recent onset of exertional angina. The patients in the studies of Krauss and Gazes and their co-workers[38,39] had a more lethal disease process and the criteria for unstable angina in these two studies are more comparable to those employed in the surgical groups presented in Figure 1.[40–42] In all of these medical and surgical studies (with the exception of that of Fulton et al.), the patients had as a minimal requirement at least a 15 minute episode of new, continuing angina of sufficient severity to warrant admission to a coronary care unit. The mortality for bypass surgery in patients with unstable angina varies considerably, with several factors affecting these results. In the series of Conti et al.,[42] for example, 40 patients with unstable angina were submitted to surgery with three of the nine nonsurvivors sustaining a cardiac arrest even before cardiopulmonary bypass could be instituted.

There is not sufficient evidence to determine whether surgery during an episode of acute coronary insufficiency or unstable angina is the most ideal method of therapy. Gazes et al.[39] have reported a 43 percent first year mortality rate in patients with unstable angina persisting for more than a few days, and bypass surgery certainly should be of value for this group. Krauss et al.,[38] however, raise an important question concerning the most opportune time for bypass operation in these patients. They report the follow-up data on 100 patients with unstable angina admitted to the coronary care unit at Massachusetts General Hospital. Only one patient died and six patients experienced acute infarction during hospitalization, but 26 late deaths occurred in patients discharged from the hospital (mean follow-up time 20 months). There was, therefore, a very high mortality rate in this group of 100 patients with unstable angina, but since there was only one death during the actual hospitalization, the authors suggest that initial conservative management should be considered for the acute syndrome except when the patient is experiencing persistent coronary pain after hospitalization.

These data emphasize the high risk of death in patients with unstable angina and suggest that bypass surgery probably would be of value if applied at the correct time. Currently, there is a prospective, randomized study of patients with unstable angina at eight institutions under the sponsorship of the Myocardial Infarction Branch of the National Heart and Lung Institute. Patients with unstable angina who enter the coronary care unit of a participating institution undergo cardiac catheterization. If they are suitable for vein bypass surgery, a card is drawn to select either medical or surgical therapy. This therapy is carried out and the patient is followed up closely for 24 months with electrocardiograms and chest roentgenograms at 3 month intervals.

In summary, there are considerable data available regarding the problem of unstable angina, and it appears that we can now better define a subset of patients who are at high risk of developing an infarction or dying. Many of these patients should benefit from a bypass operation carried out at the appropriate time. The prospective, randomized study underway at eight institutions may provide data within the near future as to the best time to proceed with bypass surgery.

Patients with an Acute Evolving Infarction

Although the bypass operation has been carried out in a few patients with acute evolving infarctions and also in a few additional patients with cardiogenic shock who were supported by aortic balloon augmentation during catheterization procedures, the role of surgery in these patients must be considered experimental at this time. If bypass surgery can be carried out within 4 hours of onset of a coronary occlusion, there may be some reversal of the periinfarction ischemic process. The few reports of bypass surgery in patients with early, acute evolving infarcts are fairly encouraging.[43,44] The results of vein bypass surgery for patients with cardiogenic shock provide less cause for optimism. However, there do appear to be some patients with cardiogenic shock who can be successfully supported during coronary angiography and bypass surgery with the aortic balloon augmentation system.[45] Although the overall survival rate in this group is low, each survivor represents the successful reversal of an almost certain fatal clinical course. It is important, therefore, that efforts be continued to utilize cardiovascular support techniques and coronary bypass procedures for this group of patients with cardiogenic shock.

Echocardiographic Features of Primary Pulmonary Hypertension

DANIEL J. GOODMAN, MD
DONALD C. HARRISON, MD, FACC
RICHARD L. POPP, MD

Stanford, California

Echocardiograms were recorded in nine patients with primary pulmonary hypertension proved at cardiac catheterization. A reduced diastolic slope of the anterior mitral valve leaflet, simulating mitral stenosis but with normal motion of the posterior leaflet, was observed in all patients. Other features found included a large right ventricular dimension (nine patients), a small left ventricular dimension (three patients), a thick interventricular septum (six patients), systolic mitral leaflet prolapse (four patients) and abnormal septal motion (four patients). The last feature was most probably due to secondary tricuspid or pulmonic insufficiency, or both. The finding of a decreased mitral valve slope, often used as a criterion for mitral stenosis, should not be accepted alone as proof of mitral stenosis; the posterior mitral valve leaflet echo must be carefully searched for and identified. This echo is often difficult to identify, but the normal motion of this structure found in all patients excludes the diagnosis of mitral stenosis as a cause for the pulmonary hypertension.

Primary pulmonary hypertension is an uncommon disease of unknown origin which, in its uncomplicated form, presents the right ventricle with a pure pressure overload.[1] Pulmonary hypertension also is a prominent feature in many patients with mitral stenosis. In rare cases the signs and symptoms may not suggest the correct diagnosis but may completely simulate those of primary pulmonary hypertension.[2,3] Many of these patients with mitral stenosis responded well to surgical treatment.[2] Therefore, treatable mitral valve disease must be definitely excluded when severe, unexplained pulmonary hypertension is encountered.

Since echocardiography provides specific ultrasonic patterns diagnostic of mitral stenosis,[4–7] we examined nine patients with primary pulmonary hypertension documented by hemodynamic studies to determine the relative value of the technique in these patients. Although all nine patients had echocardiographic findings that could be confused with the patterns of mitral stenosis, careful analysis of the records permitted the correct diagnosis. Accordingly, we report these results to emphasize the possible pitfall of making a false positive diagnosis of mitral stenosis in cases of primary pulmonary hypertension, and to present the general echocardiographic features of the right ventricular overload in these patients.

Methods

The nine patients studied had primary pulmonary hypertension documented by historical features, physical examination, electrocardiogram, chest roentgenogram and cardiac catheterization data (Table I). There were three men and six women in the study group, ranging in age from 27 to 54 years (mean age 39 years).

Echocardiographic examinations were performed with a commercially available ultrasonoscope (Smith Kline Instruments, Inc., Palo Alto, Calif.)

A = contacts septum during diastole; Abn = abnormal; Ao = aorta; CI = cardiac index (ml/min per m²); Diast = diastolic; IVS/LV = interventricular septal thickness/left ventricular posterior wall thickness; LA = left atrium; LV = left ventricle; MV = mitral valve; NI = normal; PAW = pulmonary arterial wedge; Post. = posterior; PVR = pulmonary vascular resistance (units); RV = right ventricle; s/d = systolic/diastolic; s/ed = systolic/end-diastolic; Syst = systolic.

using a 2.25 mHz transducer of 0.5 inch diameter with an acoustic lens providing collimation of the beam for a tissue depth of 5 cm. Patients were studied in the supine position, with the transducer at the left sternal border. Records were made in time-motion presentation while the ultrasound beam was directed along the course of the left ventricular outflow tract, as previously described.[8] Usually no distinct echo could be recorded from the right ventricular endocardial surface, so this surface was estimated to be located 0.5 cm posterior to the chest wall echoes.[9] Echoes were recorded from the right and left sides of the interventricular septum, the anterior and posterior mitral valve leaflets and the endocardial and epi(peri)cardial surface of the left ventricular posterior wall. In some cases the tricuspid valve could be recorded by slight medial, ventral and caudal direction of the sound beam from the position required to record the mitral valve. On these records, measurements were made at end-diastole of right and left ventricular dimensions and thickness of both the interventricular septum and left ventricular posterior wall (Fig. 1). The opening excursion and initial diastolic slope of the anterior mitral valve leaflet were measured, and the motion pattern of the posterior mitral valve leaflet was assessed. In addition, the motion pattern of the echoes from the left side of the interventricular septum and the mitral valve during systole were analyzed. All measurements were correlated and compared with normal values for our laboratory (Table I).

Results

Cardiac Catheterization

Hemodynamic data (Table I) showed that all nine patients had severe pulmonary hypertension. Eight of the nine patients had normal values for pulmonary

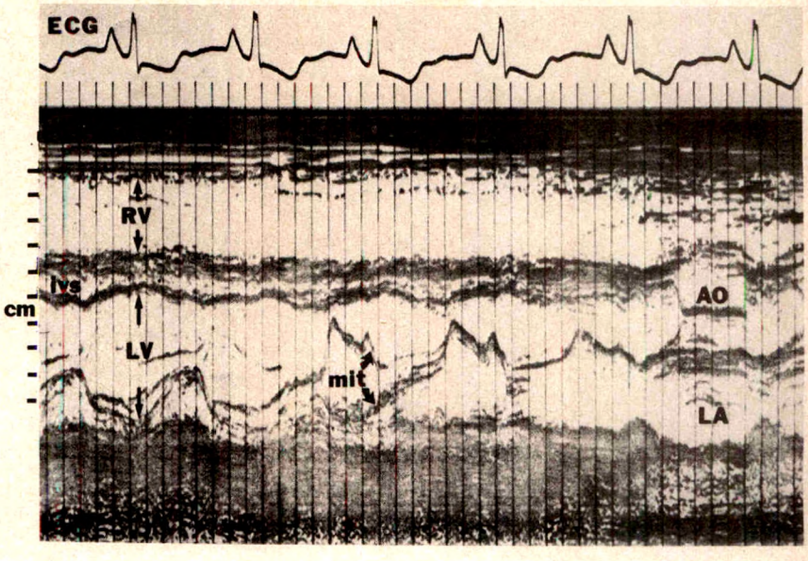

FIGURE 1. Echocardiogram showing a sweep from the aorta **(right)** to the body of the left ventricle **(left).** Measurements of the diastolic size of the right and left ventricles are taken as illustrated. The anterior leaflet of the mitral valve does not contact the septum in diastole, but the early diastolic slope is still reduced below the usually accepted normal range. AO = aorta; cm = 1 centimeter calibration; ECG = electrocardiogram; ivs = interventricular septum; LA = left atrium; LV = left ventricular diastolic dimension; mit = anterior and posterior leaflets of the mitral valve; RV = right ventricular diastolic dimension.

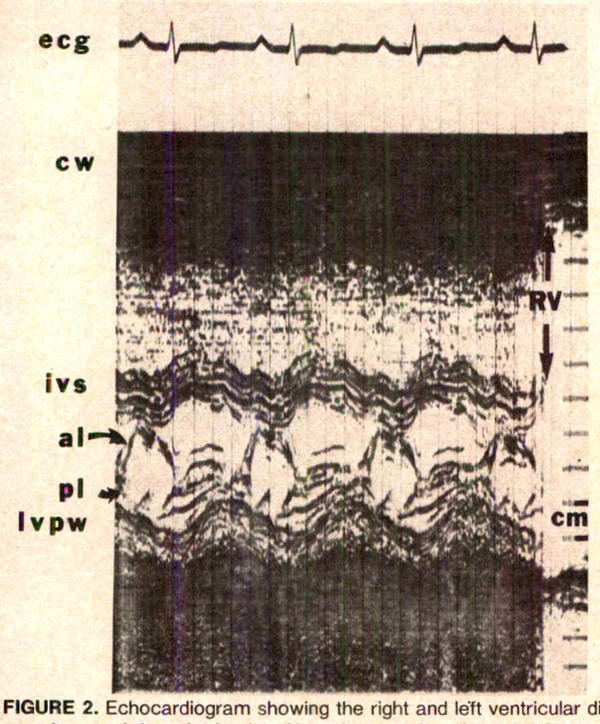

FIGURE 2. Echocardiogram showing the right and left ventricular dimensions and the mitral valve. Note the grossly enlarged right ventricular end-diastolic dimension, best defined by altering the amplification of the signals **(right).** Septal motion is abnormal, since there is no net posterior motion of the left side of the interventricular septum from end-diastole to end-systole. The anterior leaflet of the mitral valve contacts the septum during diastole, with a resulting low slope. Posterior leaflet motion is normal. al = anterior leaflet of the mitral valve; cm = centimeter calibration marks; cw = chest wall; ecg = electrocardiogram; ivs = interventricular septum; lvpw = left ventricular posterior wall; pl = posterior leaflet of the mitral valve; RV = right ventricular end-diastolic dimension.

arterial wedge pressure or left ventricular end-diastolic pressure, or both. In the ninth patient, the mean pulmonary arterial wedge pressure was increased to 16 mm Hg and cardiac index was normal. This level of pressure was out of proportion to the level of pulmonary hypertension found, and the latter was thought to be primary in nature. Oximetry and hydrogen inhalation with a pulmonary arterial electrode failed to demonstrate an intracardiac shunt in any of these patients.

The pulmonary vascular resistance was uniformly increased and cardiac index reduced in six of the eight patients whose data were available. Pulmonary vascular resistance was not affected by the breathing of 100 percent oxygen by mask for 20 minutes.

Echocardiography

All patients had an increased right ventricular dimension, with a range of 22 to 45 mm (mean 30; normal <22 mm) (Table I, Fig. 2). The left ventricular dimension ranged from 23 to 53 mm (mean 37; normal range 30 to 53 mm). One patient had a left ventricular dimension at the lower limit of our normal adult range; three patients had a value clearly below this limit. The interventricular septum was thickened and ranged from 15 to 19 mm in six of these nine patients (Fig. 3) and was at the upper limit of normal in the other three (normal 5 to 13 mm).

The opening excursion of the anterior leaflet of the mitral valve was reduced below normal (>20 mm) in eight of these nine patients, and in seven patients the leaflet appeared to contact the interventricular septum (Fig. 2 and 4). In the two cases in which this contact was not observed, the left ventricular dimension was greater than 50 mm. The initial diastolic slope of the anterior mitral valve leaflet was abnormal in all patients, with a range of 0 to 57 mm/sec (mean 27; normal >80 mm/sec). The anterior mitral valve leaflet maintained contact with the interventricular septal echoes during diastole with apparent interference with valve motion so that both valve excursion and slope were reduced. However, in all patients the motion of the posterior mitral valve leaflet was normal (Fig. 2 and 4).

The systolic motion of the mitral valve was abnormal in four patients. During systole the leaflets moved posteriorly (away from the transducer) instead of showing the normal gradual anterior motion (Fig. 4). This pattern is typical of cases with documented mitral valve prolapse.[10–12] Left ventricular angiograms were performed in Patients 1, 6 and 7 at the time of catheterization. Both the echocardiogram and the ventriculogram of Patient 6 showed mitral valve prolapse; neither technique demonstrated prolapse in Cases 1 and 7.

The echocardiograms of four patients manifested abnormal systolic septal motion with a pattern designated type B by Diamond et al.[13] Instead of the normal posterior motion of the left side of the interventricular septum during systole, there was no net motion from end-diastole to end-systole (Fig. 2).

Discussion

Many of the echocardiographic features described in these patients with primary pulmonary hypertension are those expected with pressure overload of the right ventricle. Thus, the right ventricular diastolic dimension was enlarged. Diamond et al.[13] performed echocardiography in eight patients with pulmonic stenosis and six patients with right ventricular pressure overload from other causes. Two of the patients with pulmonic stenosis and all six of the other patients had an increased right ventricular dimension index (right ventricular dimension/body surface area); the patients with right ventricular failure in addition to the pressure overload had the highest indexes. Six of our eight patients studied by catheterization had right ventricular failure as manifested by increased right ventricular end-diastolic pressure in the presence of a low cardiac index (Table I).

Septal hypertrophy: Right ventricular hypertrophy was evidenced by the thickened interventricular septum found in six patients; in the remaining three patients septal thickness was at the upper limit of normal. No patient had a known cause for left ven-

tricular hypertrophy. The left ventricular posterior wall thickness was within normal limits in all patients. It has been suggested that the ratio of interventricular septal thickness to left ventricular posterior wall thickness be used as a measure of asymmetrical septal hypertrophy and thus as a criterion for the diagnosis of hypertrophic cardiomyopathy.[14,15] Abbassi et al.[14] studied eight patients with nonobstructive cardiomyopathy and described six echocardiographic features of the disease, including a greatly thickened interventricular septum, a normal or only slightly increased left ventricular posterior wall thickness, and a ratio of thickness of the interventricular septum to that of the left ventricular posterior wall of 2.0 or greater. Henry et al.[15] reported asymmetric septal hypertrophy in 15 patients with idiopathic hypertrophic subaortic stenosis, such that the ratio of thickness of the interventricular septum to that of the left ventricular posterior wall averaged 1.68 and was greater than 1.3 in all patients. In all of our nine patients, this ratio was 1.3 or more. This asymmetric hypertrophy of the septum is commonly found in patients with right ventricular hypertrophy.[16]

The left ventricular end-diastolic dimension was abnormally small in three patients and low normal in a fourth. The explanation for this may be related in part to the reduced cardiac output and stroke volume found in these patients. In addition, the shape and position of the left ventricle may be altered by the hypertrophied and dilated right ventricle. In this situation, the left ventricular dimension recorded by ultrasound may not be identical to that recorded in a normal patient. In addition, this dimension could be recorded normally, while reflecting a normal volume distributed within a distorted ventricle.

Abnormal septal motion: Abnormal systolic septal motion, that is, flat or anterior motion of the left side of the interventricular septum during systole, instead of the normal posterior displacement, has been shown to be characteristic of diastolic volume overloading of the right ventricle.[9,13] Secondary tricuspid or pulmonic insufficiency, or both, appeared to be the cause of this abnormal septal motion in the four patients with this pattern. It has been demonstrated that septal motion is normal in patients with a pure right ventricular systolic pressure load.[13]

Mitral valve prolapse: The systolic motion of the mitral valve was abnormal in four patients, demonstrating valve prolapse (Fig. 4). Instead of the leaflets meeting at the beginning of systole and then gradually moving anteriorly, they move posteriorly toward the left atrium.[10–12] Prolapse could be confirmed in the one patient who underwent ventricular angiography. Prolapse has been demonstrated echocardiographically in patients with the mid-systolic click, late systolic murmur syndrome,[10–12] but no patient in our group had findings characteristic of this disorder. It has been postulated that some patients with primary pulmonary hypertension have a connective tissue disorder.[17–21] It then might be expected that mi-

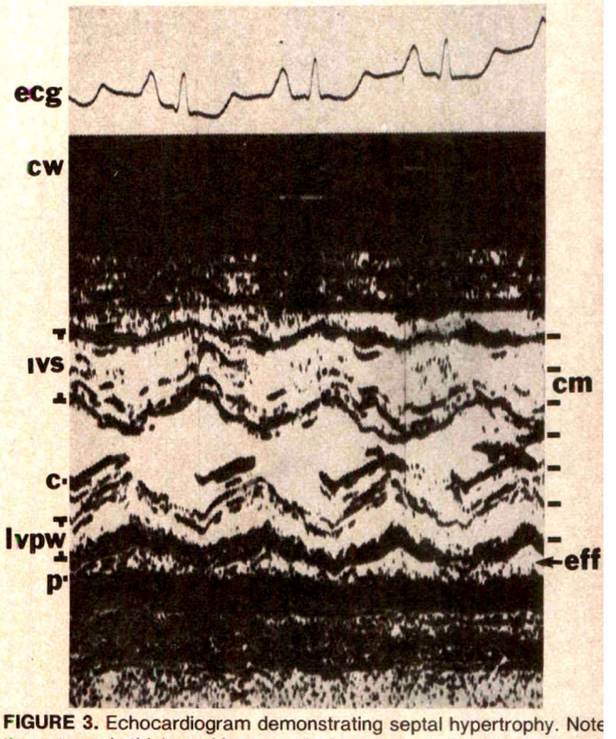

FIGURE 3. Echocardiogram demonstrating septal hypertrophy. Note the extremely thickened interventricular septum with normal left ventricular posterior wall thickness (lvpw). This thickness is well seen because of a small pericardial effusion that defines the epicardium. c = chordae tendineae of mitral valve; eff = pericardial effusion; p = pericardium. Other abbreviations as in Figure 2.

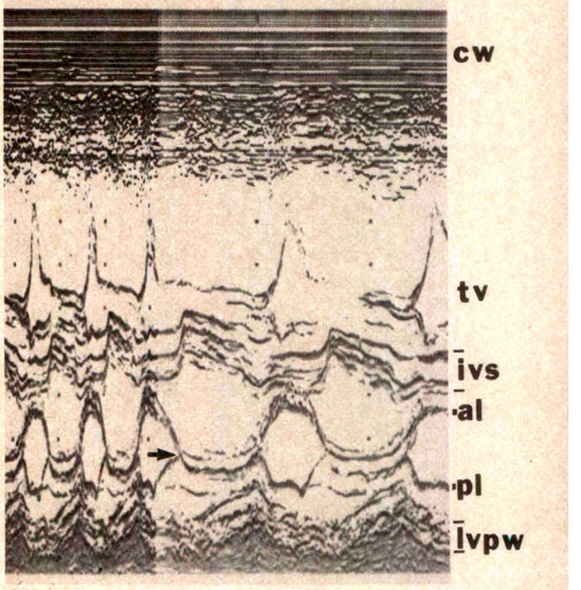

FIGURE 4. Demonstration of mitral valve prolapse. The horizontal arrow denotes the point (C point) at beginning systole when the mitral leaflets apparently meet. The leaflets then move further posteriorly (away from the chest wall) and do not show the normal smooth anterior systolic movement. Also note the contact of the anterior mitral leaflet and the septum during diastole with the normal diastolic motion of the posterior leaflet. No electrocardiogram is recorded. The tricuspid valve (tv) is recorded anterior to the interventricular septum. Abbreviations as in Figure 2.

tral valve prolapse could be related to involvement of the leaflets by such a process. There is support for this hypothesis in the recent demonstration[22] that mitral valve prolapse is a frequent feature of connective tissue disorders.

Abnormal anterior mitral leaflet motion: Perhaps the most important echocardiographic feature in this group of patients concerns the mitral valve pattern during diastole. In every case, the rate of early diastolic motion of the anterior leaflet was reduced, often to a striking degree. Such a reduced early diastolic slope has been used as the hallmark in the diagnosis and the estimation of severity of mitral stenosis.[4–7] In addition, the excursion of the anterior leaflet during diastole was reduced in eight of these nine patients. This finding also is common in rheumatic mitral stenosis.[4–7] Obviously, these patterns might lead one astray in labeling pulmonary hypertension as primary or secondary to mitral stenosis.

In seven of our nine patients, the anterior leaflet contacted the septum, and often maintained contact with the interventricular septum during the entire initial period of left ventricular filling (Fig. 2 and 4). This apparent contact was absent in the two patients with a left ventricular dimension greater than 5 cm. The phenomenon probably results from an abnormally small left ventricular chamber, so that the anterior mitral leaflet abuts on the interventricular septum during early diastole. For this reason, the measured slope probably does not carry the usual connotation related to the rate of left ventricular filling.[23] Duchak et al.[24] showed an echocardiogram of a patient with pulmonary hypertension secondary to venous occlusive disease whose anterior mitral valve contacted the septum and had a very low slope, quite similar to that of our patients. In our two patients whose anterior leaflet did not appear to contact the septum, the diastolic slope was nevertheless reduced (Fig. 1). This finding may be related to a decreased rate of left ventricular filling. Decreased diastolic mitral valve slopes are also found in patients with left ventricular hypertrophy—for example, idiopathic hypertrophic subaortic stenosis[25] and valvular aortic stenosis[23]—and the septal hypertrophy in our patients may lead to the same effect.

Posterior mitral leaflet motion and differentiation from mitral stenosis: Although the slope of the anterior mitral valve leaflet was decreased in all patients, the motion of the posterior leaflet was normal in every case. The recording of the posterior leaflet is of great value in making the diagnosis of mitral stenosis in patients whose anterior leaflet has a low slope.[24] Normally the posterior leaflet is almost a mirror image of the anterior leaflet, opening posteriorly as the larger leaflet moves anteriorly. In rheumatic mitral stenosis, the posterior leaflet moves in the same direction as the anterior leaflet,[24] presumably because of commissural fusion and the larger surface area and mobility of the anterior leaflet. In some of our cases, the echocardiogram from the posterior leaflet was difficult to identify. The excursion of the leaflet was very slight, and great care had to be taken during the echocardiographic examination to record and then to recognize this structure. In this regard, recording the echocardiogram on a strip chart recorder while directing the sound beam back and forth across the area of the junction of the left atrium and left ventricle proved to be the easiest and most reliable method of recording echoes from the posterior leaflet. Without the posterior leaflet as a guide, the mistaken diagnosis of mitral stenosis would have been possible in most of our cases of primary pulmonary hypertension.

It is to be emphasized that in rare instances, patients with mitral stenosis may have signs and symptoms almost indistinguishable from those of primary pulmonary hypertension.[2,3,26] Because surgery can benefit many of these patients, mitral stenosis must be definitively excluded in cases of severe, unexplained pulmonary hypertension.[26] Cardiac catheterization and angiography, which subject patients with primary pulmonary hypertension to a high risk,[26] have been utilized in some cases. Echocardiography may help in the differentiation of these two entities, but only if the pitfalls outlined are avoided.

The correct diagnosis of primary pulmonary hypertension, the degree of right ventricular enlargement and hypertrophy, and the presence or absence of tricuspid and pulmonic valvular regurgitation may be assessed using echocardiography. The echocardiographic picture of primary pulmonary hypertension with secondary tricuspid or pulmonic regurgitation may be difficult to differentiate from that of primary atrial septal defect with secondary pulmonary hypertension. This differentiation requires cardiac catheterization.

Acknowledgment

We thank Nolan R. Corden, MD, Harold M. Lowe, MD, and William Nelson, MD, Col MC for data on their patients, and Mrs. Dorothy McCain and Mrs. Gretchen Houd for preparation of the manuscript.

Noninvasive Methods for Recording Bundle of His Activity

ANTHONY N. DAMATO, MD

Staten Island, New York

The electrode catheter technique for recording electrical activity from various parts of the atrioventricular (A–V) conducting system (particularly bundle of His activity) has significantly contributed to understanding of a variety of A–V conduction and rhythm disturbances occurring within the human heart. Understanding of these events is further enhanced when electrode catheter recordings are made in conjunction with atrial and ventricular pacing procedures. The information derived from the many reported His bundle studies performed in several laboratories has clearly demonstrated both the value and limitations of standard 12 lead electrocardiographic recordings in reflecting underlying electrophysiologic events. It is obvious that not all patients who manifest either a transient or fixed alteration in A–V conduction or rhythm require intracardiac recordings from the specialized A–V conduction system. However, in some patients, bundle of His recordings are indispensable for proper diagnosis and treatment. At present, His bundle electrography is primarily a clinical research procedure although it is relatively simple and safe to perform. The obvious disadvantages of the procedure as currently performed relate to: (1) its invasive nature and the consequent possibility of complications, however minimal; (2) the requirement for catheterization laboratory facilities and equipment, including fluoroscope, multichannel recorder, standby defibrillator; (3) the need to have in attendance two or more physicians and a clinical nurse; and (4) the constant need for awareness of potential electrical hazards.

Perhaps the greatest limitation of the electrode catheter technique relates to the inability to perform repeated sequential studies. Thus, the development of a reliable noninvasive method for recording electrical activity of the specialized conducting system of the heart from the surface of the chest would be a welcome event. The report by Flowers and associates,[1] appearing in this issue of the Journal, represents an initial attempt toward the realization of this goal. These investigators succeeded in recording, from the surface of the chest wall of dogs, activity within the P–R segment of the surface electrocardiogram which they have cautiously termed "blips" and which appear to bear a temporal relation to intracardiac recordings of bundle of His activity. It is obvious that the individual surface recorded "blips" need to be better defined in terms of onset, duration and amplitude. The indefiniteness of some of the "blips" can best be appreciated when the surface recordings are viewed independently of the intracardiac electrograms. Undoubtedly the quality of the surface recordings will improve as technical advances or modifications in the recording apparatus are developed. Additional validation procedures also need to be applied to define more precisely the origin of the successive "blips" as well as the less conspicuous, low amplitude undulations that are also occurring within the P–R segment.

It is important to know whether the surface recorded "blips" represent electrical activity of the right side of the heart exclusively, or whether left-sided activity is also included in these recordings. If the latter is true, then consideration must be given to the effects of cancellation and summation on the configurations and timing of surface recordings. Experiments in which multiple internal recordings of various parts of the His-Purkinje system are made in conjunction with surface recordings under different conditions of A–V conduction and A–V block would substantially assist in the interpretation of the several blips recorded within the P–R segment.

Flowers et al.[1] ascribe the successive "blips" (B_1–B_2) to electrical activity generated within the bundle of His and bundle branch. Their interpretation seems reasonable within the context of their experiments. However, such an interpretation may not be valid under the conditions of an intra-His bundle conduction delay or block which could result in two or more separate His bundle deflections. Furthermore, if the surface recording technique permits simultaneous recordings of His bundle and bundle branch activity then it becomes imperative to define precisely the order in which these deflections occur during ectopic beats. It is also important to determine that the sensing electrodes on the chest wall are recording total His bundle activity. The recordings of A–V nodal activity by electrode catheter and plunge wire technique is a controversial issue. Whether chest wall recordings at high amplification can pick up A–

V nodal activity presents a challenging problem. In some of the tracings presented, minor base-line undulations precede the His bundle "blip." It needs to be determined whether these undulations represent artifact or A–V nodal or atrial activity.

It is anticipated that all of these questions will be answered as additional experiments are designed and greater experience with the surface recording technique is obtained. Whether this technique will present special problems when it is applied to clinical studies has yet to be determined.

Perfection of the surface recording technique would add a new dimension to the study of electrophysiology in the human heart not only because it would overcome some of the disadvantages cited, but also—and more importantly—because it would permit repeated studies in the same patient.

Preinfarction Ill Health

PETER G. F. NIXON, MB, FRCP
HUGH J. N. BETHELL, MB, MRCP*

London, England

Death from myocardial infarction frequently occurs before medical help can be obtained. This is a tragedy because the prognosis of the resuscitated patient is as good as that of the patient who does not require resuscitation.[1,2] Many lives might be saved if the approaching infarction could be recognized early enough for preventive action to be taken. Unfortunately, angina pectoris and electrocardiographic changes, the traditionally accepted warning signs, have failed to predict oncoming infarction and sudden death.[3] It may prove more profitable to seek other warning symptoms and signs.

Preinfarction Symptoms

Over the past few years, the importance of fatigue as a precoronary symptom has begun to be recognized. Kinlen[4] interviewed the relatives of 142 victims of apparently sudden and unexpected death from coronary artery disease and found a history of tiredness and loss of energy in 41 percent:

"It was striking how often a certain pattern of changed behaviour was described in these cases of sudden death. A man who normally did a good deal of work in the garden might give this up. He might complain of tiredness or of 'getting old,' but more often it was the case that his wife would notice him going to bed earlier in the evening or falling asleep in chairs where this was previously very unusual. In 2 cases the patient even fell asleep during meals .... The duration of these symptoms varied from two weeks to six months."

Relatives were also aware of a recent change in appearance, unusual coldness of the limbs and irritability in the weeks before death. When Kinlen interviewed surviving patients with myocardial infarction he found that these symptoms were rarely volunteered.

Tiredness and reduced activities: In an attempt to clarify the symptoms experienced before infarction, we recently questioned 40 consecutive survivors of acute infarction and, wherever possible, a close relative (Table I). The majority of the patients had a history of declining health over many months before the infarction, and two separate groups of symptoms could be recognized. One group of symptoms included tiredness and reduction of activity. Thirty-one of the 40 patients (77 percent) had suffered from an increasing and abnormal fatigue for 6 weeks to 3 years before the infarction. Excessive sleeping at inappropriate times had been noticed in 32, and in 29 (72 percent) of these this symptom was new or had increased. Typically, for 1 or 2 years before the infarction the patient had habitually fallen asleep in a chair during the evening while watching television, and sometimes on other occasions. In 32 cases (80 percent) a history of general "slowing down" and accelerated aging was obtained from the patient or relative, or both. Altered patterns of behavior were common. Libido had begun to decline in nine (22 percent). Irritability was more marked in 25 (67 percent), and the relative was usually more aware of this change than the patient. A reduction in social and leisure activities had been noticed in 25 cases (67 percent). Often the patient had stopped going out in the evening or had eliminated activities involving physical exertion such as playing golf, gardening or performing "do-it-yourself" tasks about the house. These symptoms of fatigue and diminishing energy and stamina are similar to the symptoms that often precede the onset of frank dyspnea in mitral incompetence.[5,6] In coronary artery disease these same symptoms may also be attributed to left heart dysfunction impairing the ability of the heart to increase its output in response to emotional and physical challenges.[7]

Limited exercise tolerance: The other group of symptoms comprised those that limited exercise tolerance. Angina pectoris occurred late in the period of declining health and in only half the patients. A further 10 (25 percent) had had their exercise tolerance progressively reduced by dyspnea. In eight of these the dyspnea was recognized as different from normal, not only in that it came earlier, but also in that it imposed an absolute barrier to further exertion and had an unpleasant quality variously described as "uncomfortable," "constricting," "choking" or "tight." This

barrier to continued exertion we have called a "standstill factor." The standstill factor and angina pectoris may well have a common origin in the sharp increase in left ventricular diastolic pressure in response to physical or emotional demands which is known to precede most attacks of anginal pain. In coronary artery disease there are many different causes of left ventricular dysfunction. These include long-standing atheromatous narrowing or occlusion of coronary arteries, minor coronary thromboses and platelet emboli, mitral incompetence from papillary muscle ischemia, and the hypertensive, lipidemic, platelet sticking consequences of an aggressive, self-destructive way of life.[8] Left ventricular damage from previously unrecognized infarction is a common finding when death from coronary disease has been sudden and unexpected.[9,10]

Denial of Symptoms

During our study of preinfarction symptoms, it was very noticeable that relatives were much more likely to volunteer information and be emphatic about changes in health than the patients themselves. The patient characteristically tended to minimize or conceal disability and to rationalize symptoms or attribute them to the inevitable consequences of aging. This tendency to deny or minimize disability that has become obvious to others might account for the differences between the histories Kinlen obtained from the survivors of acute infarction and the histories he obtained from the relatives of those who died.[4] This tendency may also contribute to delayed hospital admission after myocardial infarction,[11,12] and may be one reason why up to 30 percent of the infarctions revealed by population studies had not been recognized clinically.[13–15] The denial of disability appears to be an exaggeration of the normal mechanism for concealing inadequacy and declining ability as described by Kennedy.[16] This mechanism is likely to be particularly well developed in the patient with coronary disease whose pride and scorn of physical frailty may not allow him to acknowledge illness that threatens his security.[17]

Causes of Breakdown in Health

The environmental challenges that may cause breakdown in the health of industrial managers have also been described by Kennedy.[16] These same factors, with some additions, seem to have been prominent in causing the cardiac breakdown in many of our patients. This is hardly surprising in view of the gross biochemical changes that may be precipitated by everyday stresses[18] and frequent life changes.[19] Challenges in the working environment include transfer to new tasks, failure to achieve, frustrations and defeat imposed by others, actual or threatened loss of employment, loss of a colleague, change of management or management policy, change of place of work (particularly if this involves rehousing or more arduous traveling), oncoming retirement for which one is inadequately prepared and conflict between the demands of the job and the demands of the family.

TABLE I

Prevalence of Preinfarction Symptoms in 40 Consecutive Survivors of Acute Myocardial Infarction

Symptom	Patients Affected (%)
Slowing/aging	80
Abnormal fatigue	77
Excessive sleeping	72
Increased irritability	67
Reduction in leisure activities	67
Angina pectoris	52
Atypical chest pain	37
Increased dyspnea on effort	25
Reduced libido	22
"Standstill factor"	20

Challenges in the home environment include moving to a new house, loss of community ties, bereavement and the strain of bereavement anniversaries, involvement in lawsuits, adultery or divorce, incompatibility in marriage and confrontation with rebellious offspring. These causes of breakdown are likely to be nurtured and aggravated by persons of a restless and aggressive nature who create conflicts and crises by their attitudes and behavior. Friedman and Rosenman and their co-workers[20–22] have described the individual with an aggressive personality, enhanced competitive drive and inability to relax whose blood cholesterol level is raised and whose blood coagulability is increased during stress and who runs an unusually high risk of myocardial infarction. MacKinnon[23] regards the patient with coronary artery disease as self-destructive, and Nixon[24] sees him as addicted to work and tension. Carruthers[8] has indicated how aggression causes excessive catecholamine secretion, high levels of free fatty acids, lipidemia, platelet stickiness and predisposition to thrombus formation and atheroma. These self-injurious consequences of aggression are aggravated by sloth, gluttony and cigarette smoking, which may themselves result from excessive strain and tension.

Implications of the Symptoms

If one accepts as a working hypothesis that coronary illness is largely a self-inflicted breakdown in health consequent on too much strain and tension, and that left ventricular dysfunction may give rise to the changes described here before the occurrence of pain and electrocardiographic changes, a number of implications may modify the traditional clinical approach to coronary illness:

1. Public health: During the past 100 years Western social evolution has presented an ever increasing rate of challenges to adaptation. This situation is recognized to be dangerous psychiatrically,[25] and knowledge of the biochemical consequences of stress suggests that it is also dangerous cardiologically. A

reduction in the morbidity and mortality from coronary heart disease might be achieved by teaching industrial concerns and individuals that overcompetitive and stress-producing habits at work and leisure ultimately promote ill health. However, a substantial decrease in the incidence of coronary heart disease in Western countries seems unlikely to be achieved without a complete restructuring of society and a reduction in the aggressive, competitive and insecurity-generating drives presently encouraged and rewarded by capitalist nations.

2. Early diagnosis: In both England[4] and the United States,[26] it has been found that about a quarter of the victims of sudden death from coronary artery disease had visited a doctor in the week before their death without obtaining protection. Some of these subjects might be identified if doctors were taught to think of coronary illness when they encounter declining physical ability in the overstressed patient, and to seek further evidence of impaired left heart function. Often the earliest sign of left ventricular dysfunction is the palpable and audible atrial gallop.[27] This is most easily detected by turning the patient on his left side where the gallop may be more easily palpated than heard. We regard the presence of the symptoms described here together with clinical evidence of abnormal left ventricular function as a "preinfarction syndrome" warranting urgent treatment. Even if the patient is just overstressed and exhausted, it does no harm to rest him, provided that cardiac neurosis is not produced, and it should be beneficial to manipulate his attitudes and behavior as one would with a patient who had established coronary heart disease.[28]

3. Management of the symptomatic patient: Lack of interest in the early diagnosis of coronary disease is associated with the widely held belief that the course of the disease cannot be altered. This is unfortunate because there is good pathologic evidence that collateral circulation can develop to bypass coronary obstruction,[29–31] and that recanalization of vessels blocked by atheroma or thrombosis can result in a normal lumen.[32] Fulfilling the anatomic and physiologic potential for recovery from coronary artery disease requires that the causative and aggravating factors be modified. Our therapeutic approach to the symptomatic "preinfarction" patient or the subject with angina has been to rest him until he is free from symptoms, and then to set about modifying the attitudes and environmental factors that appear to be contributing to his illness.[33,34] After the patient has rested adequately, there should be such an improvement in his well-being as to convince him that he can climb out of the decline if he continues to discipline his addiction to work and tension and to live in an unstrained fashion. His recovery of physical fitness may be accelerated by a course of training in a gymnasium,[24] with the aim of making exercise a part of his routine of living. He should learn to achieve the peaceful yet active way of life he has denied himself in the past, delegate responsibilities, refuse excessive work loads and enjoy leisure.

4. Rehabilitation after myocardial infarction: A similar approach is required for the patient who has had a myocardial infarction. Before he is discharged from the hospital, his attitudes and environment must be prepared for his recovery and survival, and his progress in understanding his problems and the necessity for changing his life style should be a major factor in determining the length of his stay in the hospital.[35] If the patient believes that his infarction came without warning, invitation or cause, the rehabilitation is extremely difficult because he lives in constant fear of another attack. Failure to return to work after myocardial infarction is as likely to be caused by anxiety or depression as by cardiac disability.[36] A clear understanding of his preinfarction symptoms and the factors that produced them equips the patient and his family to protect his future. He can be taught to recover confidence and increase his physical fitness with an exercise program. He can be taught to work hard without generating tension and to lose his sense of guilt during relaxation. Under these conditions he is more likely to observe recommendations to lose weight or give up smoking. The treatment of elevated blood pressure and serum lipid levels may be obviated by their return to normal levels. The idea of working for recovery rather than passively accepting medical treatment appeals to many patients.

Conclusion

Not every patient with the symptoms described here has coronary heart disease, nor do these symptoms precede every episode of myocardial infarction. But we consider it rational and prudent to consider the diagnosis of coronary disease and to seek evidence of abnormal heart function when a patient presents with abnormal fatigue and other symptoms of declining health. In treating a patient with established coronary artery disease, it is worthwhile to make an initial assumption that he has undergone the decline in health described here and that the extrinsic and intrinsic causes of his breakdown can be manipulated well enough to allow recovery of well-being and physical ability.

ABSTRACTS: ADDENDUM*

CORRECTIVE CARDIAC SURGERY IN INFANCY: PROFOUND HYPOTHERMIA AND CIRCULATORY ARREST TECHNIQUE

Aldo R. Castaneda, M.D., FACC & Alexander S. Nadas, M.D., FACC; The Children's Hospital Medical Center, Boston, Mass.

Correction of congenital heart defects in infancy is desirable and is facilitated by the technique of profound hypothermia and circulatory arrest. Forty-three infants underwent surface cooling and rewarming.

Correctable Lesions:

Lesions	# Patients	Op. Mortality
Ventricular Septal Defect	10	1
Tetralogy of Fallot	12	0
Atrioventricular Canal	4	1*
Transposition of Great Arteries	10	2
Intact Ventricular Septum	6	1
Ventricular Septal Defect	4	1*
DORV (type I)***	1	0
TAPVC****	1	0
	38	4 (10%)
Non-Correctable Lesions:		
DORV (type III)***	1	1
Truncus Arteriosus	2	2**
Cardiac Tumor	1	1
Pulmonary Venous Atresia	1	0
	5	4 (80%)
TOTAL	43	8 (18.5%)

*Prosthetic valve replacement.
**1. Complete atrioventricular canal, 2) Advanced PVO + truncal valve insufficiency (4+).
***Double outlet right ventricle.
****Total anomalous pulmonary venous connection.

Seventeen infants weighed less than 4 kg., the smallest child to survive corrective surgery was an 11 day old (2.2 kg) premature with tetralogy of Fallot. Details of the operative technique and postoperative care will be discussed.

SURGICAL ANATOMY OF OBSTRUCTING MUSCLE BANDS OF THE RIGHT VENTRICLE IN TETRALOGY OF FALLOT

F. S. Idriss, MD; M. Lev, MD, FACC; S. Bharati, MD; H. Nikaidoh, MD; A. J. Muster, MD, FACC; and M. H. Paul, MD, FACC, Children's Memorial Hospital, Chicago, Illinois.

We have studied 197 (118 unoperated and 79 operated) autopsied hearts with tetralogy of Fallot in order to categorize the various obstructing muscle bundles in the right ventricle and provide a practical and useful descriptive nomenclature. Using the center of the arch or crista supraventricularis as a reference, the obstructive muscle bundles were divided into three groups: septal, when the obstructing bands were maximal on the septal side of the arch; parietal, when on the parietal side; or combined. These were also described as above, at, or below the level of the crista. Of the 118 unoperated hearts there were 12 classified as having primarily the septal type of obstructive bundle, 30 as the parietal type and 65 as the combined type. In 11 hearts we observed the so-called excavated crista pathology where the arch was minimal or non-existent. Fourteen hearts exhibited, additionally, an aberrant muscle bundle that crosses from the septum to the parietal wall. Observations were made on the 79 operated postmortem hearts where some of the obstructive muscle bundles were not adequately identified and resected. This study will guide the surgeon toward a more complete removal of the obstructive pathology.

EFFECT OF MATERNALLY ADMINISTERED DIGOXIN UPON FETAL CARDIAC OUTPUT

Antonio Hernandez, MD; Arnold Strauss, MD; David Goldring, MD, FACC; Robert M. Burton, PhD, Washington University School of Medicine, St. Louis, Mo.

The effect upon the fetal left ventricular output, (LVO), of a chronically digitalized mother is unknown. Placental transfer of tritiated digoxin, (tD), when the drug is chronically administered to the ewe during the entire pregnancy in dosage equivalent to that in man was studied, and the short term preservation of LVO in the exteriorized fetus at the termination of the pregnancy was evaluated. Seven ewes were given 6 μg/kg body weight, (bw), of tD daily (20 per cent of total digitalizing dose 0.03/kg) bw for the entire pregnancy. The fetus was exteriorized between the 120 and 140 days of gestation and the LVO determined serially by dye-dilution technique for one hour. The ewe and its fetus were then killed, and the mean tissue concentrations in μg/gm for the ewes were: heart, 5.7 ± 1.76; liver, 3.38 ± 1.38; kidney, 41.9 ± 12.3. Corresponding values for the fetuses were: 1.55 ± 1.01; 0.78 ± 0.35; 2.48 ± 1.18. The mean serum level for the ewe at end of one hour was 1.65 ng/ml ± 0.48 and for the fetus 1.22 ± 0.20. The amniotic fluid contained 1.45 ng/ml ± 0.27. At the end of one hour the mean LVO had decreased by 39 per cent ± 15 of its control value. This study again confirms that tD crosses the placenta. Although the fetal serum level of tD was similar to that found in the mother and the amniotic fluid contained significant amount of tD, the fetal tissue concentration of tD was not sufficient to produce any demonstrable inotropic effect as measured by the LVO in contrast to acute administration of tD (0.03 mg/kg) bw which did preserve fetal myocardial function but the tissue levels of the fetus in this instance were greater by a factor of 10, (previously reported work from this laboratory).

OCCURRENCE OF ASYMMETRIC SEPTAL HYPERTROPHY (ASH) IN INFANCY.

Barry J. Maron, MD; Jesse E. Edwards, MD; Walter L. Henry, MD; Chester E. Clark, MD; and Stephen E. Epstein, MD, NHLI, Bethesda, Md.

Asymmetric septal hypertrophy (ASH) is a disorder of cardiac muscle characterized by disproportionate hypertrophy of the ventricular septum (ratio of septal to left ventricular free wall thickness >1.3) that appears to be transmitted as an autosomal dominant trait. Disorganization of cardiac muscle cells is a characteristic histologic feature of the disease. ASH has been recognized only rarely in early childhood and has not been documented in the first few months of life. It thus has not been considered among the causes of infant death. However, we have found ASH at necropsy in two male infants, aged 5 mos and 1-1/2 mos, and a male stillborn. The two infants had severe congestive heart failure; a loud systolic ejection murmur in both suggested the presence of outflow obstruction. Septal to posterobasal left ventricular free wall thickness ratios were 2.3 and 2.6 in the infants and 1.9 in the stillborn. Histologic examination of myocardium from the ventricular septum demonstrated morphologic abnormalities similar to those present in adult patients with ASH; muscle cells were markedly hypertrophied and small foci of abnormally oriented muscle cells were present. Numerous disordered bundles of hypertrophied muscle cells were interlaced among more normally arranged cell bundles. These morphologic findings were less marked or absent in the left and right ventricular free walls. Echocardiographic studies documented ASH in asymptomatic relatives of all three infants. These observations provide further evidence that ASH is a genetic disorder and indicate that the disease may be clinically manifest in infancy. Whether this disease is a rare or common cause of cardiac death in infancy is unknown.

*Abstracts from papers presented at the 23rd Annual Scientific Session of the American College of Cardiology, February 11–14, 1974. They should be added to those published in the January issue of the Journal (Am J Cardiol 33:121–180, 1974).

CARDIAC CATHETERIZATION AND SELECTIVE ANGIOGRAPHY IN INFANTS WITH A NEW FLOW-DIRECTED CATHETER.
David C.Schwartz, M.D., F.A.C.C., and Samuel Kaplan, M.D., F.A.C.C., Division of Cardiology, Children's Hospital, Cincinnati, Ohio 45229

The overall risk of serious complication during cardiac catheterization in infants less than 30 days of age is reported to be as high as 15%. Cardiac perforation during catheter manipulation and selective angiography accounts for the majority of deaths in this age group. It is the purpose of this presentation to report the development and use of a prototype flow-directed infant angiography catheter* which minimizes the occurence of these complications. This double lumen 5F 60 cm. cathter combines both the flow directed (gas filled balloon) features of the standard Swan-Ganz catheter with the highflow contrast delivery characteristics of the standard NIH infant angiography catheter. These features provide easy accessibility to all cardiac chambers and great vessels with virtually no risk of perforation and minimal arrhythmia as well as delivery of contrast at high flow rates through side holes proximal to the balloon for selective angiography of diagnostic quality without fear of intramyocardial injection. Preliminary experience with 16 infants demonstrates the value of this catheter in providing a safe and rapid method of R & L heart catheterization and selective angiography.

EARLY PRIMARY REPAIR OF TETRALOGY OF FALLOT
P. Venugopal, M.D., S. Subramanian, M.B., F.R.C.S.
Children's Hospital, Buffalo, New York

Thirty-three children under the age of five years who have undergone corrective surgery for Tetralogy of Fallot in the last four years are presented. In 22 children, (Grp.1) primary correction (no previous shunt procedure) was done with one death. There were no deaths in a group of eight infants under two years of age. Eleven children (Grp.2) underwent secondary correction after one or more shunts and there were two deaths in this group. There was little patient selection in Grp.1. All patients were moderately or severely cyanotic, some with cyanotic spells. In no instance was an acyanotic child operated to prevent "progression of the disease". The only contraindication to primary correction was hypoplasia of the pulmonary artery branches. Hypoplastic conus, severe infundibular stenosis and annular hypoplasia do not preclude primary corrective surgery. The youngest patient who underwent successful primary repair was five weeks old. It was observed in the infant group (<two years) that the major determinant of successful outflow repair was an annulus diameter >than 12 mm. If preliminary inspection and measurement of the annulus revealed a diameter <12mm., an outflow patch of pericardium was used.

Deep hypothermia and circulatory arrest in children 15Kg. in weight greatly facilitated the operative technic. Heart block was not encountered and outflow aneurysm was seen in only one patient who had residual distal obstruction.

It is proposed that primary correction rather than two stage operation should be offered to infants and young children with Tetralogy of Fallot in view of the acceptable mortality and lack of long term morbidity.

INTRAMYOCARDIAL PRESSURE: THE EFFECT OF PRELOAD ON THE TRANSMURAL DISTRIBUTION OF SYSTOLIC CORONARY FLOW
Joseph P. Archie, Jr., Ph.D., M.D., University of Alabama Birmingham, Alabama

Impairment of systolic coronary blood flow (CBF) may be mediated by intramyocardial pressure (P_{IM}). However, the effect of systole on the magnitude and transmural distribution of CBF has not been investigated. The purpose of this study was to measure this and indirectly P_{IM}. It is assumed that P_{IM} acts on the coronary vessels as a Starling resistor, such that local CBF is determined by the equation: $P_c - P_{IM} = R \cdot CBF$, where P_c is coronary perfusion pressure and R resistance. This equation was integrated with respect to time and solved simultaneously for P_{IM} and R by measuring regional CBF (radioactive microspheres) during maximal coronary vasodilitation in two states: beating and hypocalcemic diastolic arrest. Measurements were made in 7 to 16 concentric layers of the left ventricle (LV) of 16 dogs. P_{IM} ranged from near zero to twice peak LV pressure. The transmural distribution of P_{IM} and systolic CBF depended on preload. The transmural distribution of the ratio of P_{IM} to P_c was not significantly different from one across the LV wall at low preload (0-4mmHg). At moderate to high preload (7-35mmHg) in the inner two 1/5 of the LV wall this ratio was not different from unity (mean 1.03 and 0.96), but in the middle and two outer 1/5 this was significantly lower(mean 0.79, 0.64, 0.41 respectively). These data show that P_{IM} shuts off systolic CBF across the entire LV wall at low preload and at high preload P_{IM} determines a gradient of decreasing systolic CBF from the subepicardium to zero in the subendocardial layers. This suggests that dilated or failing LV receive systolic flow to the outer myocardial layers, where as, at low preload myocardial perfusion is entirely diastolic.

REGIONAL WALL MOTION ABNORMALITIES OF ACUTE MYOCARDIAL ISCHEMIA: EFFECTS OF CORONARY REPERFUSION WITH AND WITHOUT ALTERATIONS OF ARTERIAL PRESSURE AND HEART RATE.
Richard E. Kerber, MD, U of Iowa Hosp, Iowa City, Iowa.
The effect of alterations in blood pressure (BP) and heart rate (HR) on segmental dyskinesis induced by acute coronary ligation, and on the subsequent response to coronary reperfusion (CR) was evaluated in 77 open-chest dogs. Wall motion was recorded by ultrasound reflected directly off the ischemic muscle. Acute ischemia (I) produced characteristic regional wall motion abnormalities: aneurysmal bulging during isometric contraction and markedly reduced wall velocity (WV) during ventricular ejection. During 60 minutes of I the dogs underwent interventions to raise BP 25-50%: methoxamine (M), phenylephrine (P) or norepinephrine (NE); other animals had BP lowered 25-50% with nitroprusside (NP) or hemorrhage (H) during I, or underwent atrial pacing (AP) to increase HR 25-50%. A control group (C) underwent no intervention during I. During I WV was markedly reduced by M and improved by NE. After cessation of drugs and 60 minutes of CR the relative order of improvement of WV was: NE: 11+2 mm/sec (ischemia) to 24+3 mm/sec (reperfusion), C: 12+3 to 20+3, NP: 13+2 to 20+1, H: 10+2 to 18+2, AP: 14+1 to 20+2, PE: 9+1 to 9+2, M: 14+2 to 12+1. The aneurysmal bulging during isometric contraction also was reduced to a greater degree after NE than other interventions. The deleterious effects of increased afterload with M or PE thus outweighed the beneficial effects (increased coronary perfusion) and exacerbated the dyskinesis of the central portion of the ischemic area during the drug and after CR. NE, however, reduced dyskinesis, probably by decreasing ventricular size and wall tension. We conclude that elevation of BP, although known to reduce infarct size, may have deleterious effects on regional wall motion abnormalities depending on the pressor agent used.

THE RELATIONSHIP BETWEEN CORONARY PERFUSION PRESSURE, FLOW, AND RESISTANCE IN STENOSED HUMAN CORONARY ARTERIES: THE CRITICAL IMPORTANCE OF SMALL CHANGES IN % STENOSIS.

Samuel E. Logan PhD, John V. Tyberg MD, PhD, William W. Parmley, MD, FACC, H.J.C. Swan, MD, PhD, FACC. Cedars-Sinai Medical Center, Los Angeles, California 90029.

Nineteen proximal coronary arteries with varying focal stenoses (2%-98%) were dissected from fresh post mortem adult hearts and perfused with isotonic glycerol saline (n=2.7 centipoise) at constant pressures of 30, 50, 75, 100, 150 and 200 mmHg, while varying the distal bed resistance (r_b) over the range 0.1 to 5 mmHg/ml/min. Flow rate (Q) and arterial segment pressure drop (ΔP) were measured at each perfusion pressure and r_b, and a permanent cast of silicone rubber was made under 100 mmHg pressure following perfusion. Hydraulic resistance ($R=\Delta P/Q$) was proportional to a Poiseuillian scaling ($R_o \alpha 1/r^4$) at lowest flow rates (10-30 ml/min), with R increasing to 2 or 3 times R_o at higher flow rates (30-100+ ml/min). Curves of flow rates vs. % stenosis showed that flow rate was relatively constant with stenoses less than 70-80%. With a small further increase in stenosis, however, flow rate decreased dramatically. Furthermore, significant reductions in flow rate occurred at lower % stenoses for greater demands (lower r_b). Elastic effects were important in arteries with an eccentric lesion, in that an 80% eccentric stenosis had an additional flow loss of 5% (as compared to a concentric stenosis) when the perfusion pressure was lowered from 100 to 70 mmHg. In conclusion, small changes in % stenosis, perfusing pressure, or increased "demand" (decreased r_b) had dramatic effects on the pressure-flow relationship across focal lesions in human coronary arteries. These results have important implications relative to the quantitation of lesions on coronary angiograms, the alteration of perfusing pressure or changes in myocardial O_2 demand.

CAPILLARY AND CELL WALL PERMEABILITY TO POTASSIUM IN ISOLATED DOG HEARTS

Robert G. Tancredi, MD; Tada Yipintsoi, MD; James B. Bassingthwaighte, MD, Mayo Clinic, Rochester, MN.

From venous tracer-dilution curves recorded after 34 pulse injections of ^{42}KCl and ^{131}I-labeled albumin into the coronary artery inflow of six isolated canine heart preparations, we calculated maximal fractional extractions (E_{max}) and capillary permeability-surface area products (PS_{cap}) for K^+ over a range of plasma flows (F_p) from 0.4 to 1.6 ml min^{-1} g^{-1}. At low F_p (< 1.0), E_{max} was 0.56 ± 0.05 (mean ± SD) and PS_{cap} was 0.59 ± 0.18 ml min^{-1} g^{-1}; at high F_p (>1.0), E_{max} decreased to 0.47 ± 0.08 and PS_{cap} increased to 0.84 ± 0.22. Continuous recording (gamma detector) of residual $^{42}K^+$ in four additional hearts showed that the fractional escape rate of tracer became constant at 0.008 to 0.010 min^{-1} at 2 to 4 hours after injection. The cell wall and the capillary membrane are the primary barriers to $^{42}K^+$ washout from the sarcoplasm. Using PS_{cap} measured at various flows and considering the virtual intracellular volume of distribution for K^+ to be 20 ml/g, we calculated the permeability-surface area product for sarcolemma, PS_{cw}, as 0.18 to 0.29 ml min^{-1} g^{-1}. On the basis of sarcolemmal surface area (S_{cw}) of 4,200 cm^2 g^{-1} and capillary surface area (S_{cap}) of 500 cm^2 g^{-1}, cell permeability is very low, with $P_{cw}:P_{cap}$ being 0.02 to 0.06. We concluded that the cell membrane provides the major resistance to the exchange of K^+ between sarcoplasm and capillary blood.

INVESTIGATION OF THE MECHANISM OF THE INOTROPIC EFFECT OF HYPERTONIC MANNITOL IN ISOLATED CARDIAC MUSCLE AND OF MANNITOL'S INFLUENCE ON REGIONAL MYOCARDIAL BLOOD FLOW IN DOGS WITH MYOCARDIAL ISCHEMIA

James T. Willerson, MD, U. Tex. Southwestern Med. Sch. at Dallas, Dallas, Texas.

To further evaluate the potential ability of hypertonic mannitol (M) to improve myocardial performance and increase coronary blood flow the following studies were performed. Forty-five isolated isometrically-contracting cat papillary muscles were studied in Krebs-Ringers bicarbonate with 18 mM glucose and varying extracellular calcium concentrations. Six awake unsedated and 21 anesthetized dogs on right heart bypass (RHBP) with acute myocardial ischemia (AMI) were also evaluated. M (50 mOsm above control) significantly increased developed tension (DT) and the maximal rate of tension rise (dT/dt) in isolated cardiac muscle in 2.5 mM Ca but significantly depressed DT and dT/dt in 10 mM calcium. Norepinephrine (10^{-6} M), however, significantly increased DT and dT/dt in 10 mM Ca in the same muscles. D600 (10^{-6} M), a potent pharmacological inhibitor at the cell membrane of the intracellular transfer of calcium, decreased DT and dT/dt by 75% and completely abolished the inotropic effect of increasing stimulation rate (treppe) but did not alter M's inotropic effect. Paired pacing produced the same changes as M. Myocardial ischemia (AMI) was produced by 10 minutes of proximal LAD occlusion. Regional myocardial blood flow (RMBF) was measured using radioactive microspheres (8μ). In awake dogs M (20 mOsm above control) significantly improved ventricular performance and increased RMBF 30-50% to all myocardial areas. In anesthetized dogs on RHBP M significantly increased RMBF to the RV, the ventricular septum, the nonischemic LV, and the total LV by 30-40%. RMBF to the LV ischemic area significantly increased by 15%. The increases in RMBF in dogs on RHBP after M occurred without significant changes in cardiac output, heart rate, and mean arterial pressure. In awake, unsedated dogs with AMI M produced essentially the same increases in RMBF. These data suggest that the inotropic effect of M in isolated cardiac muscle is critically dependent on and linked to alterations in intracellular Ca and not significantly influenced by inhibition of cell membrane systolic Ca flux. M *in vivo* increases RMBF to all myocardial areas in awake and anesthetized dogs with AMI suggesting its potential ability to limit the area of AMI under physiological circumstances.

BOOK REVIEWS

MYOCARDIAL BLOOD FLOW IN MAN, METHODS AND SIGNIFICANCE IN CORONARY DISEASE, edited by A. Maseri. Torino, Minerva Medica, 1971, 576 pages

This volume consists of the proceedings of an international symposium drawing together recognized experts to discuss methods in research into myocardial blood flow. Published under the auspices of the World Health Organization, it represents the latest sum of knowledge and opinions up to June 10, 1971—the time the conference was held. It is an excellent reference for advanced students of the subject who plan to utilize these methods in clinical studies. It is not recommended for the general practicing physician, medical student or even the cardiologist who is not one of the limited group of experts familiar with the methodology, mathematics and language of this important aspect of cardiologic research. Since there is no systematic attempt to begin from the beginning, the papers are, by and large, intelligible only to those who already have considerable basic knowledge and experience within the field.

A major section is devoted to theoretical and technical problems in myocardial blood flow measurement in man. There is an excellent paper by K. L. Zierler in this section concerning the mathematical analysis of assumptions and limitations of the measurements of absolute flow, outflow detection, relative blood flow by residue detection and external monitoring by cinedensitometry. The application of these methods to evaluation of the patient with coronary disease is also treated in papers on use of the nitrous oxide method, xenon clearance, thermistor method of detection of coronary sinus outflow, among others. Methods of studying and quantifying blood flow inhomogenity within the myocardial wall are presented, and the singular significance of this aspect of coronary blood flow is emphasized. Overperfusion of relatively normal myocardial vascular beds can conceal the presence of underperfusion of diseased areas when total flow alone is measured. Finally, there is a roundtable on the clinical correlation of ischemic heart disease, and the present methods of study and guidelines for future research are summarized by Dr. L. Donato after an extensive discussion by Drs. G. Baroldi, R. J. Bing, R. Gorlin, D. E. Gregg, M. McGregor, M. F. Oliver, A. Schwartz, E. H. Sonnenblick, E. Varnauskas and K. L. Zierler.

President's Page

It is with pleasure and satisfaction, but with a sense of overwhelming humility, that I shall attempt to fill the shoes so recently worn by Dr. H. J. C. Swan. They are big shoes—they were worn many miles for the College—and because they were worn by Dr. Swan the College is the better and has gained in stature and prestige on the scene of American medicine. The College shall always be in debt to Dr. H. J. C. Swan because he was President in 1973–74.

The restraints of journalism are such that this letter for the March issue of the Journal was due January 5. (At that time H. J. C. was still President and as President-Elect I was still able to "let him do it.") But it is not inappropriate that this first letter as President be composed on New Year's Day.

I am not a seer and cannot predict what will be our lot in March 1974. But on this New Year's Day one cannot help but be a bit concerned for the future. The year 1973 has seen the overwhelming vote of confidence in our national leadership vanish with the resignation of the Vice-President, who preferred not to contest the truthfulness of charges; the evidence that power might well have been ruthlessly used for no other purpose than acquiring more power; the decline of confidence in our chief executive on the domestic front despite rather remarkable accomplishments in some sectors of the international front. 1973 was a year in which the social and the political fiber of our country was stretched to and beyond the breaking point. If this was not enough, as a nation we were forced to recognize that we were no longer the master of our economy but that our purse strings could be controlled by others if for no other reason than military gains. These and other events prompted Jack Anderson to report in his syndicated column of January 1, 1974: "There is a strong feeling that it is up to the American people to bail the country out of its difficulties because the leadership in government cannot do it."

It is into the unknown of 1974 that I must wear the shoes of the President of the American College of Cardiology. When I turn them over in 1975 to the President Elect, Dr. Charles Fisch, they will be worthy of wearing only if you have helped during 1974.

In the past it has been proper for the President of a distinguished medical organization such as the American College of Cardiology to enunciate at the beginning of his term how the profession has been wronged and what he proposes to do about it. Future letters in the Journal shall be devoted to the personal problems of the College and its membership: Heart House, PSRO, third party payment, fellowship training, research support, and the like. But now is the time for bigger concerns—concerns outside our usual interests. Now is the time for physicians, for cardiologists, to think and act as citizens individually and collectively to provide the leadership this country so desperately needs.

The individual and collective freedoms that we have cherished and have grown accustomed to are being challenged. Now is the time for men and women of integrity, dedication, vision and good will to come to the fore and contribute to the betterment of their city, their state, their nation and their world. Since the founding of our country, physicians have assumed roles of leadership. If ever such leadership was needed, it is now. So I challenge the Fellowship of the College—the entire membership of the College—to think beyond their practice, their laboratory, their institution to their city, their state and their nation. I challenge the members of the College to identify something that they can do as citizens to assume leadership in community projects, right wrongs and set examples of decency and dedication. I give to you, as I gave to the College at the Convocation in New York, the challenge enunciated in 1960 by the late John F. Kennedy: "Ask not what your country can do for you but what you can do for your country."

The College is over 6,000 strong. Each member is a leader in his own right, but each was selected from many and is a physician because of the efforts and financial sacrifices of many; each owes a debt to society and now society is looking to its doctors for leadership. There is a time for doctors to be vocal about PSRO, HMO and Phase 4 restrictions, but I urge each member of the College to extend his interests and efforts beyond these personal concerns and look to the broader needs of society as a whole. For "there is a strong feeling that it is up to the American people to bail the country out of its difficulties because the leadership in government cannot do it."

Will you not dedicate yourself despite the pressures of practice, the laboratory and teaching to devote a bit of time each day to improving the lot of society as a whole in areas quite remote from medicine? If you do, the image of the College and of medicine will glow brighter in 1974 than it ever has before.

1974 will be a year of decision. Jack Anderson wrote, "Two sets of alternatives lie ahead of us. Decline can result in search either for scapegoats or self-knowledge. The collapse of illusions can bring either panic or maturity, the fall of idols either demoralization or resilience. Defeat can bring on a retreat into destructive egocentrism or a quest for a wider and truer communion."

Which will it be? Will the American people bail the country out? Knowing the membership of the College I know that we can, but will we? We can and we will if we devote our efforts beyond our own self-centered interests. We can and we will if we maintain the optimism of leaders in our College such as George Griffith who, when opening the William Likoff Symposium last December in New York, quoted William Allen White, and said "I am not afraid of tomorrow, for I have seen yesterday and am in love with today."

Calendar of Continuing Medical Education Programs

The National Committee for Continuing Medical Education, William Likoff, MD, FACC, Chairman, announces the following calendar of programs.

Each program is designed to enlarge knowledge and clarify the endlessly changing frontiers which mark scientific achievements in the recognition and treatment of cardiovascular disease. Although the disciplined objective of each program as well as its content, format and faculty are primarily determined by the Program Director, the National Committee for Continuing Medical Education always exercises the prerogative of final review and approval, whether the program is sponsored solely by the College or in collaboration with universities, colleges, hospitals and other professional societies.

Subject matter reflects national interest and needs in the fields of patient care, research and teaching. The program structures vary in method of education.

The National Committee for Continuing Medical Education of the College earnestly solicits the interest of member and nonmember physicians alike in continuing education for the clear reason that participation provides a unique opportunity to deepen one's understanding of heart disease, the most formidable and challenging health problem of our time.

Programs and faculty are subject to change. For further information write Mary Anne McInerny, Director, Department of Continuing Education Programs, American College of Cardiology, 9650 Rockville Pike, Bethesda, Md. 20014.

MARCH TO JUNE, 1974

MAR. 18–22 **Consultant's Course in Cardiology.** Simon Dack, FACC, director. Mt. Sinai Medical Center, New York, N. Y.

MAR. 21–23 **Core Curriculum: Pathology of the Heart.** Maurice Lev, FACC, and Jesse E. Edwards, FACC, directors. Palmer House, Chicago, Ill.

MAR. 25–27 **Electrocardiographic Interpretation of Arrhythmias: A Physiological Approach.** Charles Fisch, FACC, director. Indiana University Medical Center, Indianapolis, Ind.

MAR. 28–30 **High Blood Pressure—When and How To.** Robert S. Eliot, FACC, director. Gerald L. Wolf and Francis L. Land, co-directors. University of Nebraska Center for Continuing Education, Omaha, Nebr.

APR. 1–10 **Cardiology for the Consultant: A Clinician's Retreat.** E. Grey Dimond, FACC, director. Rancho Santa Fe Inn, Rancho Santa Fe, Calif.

APR. 4–6 **Advances in Clinical Cardiology.** Lawrence S. Cohen, FACC, director and Alfred L. Aronson, William W. L. Glenn, FACC, Allan V. N. Goodyer, FACC, Norman S. Talner, FACC and Steven Wolfson, FACC, co-directors. Yale University School of Medicine, New Haven, Conn.

APR. 17–19 **Core Curriculum—Vectorcardiography (A Basic Workshop).** Alberto Benchimol, FACC, director. Scottsdale Hilton Hotel, Scottsdale, Ariz.

APR. 22–25 **Current Concepts in Cardiology—1974.** Philip R. Akre, director and John A. Bowers and Masato Takahashi, FACC, co-directors. MGM Grand Hotel, Las Vegas, Nev.

MAY 6–9 **The Recognition and Management of Coronary Syndromes.** J. Willis Hurst, FACC and Robert C. Schlant, FACC, directors. Royal Coach Motor Hotel, Atlanta, Ga.

MAY 9–11 **The Ventricular Ectopic Beat: Heart-throb or Harbinger of Death.** Bernard Tabatznik and J. O'Neal Humphries, FACC, directors. Cross Keys Inn, Baltimore, Md.

MAY 15–17 **Clinical Auscultation of the Heart.** W. Proctor Harvey, FACC, director. Georgetown University School of Medicine, Washington, D. C.

MAY 17–19 **Core Curriculum: Rationa Drug Therapy in Cardiovascular Disease.** Robert J. Lee, PhD., director. The Nassau Inn, Princeton, N. J.

MAY 23–25 **Cardiologist's Appraisal o Operable Heart Disease.** Arthur Selzer, FACC and Keith E. Cohn, FACC, directors St. Francis Hotel, San Francisco, Calif.

JUNE 6–8 **Core Curriculum in Echocardiography: New Developments in Cardiac Ultrasound.** Arthur D. Hagan, director and Robert A. O'Rourke, FACC, co-director. Town and Country Hotel, San Diego, Calif.

New Members Elected

The following individuals were elected to membership in the American College of Cardiology on November 5, 1973 in the category indicated.

INSTRUCTIONS FOR AUTHORS

The editors and publishers of THE AMERICAN JOURNAL OF CARDIOLOGY welcome concise articles devoted to cardiovascular disease. Articles must be contributed solely to THE AMERICAN JOURNAL OF CARDIOLOGY and become the property of the Publisher. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced in any form without the written permission of the Publisher. Statements in articles are the responsibility of the authors. Authors will assist the editors in the prompt processing of manuscripts if these instructions are followed:

THE WHOLE PAPER

- **Address manuscript** to Simon Dack, MD, American Journal of Cardiology, 666 Fifth Ave., New York, NY 10019.
- **Submit two copies** of all elements of the article: text, references, legends, tables and figures.
- **Arrange the paper** in this order: (1) title page; (2) abstract; (3) text; (4) references; (5) legends; (6) tables; and (7) figures.
- **Number all pages** in above sequence, beginning with title page as 1, abstract as 2, etc.
- **Type all matter:** (1) on 8½ × 11 opaque white bond paper; (2) in duplicate; (3) on **one side** of each sheet only; (4) double-space; (5) leave wide margins, all four sides.

THE TITLE PAGE

- **Number title page** as page 1.
- **Include first names,** degrees and, where applicable, FACC for all authors.
- **Insert at bottom:** name and address of institution from which work originated plus information about grants.
- **Add at bottom** the phrase "Address for reprints: . . ." followed by full name and address with zip code.

THE ABSTRACT

- **Limit words as follows:** 100 to 250 words for major articles; 50 to 100 words for case reports.
- **Add at end of abstract:** an alphabetical list of 2 to 6 key words and subjects for indexing.

THE TEXT

- **Number pages** in sequence after abstract.
- **Type in duplicate;** double-space.
- **Do not use abbreviations** such as SVC, WPW: write out; superior vena cava, Wolff-Parkinson-White.

Abbreviate measurements (mm, kcal and the like) as recommended in the Style Manual for Biological Journals, American Institute of Biological Sciences, 3900 Wisconsin Avenue, N.W., Washington, D. C.

- **Cite in numerical** order every reference, figure and table. (Order of mention in text **determines the number** given to each.)
- **Place acknowledgments** at end of text, before references.

THE REFERENCES

- **Type in duplicate;** double-space.
- **Place immediately** after text, and number pages in sequence after text page numbers.
- **Number the references** in order in which they are mentioned in text.
- **Follow the general** arrangement, abbreviations and punctuation styles shown below.

THE FIGURE LEGENDS

- **Start at top** of new page.
- **Type in duplicate;** double-space.
- **Number pages** in sequence after last page of references.
- **Identify at** the end of each legend and **in alphabetical order** all abbreviations in the figure described.

THE TABLES

- **Start each** table at top of new page.
- **Type in duplicate;** double-space.
- **Number pages** in sequence after last page of legends.
- **Give each table** a number (in roman numerals: Table I, II, etc.) and a title. Number the tables in order in which they are mentioned in the text.
- **Provide a footnote** to each table—identifying **in alphabetical order** all abbreviations used.

THE FIGURES

- **Submit 2 glossy prints** (not originals) of each photo and drawing.

Please note that art work of published articles will not be returned.

- **Use black ink** for all charts (line drawings). Make decimals, broken lines, etc. strong enough for reproduction.
- **Use arrows** to designate special features.
- **Crop photomicrographs** to show only essential field.
- **Identify figures** on back by number and author's name.
- **Number figures** in order in which they are mentioned in the text.
- **Indicate top** of each figure.
- **Submit written permission** from publisher and author to reproduce any previously published figures.
- **Limit figures** to number necessary for clarity. The publisher allows a limited sum toward reproduction.

Examples of Styles of References

For periodicals, follow INDEX MEDICUS:

31. Bellet S, Feinberg LJ, Sandberg H, et al: The effects of caffeine on free fatty acids and blood coagulation parameters of dogs. J Pharmacol Exp Ther 159: 250-254, 1968

(Author: please note that no periods are used after authors' initials.)

For books (edited by other than author of article):

28. Schiebler GL, Van Mierop LHS, Krovetz LJ: Diseases of the tricuspid valve, chap 20. In, Heart Disease in Infants, Children and Adolescents (Moss AJ, Adams F, ed). Baltimore, Williams & Wilkins, 1968, p 134

For books (with identical author and editor):

36. Berne E: Principles of Group Treatment. New York, Oxford University Press, 1966, p 26

(Author: all book references should have specific page numbers)

Ready This Fall

THE AMERICAN JOURNAL OF CARDIOLOGY 5 YEAR CUMULATIVE INDEX*

Covers all material published in THE AMERICAN JOURNAL OF CARDIOLOGY from January 1968 through December 1972.

- **CLINICAL STUDIES**
- **EXPERIMENTAL STUDIES**
- **SYMPOSIA**
- **REPORTS ON THERAPY**
- **REVIEWS**
- **SEMINARS**
- **CASE REPORTS**
- **DIAGNOSTIC SHELF**
- **HISTORICAL MILESTONES**

Includes Author Index—and—Subject Index

All subjects are cross indexed for quick and easy reference

*There is a limited supply of the 10 Year Cumulative Index available—January 1958 through December 1967. —Price $10.00. While supply lasts order both for only $15.00.

Please use order form below.

THE AMERICAN JOURNAL OF CARDIOLOGY
P. O. Box 1172, Radio City Station, New York, N. Y. 10019

Send me THE AMERICAN JOURNAL OF CARDIOLOGY Cumulative index or indexes as checked below.

Enclosed is my check for $8 ☐ for 5 YEAR CUMULATIVE INDEX 1968–1972
Enclosed is my check for $10 ☐ for 10 YEAR CUMULATIVE INDEX 1958–1967
Enclosed is my check for $15 ☐ for both the 5 and 10 YEAR CUMULATIVE INDEXES

Today's best reason to consider our monitoring systems: tomorrow's needs.

When it comes to monitoring equipment decisions, perhaps it's not enough to learn that General Electric has been around for some time. More important than stability is the assurance that GE will continue as the innovator in monitoring systems, and make these concepts readily available to present users.

The specifics:

Today, GE offers a broad spectrum of monitoring configurations to serve in ICU/CCU, and surgery.

In addition, a mobile system can be wheeled to any care area to alleviate patient loads in outpatient or emergency units. And GE Telemetry can monitor and transmit ECG data from ambulatory patients —enabling you to evaluate heart activity during the still-crucial period prior to patient release.

Tomorrow, General Electric's new Patient Data System, a third generation monitoring concept, will put more kinds of patient data at your fingertips. Computer integration can provide the recall of patient parameters from the previous 1, 4, 8 or 24 hours; the generation of complex derived parameters relating to the cardiovascular and respiratory system; and more sophisticated alarm schemes to indicate proper intervention based on data you've programmed-in.

Yet PDS can provide derived patient information without a computer. Bedside and nurse station displays present dynamic waveforms, derived parameters, alarm limits, physiological alarms, trend graphs, and multiparameter plots of patient data. Computer integration, but not dependency. It's the unique reason PDS is designed to meet both immediate, basic monitoring requirements and also extremely sophisticated long-term needs.

Today's monitoring systems.
With the prerogative of upgrading
to tomorrow's when you desire.
More incentive to see your GE
representative about upcoming
monitoring requirements now.
General Electric Medical Systems,
Milwaukee, Toronto, Liege, Madrid

BOOKS FOR YOUR WORKING LIBRARY

CARDIAC ARRHYTHMIAS: PRACTICAL ECG INTERPRETATION

By Steleio Mangiola, M.D., and Michael G. Ritota, M.D., F.A.C.P.

Using a unique graphic style, this new book provides a logical, simplified and sequential method of interpretation in which each arrhythmia is presented conveniently on facing pages: left hand pages have full-size tracings with ECG criteria and analytical Lewis Ladder diagrams; right hand pages illustrate the arrhythmia with 3–8 tracings. Magnified detail focuses attention on key features, and arrhythmias are presented in terms of atrial, nodal and ventricular components. An introductory chapter reviews the electro-physiology and anatomy of the heart with explanatory diagrams. Another presents Artificial Pacemaker Rhythms. A self-testing chapter is included.

about 225 pages / about 412 illustrations / 1974 / about $20.00

ESSENTIALS OF PEDIATRIC CARDIOLOGY

By Dennis J. Vince, M.D., F.R.C.P. (C)

This is a practical, down-to-earth exposition of the current state of the art in the management of youngsters with disorders of the cardiovascular system. Problems covered are those of daily concern to the practitioner, and much emphasis is devoted to development of clinical data based on the physical examination. Content covers clinical assessment, identification of functional disturbance, pathogenesis of functional disturbance, and treatment.

256 pages / illustrated / 1974 / soft cover, about $9.75

PRACTICAL PEDIATRIC ELECTROCARDIOGRAPHY

By Arthur J. Moss, M.D., and George C. Emmanouilides, M.D.

Knowledge essential to registering and interpreting pediatric ECGs is presented pictorially, and in outline, in this new work. An abundance of ECG tracings and diagrams in actual size illustrate normal and abnormal pediatric heart conditions. Topics include the PQRSTU cycle, electrical axis, disorders of rate and rhythm, ventricular hypertrophy, atrial enlargement and myocarditis.

148 pages / 150 illustrations / 1973 / $17.00

DIAGNOSTIC ELECTROCARDIOGRAPHY

By Michael C. Ritota, M.D., F.A.C.P.

Basic electrocardiography is presented as a working tool for the clinician in this concise, clearly written guide. Nearly 40 of the most common and important patterns are depicted in large illustrations and succinct text. Underlying pathology is explained and lists of essential criteria are included.

174 pages / 227 illustrations / 1969 / $15.00

Please send me the following books:

- ☐ CARDIAC ARRHYTHMIAS . . . . . about $20.00
- ☐ ESSENTIALS OF PEDIATRIC CARDIOLOGY . . . . . about $ 9.75
- ☐ PRACTICAL PEDIATRIC ELECTROCARDIOGRAPHY $17.00
- ☐ DIAGNOSTIC ELECTROCARDIOGRAPHY $15.00
- ☐ PAYMENT ENCLOSED ☐ CHARGE AND BILL ME

NEWS FROM THE AMERICAN HEART ASSOCIATION

VOLUME AUTHOR INDEX

VOLUME SUBJECT INDEX

Before treatment of hyperlipidemia can begin, you have to

detect the suspect.

ICN UML offers you a choice of five ways to detect and classify hyperlipidemia suspects

Serum Lipid Profile—consists of cholesterol and triglycerides, plus lipoprotein electrophoresis and classification.

Serum Lipid Screen—includes cholesterol, triglycerides and electrophoresis option.

Serum Lipids—consists of total lipids, triglycerides, cholesterol and phospholipids.

Five standard profiles—with triglyceride and electrophoresis options.

Individual tests—triglycerides; cholesterol.

and ICN UML is one of the few clinical laboratories in which electrophoretic classification is backed up by analytical ultracentrifugation.

THE BROADMOOR, April 15, 16 and 17, 1974
COLORADO SPRINGS, COLORADO

In view of the growing impact of ultrasound in cardiology and the lack of adequate training facilities, we are happy to announce a course in diagnostic echocardiography. This will be an informal seminar and workshop series to focus on the practical aspects, clinical uses and new techniques of diagnostic ultrasonics. Emphasis will be on the actual use of ultrasound and will provide supervised training conducted by physicians and technicians well versed in ultrasonic procedures. Only a limited number of registrations will be accepted to allow opportunities for participants to practice performing actual ultrasonic examinations.

For program and registration information, write or call:

ULTRASONIC SEMINAR

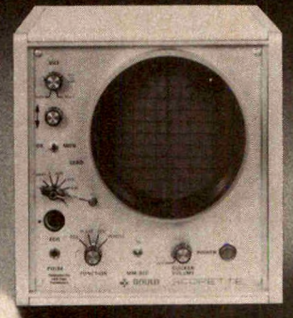
(303) 343-8330

The Gould Scopette Cardioscope. The workhorse of thousands of hospitals.

In hospitals all over the world, the Gould Scopette has proven its dependability for OR, ER, ICU, and CCU monitoring.

It comes with built-in ECG and pulse preamplifiers, bright traces for maximum visibility, simplified controls for easy operation, and a lot more.

Write Gould Inc., Instrument Systems Division, 3631 Perkins Avenue, Cleveland, Ohio 44114. Or Kouterveldstraat Z/N, B 1920 Diegem, Belgium.



GOULD

The Brush 481. An 8-channel recorder with built in signal conditioners.

The Brush 481 is ideal for a wide range of scientific and industrial applications.

It has our exclusive pressurized ink writing system for crisp, clear traces, built in signal conditioners, an assured 99.5% linearity, 12 pushbutton chart speeds, and a whole lot more. It comes in rack mounting or portable models with accessories to fit your needs.

Let us tell you more. Write Gould Inc., Instrument Systems Division, 3631 Perkins Avenue, Cleveland, Ohio 44114. Or Kouterveldstraat Z/N, B 1920 Diegem, Belgium.

New Clinical Knowledge in the Mechanism,
Recognition and Therapy of Arrhythmias

Symposium on

ELECTROPHYSIOLOGIC CORRELATES OF CLINICAL ARRHYTHMIAS

Guest Editor: Charles Fisch, MD, FACC, Indiana University Medical Center

Contributions by prominent specialists from universities and medical centers across the country.

Presents examples of arrhythmias with mechanisms that have been deduced by analysis of clinical tracings and are being confirmed by electrophysiologic studies.

Originally published in the September, October and November 1971 issues of THE AMERICAN JOURNAL OF CARDIOLOGY—a $15.00 value—**now available to you under one cover for only $8.00.**

Papers include: Automaticity and Automatic Rhythms . . . The Concepts of Reentrant Activity Responsible for Ectopic Rhythms . . . Atrial Fibrillation . . . Ventricular Fibrillation . . . Atrioventricular Block . . . Aberrancy: Electrophysiologic Aspects . . . Exit Block . . . Concealed Conduction . . . Specialized Tissues and Preferential Conduction in the Atria of the Heart . . . Contribution of His Bundle Recordings to the Understanding of Clinical Arrhythmias . . . Wolff-Parkinson-White Syndrome. A New Look . . . Artificial Pacing of the Human Heart. Its Contribution to the Understanding of Arrhythmias . . . The Electrophysiologic Effects of Antiarrhythmic Drugs . . . The Postextrasystolic T Wave Change.

The Honeywell patient care commitment...

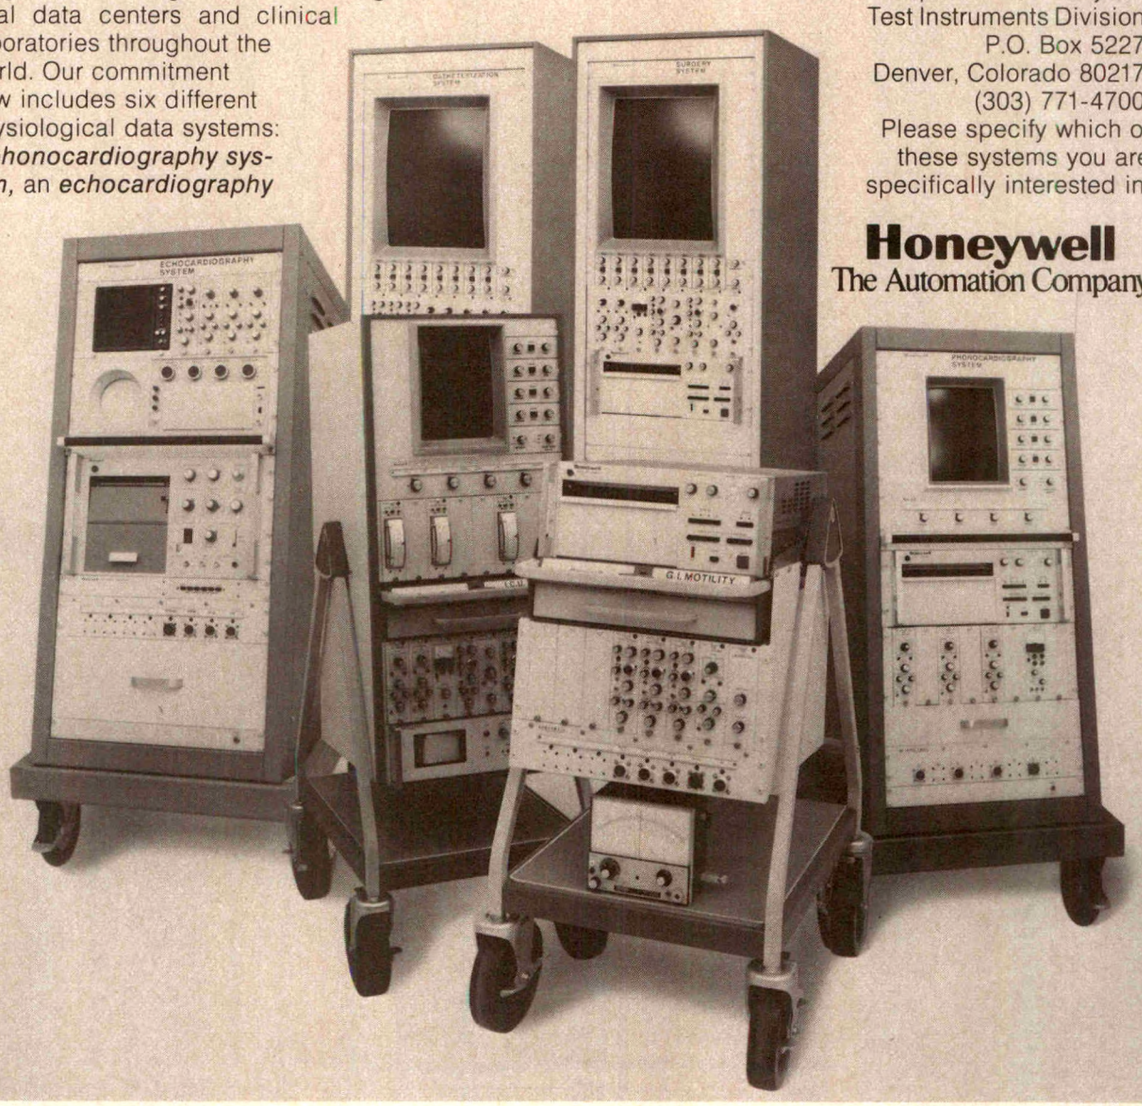
Yesterday, today, and tomorrow.

Yesterday. The Honeywell patient care commitment began more than 15 years ago, when we first offered products and systems for biomedical application. Even back then, Honeywell recognized the fact that physiological data systems should consist of more than just good hardware. And that our commitment to you and to better patient care must be total.

Today. Today, Honeywell products for health care can be found in cardiovascular diagnostic, surgical monitoring facilities, hospital data centers and clinical laboratories throughout the world. Our commitment now includes six different physiological data systems: a *phonocardiography system,* an *echocardiography system,* a *catheterization system,* a *surgery system,* a *surgical intensive care system* and a *G.I. motility system.* Each of these was designed to fit a specific area or application, and are all backed by the Honeywell commitment. Which means that they have been medical-engineered and are supported by Honeywell application specialists – to assist you in configuring them – by professional training for your people in their use, and by a comprehensive service program.

Tomorrow. Tomorrow's biomedical monitoring systems are being designed and built now in Honeywell R/D facilities...to make your job easier, to make diagnosis more accurate and to help ensure even better patient care. When these systems are ready to be released, they, too, will be backed by the Honeywell *total* commitment.

To get more information on the Honeywell biomedical systems mentioned above, please call or write: Peter Hamilton, Biomedical Products Department, Honeywell Test Instruments Division, P.O. Box 5227, Denver, Colorado 80217, (303) 771-4700. Please specify which of these systems you are specifically interested in.



Honeywell
The Automation Company

BLOOD FLOW

for clinical applications

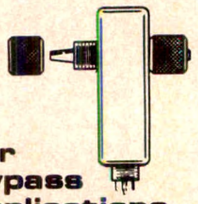
- Designed for clinical O.R. or cath lab use
- Easily applied handle-type probe
- Patient safety assured through isolation circuitry
- Simple to operate - minimum controls - direct meter readout in milliliters per minute

FLOW PROBES

for clinical applications

- Convenient, handle-type probe with positive capture slide
- Designed for O.R. and cath lab use
- For rapid analysis of flow through exposed blood vessels
- Use with Biotronex clinical blood flowmeter

FLOW PROBES



for bypass applications

- Use with heart-lung machine, artificial kidney or similar systems
- Iron core construction provides high sensitivity and accuracy
- Operates with BLI research and clinical blood flowmeters
- Available in sizes to fit most tubing

BLI **Biotronex Laboratory, Inc.** 9153 Brookville Road Silver Spring, Maryland 20910 Phone: 301/588-6400

portable
ECG PLUS...

EEG
PRESSURES
TEMPERATURE

4-Channel Medilog records ECG plus three other patient parameters for 24-hour period on one C120 cassette

- Data Reduction—SEPARATE UNIT replays 24-hour day into 24 minutes in analog form compatible with rapid writer, computer or Medilog Display System
- TINY—does not interfere with normal activity; weighs less than 1 lb.
- Portable—Battery Operated
- Automatic Analysis—for arrhythmia, ST-segment, histogram, etc. in separate unit

Medilog is a complete physiological data acquisition system with 4 channels, any of which can be dedicated to ECG, allowing related and comparative data to be collected and correlated.

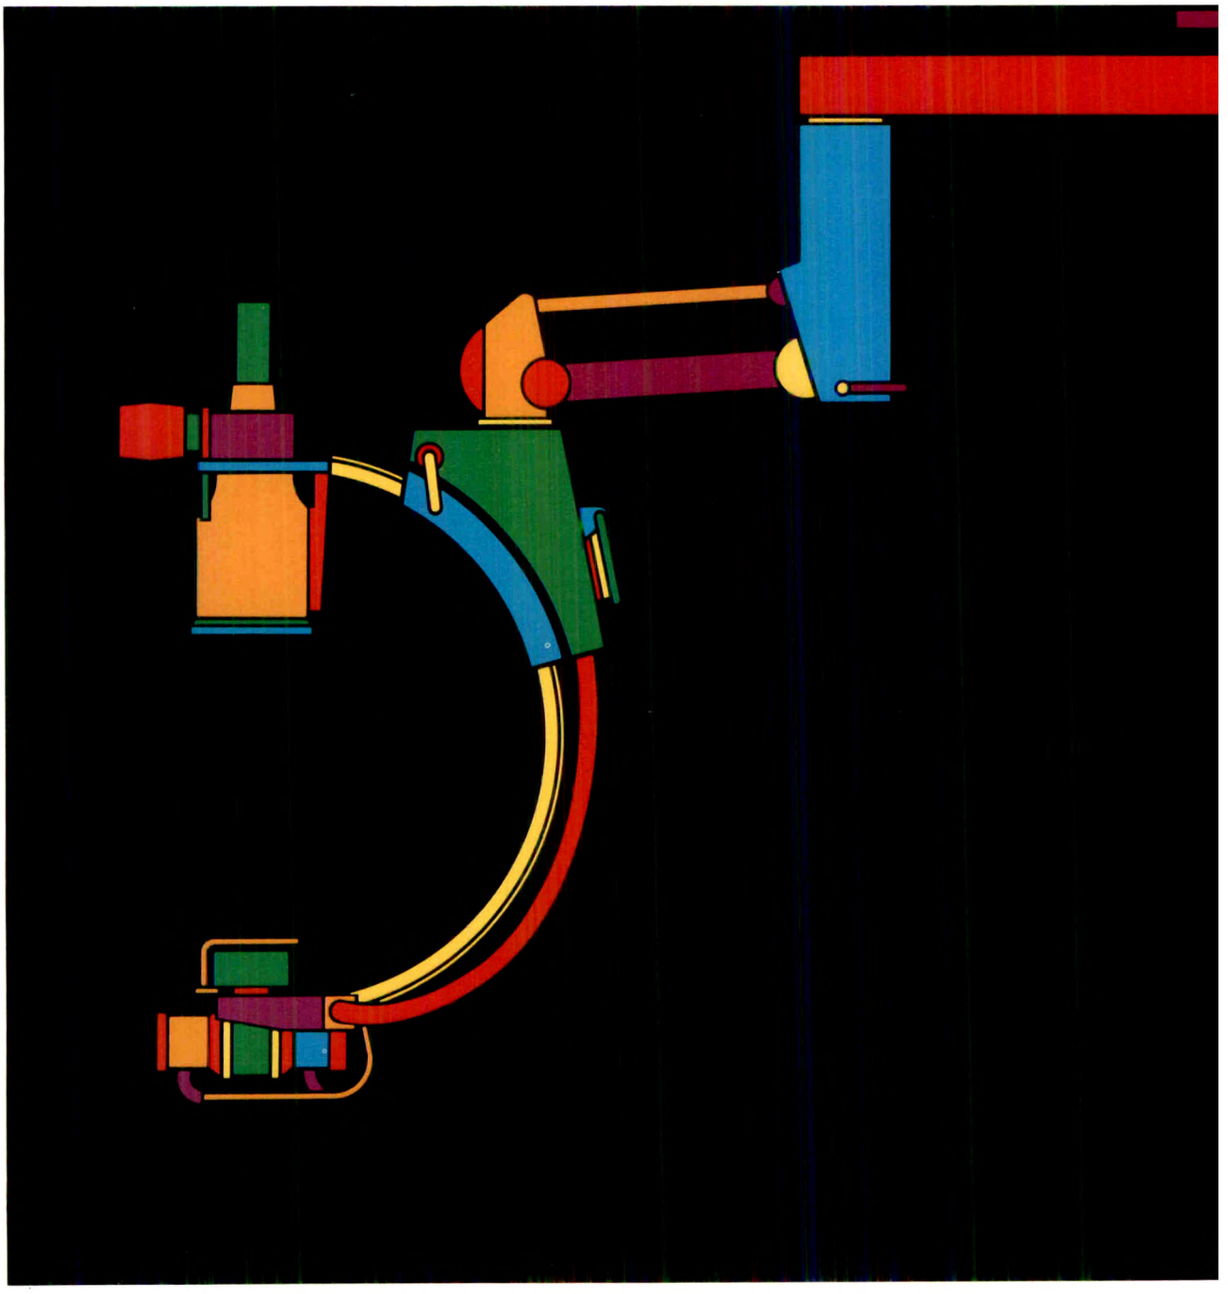
PHILIPS®

® TM N.V. Philips of Holland

You can opacify the coronary vessels while still in the OR

The Philips Diagnost OP is an x-ray system *designed* for the operating room—not *adapted* to it!

Once you've completed a coronary procedure (such as a vein by-pass), the



Diagnost OP allows you to demonstrate contrast media injections by brilliant image-intensified fluoroscopy and 70 mm rapid sequence films.

The OP parks far away from the surgical table when not in use, so you hardly know it's around. When you need it, it moves just as conveniently into place—but without ceiling tracks or undraped cables to carry any dust to the sterile field.

If ever there was a way to get excellent films of the coronary vessels during or immediately following surgery . . . this is it!

Write for more information.

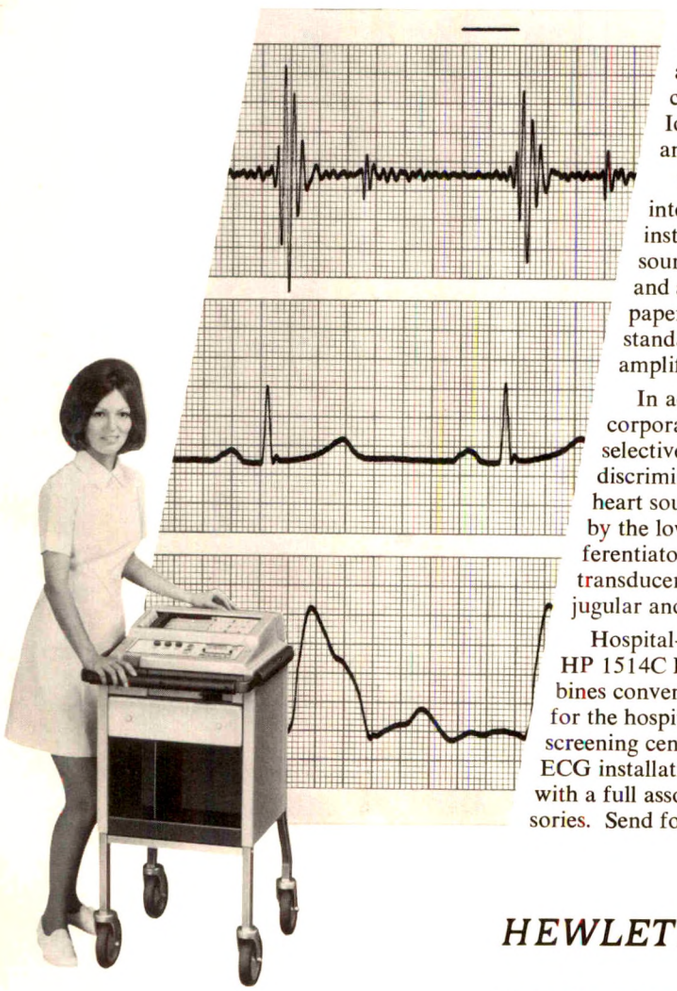
ECGs, PCGs and STIs with one easy-to-use instrument.



It's the new HP 1514C ECG/Phono/Pulse System. A new three-channel cardiograph that automatically records, marks and calibrates a complete 12-lead cardiogram in 10 seconds. Ideal for successive cardiograms before, during and after exercise.

You get complete, non-invasive systolic time interval studies on-the-spot. For example, the instrument can simultaneously record a heart sound on channel one, an ECG on channel two and a carotid pulse on channel three. The new paper drive provides 100 mm/sec as well as the standard chart speeds. And a new heart sound amplifier detects even subtle heart murmurs.

In addition, this easy-to-use instrument incorporates many important features such as selective heart sound filtering which helps you discriminate murmurs and other high frequency heart sounds that might otherwise be masked by the low frequency components . . . a differentiator for the pulse waveforms . . . plus transducers specifically designed for carotid, jugular and apex recordings.

Hospital-rugged yet office-practical, the new HP 1514C ECG/Phono/Pulse System combines convenience with valuable diagnostic help for the hospital heart station, outpatient clinic, screening center, cardiologist's office, or any ECG installation. Complete and ready to run with a full assortment of transducers and accessories. Send for our brochure No. 3658.

"The drug of choice for oral replacement of potassium is potassium chloride solution."

AMA Drug Evaluations 1971, First Edition, Chicago, American Medical Association, p. 121.

Kay Ciel® Elixir is potassium chloride... tastes good too!

COMPOSITION: Each 15 cc. (one tablespoonful) contains potassium chloride 1.5 Gm., supplying 20 mEq. of elemental potassium, in a cherry-flavored, palatable base, alcohol 4%. Contains no sugar.
INDICATIONS: Treatment of potassium deficiency occurring especially during thiazide diuretic or corticosteroid therapy, digitalis intoxication, low dietary intake of potassium or as a result of excessive vomiting and diarrhea.
CONTRAINDICATIONS: Impaired renal function, untreated Addison's Disease, dehydration, heat cramps, and hyperkalemia.
PRECAUTIONS: Potassium chloride should be administered with caution and adjusted to the requirements of the individual patient, since the amount of deficiency and corresponding daily dose is often not known. Excessive or even therapeutic dosages may result in potassium intoxication. Patients should be frequently checked and periodic ECG and/or plasma potassium levels made. High plasma concentrations of potassium ion may cause cardiac depression, arrhythmias or arrest. Use with caution in patients with cardiac disease. In hypokalemic states, attention should be directed toward the correction of the frequently associated hypochloremic alkalosis.
SIDE EFFECTS: Vomiting, nausea, abdominal discomfort and diarrhea may occur. Symptoms and signs of potassium intoxication include listlessness, mental confusion, paresthesia of the extremities, weakness of the legs, flaccid paralysis, fall in blood pressure, cardiac arrhythmias, and heart block. When hyperkalemia exists, it should be promptly treated with the discontinuance of potassium administration or other steps to lower serum levels if indicated, since sudden shift in plasma levels may induce potentially dangerous cardiac arrhythmias.
DOSAGE AND ADMINISTRATION: Adults, one tablespoonful (15 cc.) diluted in one glass of water, twice daily after the morning and evening meal. Larger doses may be indicated according to the individual patient's requirements but should be administered under close supervision due to the possibility of potassium intoxication. Patients should be cautioned to follow directions explicitly in regard to dilution of Kay Ciel Elixir to prevent gastrointestinal injury.
HOW SUPPLIED: One pint and one gallon bottles.

Cooper Cooper Laboratories, Inc., Wayne, N.J. 07470/Ste. Therese, P.Q., Canada

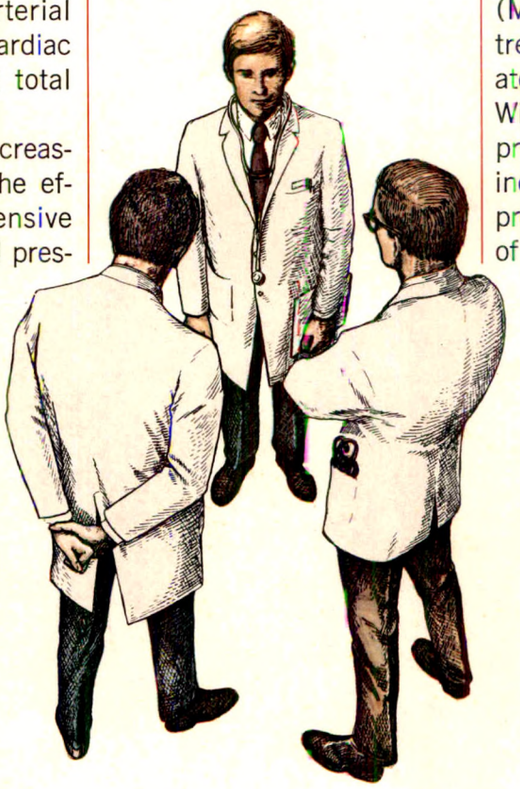
A YORKE MEDICAL JOURNAL

The more physicians consider the hemodynamics of lowering blood pressure...

Most physicians now agree on the importance of reducing blood pressure in the hypertensive patient. But high blood pressure exists, of course, only as part of a complete clinical picture. The hemodynamic profile of well-established essential hypertension is characterized by elevated arterial blood pressure, normal cardiac output, and increased total peripheral resistance.

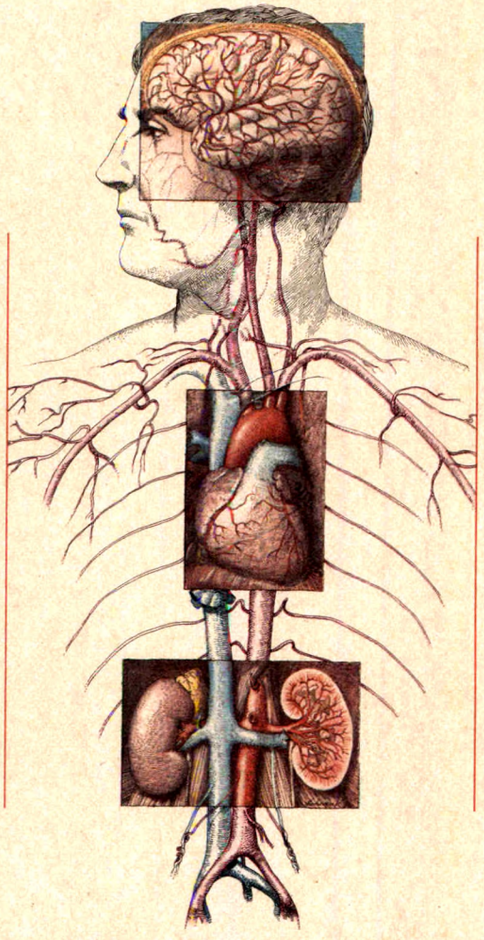
And so, physicians are increasingly concerned with the effects of an antihypertensive agent not only on blood pressure itself but also on the hemodynamic pattern—in short, with the total effect of the drug. *Does* it indeed help lower blood pressure effectively? *Is* peripheral resistance reduced? *Are* cardiac output and renal functions maintained? And, also, is there likely to be drug-induced postural hypotension serious enough to pose a threat to the patient's cerebrovascular status?



With this emphasis on overall drug performance has come a growing reliance on ALDOMET® (Methyldopa, MSD) in the treatment of sustained moderate hypertension.

With its unique hemodynamic profile, ALDOMET has drawn increasing attention and approval from physicians. First, of course, for its efficacy in

the more physicians rely on this unique antihypertensive



lowering blood pressure. But there are other considerations as well. Cardiac output is usually maintained with no cardiac acceleration; in some patients the heart rate is actually slowed. Peripheral resistance is apparently reduced. ALDOMET does not usually compromise existing renal function; it generally does not reduce renal blood flow, glomerular filtration rate, or filtration fraction. And ALDOMET usually does not cause symptomatic postural or exercise hypotension.

Some patients on continuous methyldopa therapy may develop a positive direct Coombs test. For more details, see the brief summary of prescribing information.

Contraindicated in active hepatic disease and known sensitivity to the drug. Not recommended in pheochromocytoma or pregnancy. It should be used with caution in patients with a history of liver disease or dysfunction. Discontinue the drug if fever, abnormal liver function, jaundice, or acquired hemolytic anemia occurs.

In most cases of sustained moderate hypertension

TABLETS, 250 mg

ALDOMET®
(METHYLDOPA | MSD)

smoothly lowers blood pressure

For a brief summary of prescribing information, please see following page.

UNIVERSITY COLLEGE OF MEDICINE LIBRARY

In most cases of sustained moderate hypertension

TABLETS, 250 mg

ALDOMET®
(METHYLDOPA | MSD)

smoothly lowers blood pressure

Contraindications: Active hepatic disease, such as acute hepatitis and active cirrhosis; known sensitivity. Not recommended in pheochromocytoma. Unsuitable in mild or labile hypertension responsive to mild sedation or thiazide therapy. Use cautiously in patients with history of previous liver disease or dysfunction.

Warnings: Acquired hemolytic anemia has occurred rarely in association with therapy with methyldopa. Should clinical symptoms indicate the possibility of anemia, hemoglobin and/or hematocrit determinations should be performed. If anemia is present, appropriate laboratory studies should be done to determine if hemolysis is present. Evidence of hemolytic anemia is an indication for discontinuation of the drug. Discontinuation of methyldopa alone or the initiation of adrenocortical steroids usually results in a prompt remission of the anemia. Rarely, however, fatalities have occurred.

Some patients on continued therapy with methyldopa develop a positive direct Coombs test; incidence reported has averaged between 10% and 20%. It rarely occurs in first six months of therapy, and if not seen within twelve months, is unlikely to develop with continued administration. Positive Coombs test is dose-related; lowest incidence occurs in patients on 1 g methyldopa or less per day. Reversal of the positive Coombs test occurs within weeks to months after discontinuation of methyldopa. Prior knowledge of a positive Coombs reaction aids in evaluation of cross match for transfusions. Patients with positive Coombs tests at time of cross match may exhibit incompatible minor cross match. When this occurs, an indirect Coombs test should be performed. If negative, transfusion with blood otherwise compatible in the major cross match may be carried out. If positive, advisability of transfusion with blood compatible in major cross match should be determined by hematologist or expert in transfusion problems.

Fever has occurred within first three weeks of therapy, sometimes with eosinophilia or abnormalities in liver function tests, such as serum alkaline phosphatase, serum transaminases (SGOT, SGPT), bilirubin, cephalin cholesterol flocculation, prothrombin time, and bromsulphalein retention. Jaundice, with or without fever, may occur, with onset usually in the first two to three months of therapy. Rare cases of fatal hepatic necrosis have been reported. Liver biopsy in several patients with liver dysfunction has shown microscopic focal necrosis compatible with drug hypersensitivity. Rarely, reversible reduction in leukocyte count with primary effect on granulocytes has been seen; reversible agranulocytosis has been reported. Methyldopa may interfere with measurement of creatinine by alkaline picrate method and of uric acid by phosphotungstate method. When used with other antihypertensive drugs, potentiation of antihypertensive action may occur.

Usage in Pregnancy and Childbearing Age—Not recommended in pregnancy. In women of childbearing age, weigh potential benefits against possible fetal hazards.

Precautions: Perform periodic hepatic function tests and white cell and differential blood counts during first six to twelve weeks of therapy or in unexplained fever. Discontinue if fever, abnormalities in liver function tests, or jaundice appears. Since methyldopa causes fluorescence in urine samples at the same wavelengths as catecholamines, spuriously high levels of urinary catecholamines may be reported. This will interfere with the diagnosis of pheochromocytoma. Discontinue drug if involuntary choreoathetotic movements occur in patients with severe bilateral cerebrovascular disease. Anesthetics requirements may be reduced; hypotension occurring during anesthesia usually can be controlled with vasopressors. Hypertension may occur after dialysis because methyldopa is removed by this procedure.

Dosage should be limited initially to 500 mg daily when following previous antihypertensive agents other than thiazides. Do not exceed recommended daily dose of 3.0 g. Patients with impaired renal function may respond to smaller doses than patients with normal kidney function. Syncope in older patients has been related to increased sensitivity in those with advanced arteriosclerotic vascular disease; this may be avoided by lower doses. Tolerance occasionally seen either early or late, but more likely between second and third month after initiation of therapy; increased dosage or combined therapy with a thiazide frequently restores effective control.

Adverse Reactions: Sedation, usually transient, may be seen during initial therapy or when dosage is increased. Headache, asthenia, or weakness may be noted as early, transient symptoms. Symptoms associated with effective lowering of blood pressure, including dizziness, lightheadedness, and symptoms of cerebrovascular insufficiency, are seen occasionally. Angina pectoris may be aggravated. Symptoms of orthostatic and exercise hypotension may occur; if symptoms occur, reduce dosage. Bradycardia, nasal stuffiness, mild dryness of mouth, and gastrointestinal symptoms including distension, constipation, flatus, and diarrhea occur occasionally; these can be relieved by reducing dosage. Nausea and vomiting have been reported in only a few patients. Sore tongue or "black tongue," pancreatitis, and inflammation of salivary glands may occur.

Weight gain and edema occur infrequently; if edema progresses or signs of pulmonary congestion appear, discontinue drug. Rarely, urine exposed to air may darken due to breakdown of methyldopa or its metabolites. Other rare reactions include breast enlargement, lactation, impotence, decreased libido, skin rash, mild arthralgia, myalgia, paresthesias, parkinsonism, psychic disturbances including nightmares, reversible mild psychoses or depression, reversible thrombocytopenia, drug-related fever and abnormal liver function studies with jaundice and hepatocellular damage (see **Warnings** and **Precautions**), rise in BUN, and a single case of bilateral Bell's palsy.

Supplied: Tablets, containing 250 mg methyldopa each, in single-unit packages of 100 and bottles of 100 and 1000.

For more detailed information, consult your MSD representative or see full prescribing information. Merck Sharp & Dohme, Division of Merck & Co., INC., West Point, Pa. 19486

MSD
MERCK SHARP & DOHME

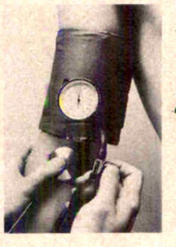
ADDENDUM

Let's make blood pressure "required reading" for all physicians.

With recent estimates that about 23 million Americans have high blood pressure—and that half of them are not even aware of it—detection of the problem in asymptomatic persons has become an issue of national importance.

Family physicians are being urged to take blood pressure readings as a matter of office routine, regardless of the presenting complaint or the reason for the visit. And because many people do not see a family physician for relatively long periods of time, some experts are suggesting that ophthalmologists, gynecologists, dermatologists, orthopedists, psychiatrists, dentists, school nurses, family planning counselors, and other health-care personnel make blood pressure reading a routine part of every examination or consultation.

Of course, a diagnosis of hypertension cannot be made on the basis of a single reading, but routine blood pressure readings can uncover potential trouble in a certain proportion of patients. And when trouble is suggested, further evaluation can be pursued more effectively.



Blood pressure—"required reading" for all physicians.

The patient with cardiac arrhythmia may need medication most when he's least likely to take it...

while he's sleeping.

Quinaglute® Dura-Tabs® (quinidine gluconate) "a pharmacologic pacemaker":

- produces sustained serum quinidine levels, thus providing a convenient 8 or 12 hour dosage schedule
- usually insures uninterrupted therapeutic quinidine gluconate levels during sleep
- avoids peaks and valleys in plasma levels during which time the arrhythmias may recur
- maintains normal sinus rhythm following conversion by other techniques
- well tolerated to enhance patient cooperation—few G.I. disturbances

Contraindications: Quinaglute Dura-Tabs are contraindicated in patients with partial A-V or complete heart block, or intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening; in patients manifesting idiosyncrasy or sensitivity to quinidine (e.g. febrile reactions, skin eruptions, thrombocytopenia, etc.), in patients with renal disease resulting in significant azotemia, or those developing cardiotoxic effects such as conduction defects; ventricular premature beats, ventricular tachycardia or flutter while on the drug. It may be contraindicated in certain patients who have marked cardiac enlargement, particularly with congestive failure, poor renal function, and especially renal tubular acidosis.

Precautions: The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate should be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered; especially during the first weeks of therapy.

Signs of idiosyncrasy include febrile reactions, skin eruptions, thrombocytopenic purpura, and respiratory embarrassment. Extreme caution should be exercised in using the drug in patients with severe heart disease and congestive heart failure, with digitalis intoxication, or renal insufficiency. It should be administered cautiously, if at all, to senile patients. Hospitalization for close clinical observations, electrocardiographic monitoring, and possibly plasma quinidine levels, is indicated when large doses are used, or with patients who present an increased risk.

As with all quinidine preparations, the titrating of the exact quinidine dosage will vary with each individual patient. With the dosage regimen of 2 tablets every 8 hours, higher blood levels than necessary for maintenance of normal sinus rhythm could be reached, whereas with 1 tablet every 12 hours, the blood levels may be too low to maintain normal sinus rhythm.

As with other quinidine products, Quinaglute Dura-Tabs should not be used during pregnancy.

Adverse Reactions: The patient should be advised to report immediately to the physician any symptoms of cinchonism (including tinnitus, decreased auditory acuity, vertigo, blurred vision, color perception disturbances, photophobia, diplopia, night blindness, scotomata, reduced visual fields, mydriasis and respiratory distress).

Where such symptoms develop, or if evidence of hypotension appears, the drug should be discontinued. Gastrointestinal disturbances have only rarely been reported. If they occur, they may be minimized by administering the drug with food. If they persist, dosage should be decreased.

Dosage: For the prevention of premature atrial, nodal or ventricular contractions, the dose usually ranges from 1 to 2 tablets every 8 or 12 hours.

Before prescribing or administering, please refer to QUINAGLUTE full product information.

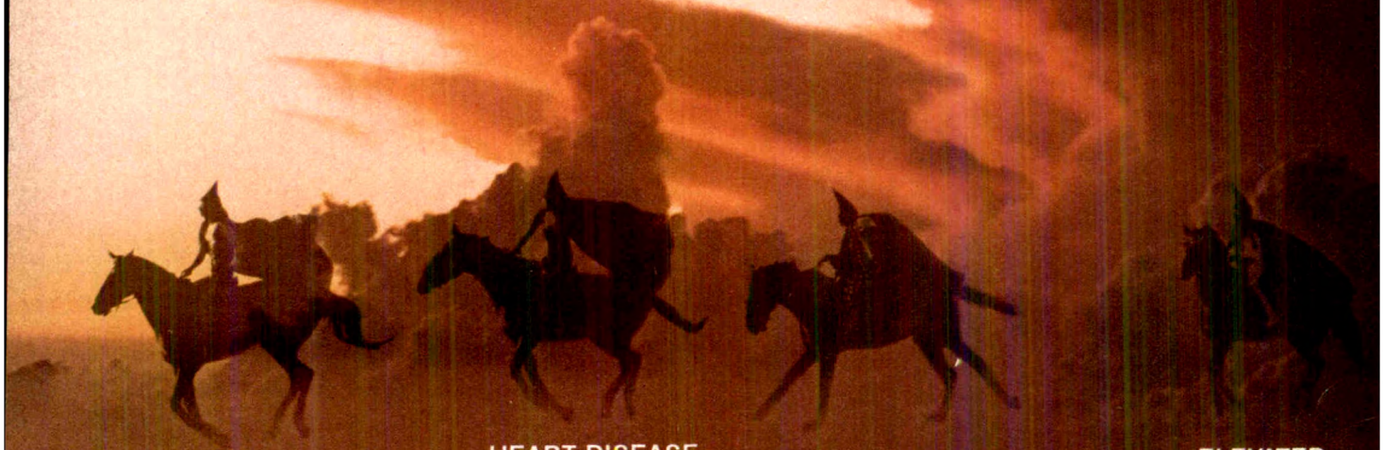
The Four Horsemen of Stroke...



HYPERTENSION

HEART DISEASE

DIABETES

ELEVATED CHOLESTEROL

You have your own therapeutic regimen to reduce these risk factors—the "Big Four" accelerators of stroke.

...and TIA's-the Prophetic Fifth Horseman

Transient Ischemic Attacks (TIA's) are another signal of impending stroke that is particularly ominous. In fact, 33% of patients with TIA's will develop a severe neurological deficit within 5 years.*

For such patients, PAVABID® (papaverine HCl) vasodilatation helps to preserve cerebral circulation. By reducing arterial tone, Pavabid therapy helps block vasospasm that can result in neurological damage.

*Meyer, J. S., and Gilroy, J.: *Medical Neurology,*

PAVABID®
(papaverine HCl, 150 mg.) Plateau CAPS®

Pavabid® Plateau CAPS® (Papaverine HCl, 150 mg.)—Each capsule contains papaverine hydrochloride, 150 mg. in a special base for prolonged therapeutic effect. *Indications:* For the relief of cerebral and peripheral ischemia associated with arterial spasm and myocardial ischemia complicated by arrhythmias. *Dosage:* One capsule every 12 hours. In difficult cases, administration may be increased to one capsule every 8 hours, or two capsules every 12 hours. *Precaution:* Use with caution in patients with glaucoma. Hepatic hypersensitivity has been reported with gastrointestinal symptoms, jaundice, eosinophilia and altered liver function tests. Discontinue medication if these occur. *Side effects:* Infrequently reported side effects of papaverine include nausea, abdominal distress, anorexia, constipation, malaise, drowsiness, vertigo, sweating and headache, diarrhea and skin rash.

WHEN YOUR DIGITALIZED PATIENT NEEDS A DIURETIC

SHE NEEDS DYAZIDE®

RELIEVES EDEMA*

and maintains diuretic efficacy throughout therapy, regardless of aldosterone level

CONSERVES NATURAL POTASSIUM STORES

to reduce the risk of hypokalemia and its symptoms: malaise, fatigue and muscle cramps

REDUCES THE RISK OF DIGITALIS INTOXICATION

due to potassium depletion. Potassium depletion sensitizes the myocardium to the toxic effects of digitalis and reduces its inotropic effect.

The Dyrenium (triamterene, SK&F) component of 'Dyazide' conserves potassium. Therefore, dietary potassium supplements or potassium salts should not be used with 'Dyazide' unless hypokalemia develops or dietary intake of potassium is markedly impaired.

'Dyazide' can occasionally cause hyperkalemia. Accordingly, serum potassium and BUN should be checked during therapy, particularly in patients with suspected or confirmed renal insufficiency (e.g., elderly or diabetic patients).

If hyperkalemia develops, 'Dyazide' should be withdrawn and a thiazide alone substituted.

Use 'Dyazide' with caution during pregnancy or in women who might bear children. Its potential benefits should be weighed against possible hazards to the fetus.

*See next page for indications and brief prescribing information.

Trademark

DYAZIDE®

Each capsule contains 50 mg. of Dyrenium® (brand of triamterene) and 25 mg. of hydrochlorothiazide.

MEETS THE HEARTFELT NEED FOR POTASSIUM CONSERVATION

Trademark

DYAZIDE®

Each capsule contains 50 mg. of Dyrenium® (brand of triamterene) and 25 mg. of hydrochlorothiazide.

MEETS THE HEARTFELT NEEDS OF THE DIGITALIZED PATIENT

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

Indications: Edema associated with congestive heart failure, cirrhosis of the liver, the nephrotic syndrome; steroid-induced and idiopathic edema; edema resistant to other diuretic therapy. Also, mild to moderate hypertension.

Contraindications: Pre-existing elevated serum potassium. Hypersensitivity to either component. Continued use in progressive renal or hepatic dysfunction or developing hyperkalemia.

Warnings: Do not use dietary potassium supplements or potassium salts unless hypokalemia develops or dietary potassium intake is markedly impaired. Enteric-coated potassium salts may cause small bowel stenosis with or without ulceration. Hyperkalemia (> 5.4 mEq/L) has been reported in 4% of patients under 60 years, in 12% of patients over 60 years, and in less than 8% of patients overall. Rarely, cases have been associated with cardiac irregularities. Accordingly, **check serum potassium during therapy, particularly in patients with suspected or confirmed renal insufficiency (e.g., elderly or diabetics). If hyperkalemia develops, substitute a thiazide alone. If spironolactone is used concomitantly with 'Dyazide', check serum potassium frequently**—both can cause potassium retention and sometimes hyperkalemia. Two deaths have been reported in patients on such combined therapy (in one, recommended dosage was exceeded; in the other, serum electrolytes were not properly monitored). Observe patients on 'Dyazide' regularly for possible blood dyscrasias, liver damage or other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving Dyrenium (triamterene, SK&F). Rarely, leukopenia, thrombocytopenia, agranulocytosis, and aplastic anemia have been reported with the thiazides. Watch for signs of impending coma in acutely ill cirrhotics. Thiazides are reported to cross the placental barrier and appear in breast milk. This may result in fetal or neonatal hyperbilirubinemia, thrombocytopenia, altered carbohydrate metabolism and possibly other adverse reactions that have occurred in the adult. When used during pregnancy or in women who might bear children, weigh potential benefits against possible hazards to fetus.

Precautions: Do periodic serum electrolyte and BUN determinations. Do periodic hematologic studies in cirrhotics with splenomegaly. Antihypertensive effects may be enhanced in postsympathectomy patients. The following may occur: hyperuricemia and gout, reversible nitrogen retention, descreasing alkali reserve with possible metabolic acidosis, hyperglycemia and glycosuria (diabetic insulin requirements may be altered), digitalis intoxication (in hypokalemia). Use cautiously in surgical patients. Concomitant use with antihypertensive agents may result in an additive hypotensive effect.

Adverse Reactions: Muscle cramps, weakness, dizziness, headache, dry mouth; anaphylaxis; rash, urticaria, photosensitivity, purpura, other dermatological conditions; nausea and vomiting (may indicate electrolyte imbalance), diarrhea, constipation, other gastrointestinal disturbances. Rarely, necrotizing vasculitis, paresthesias, icterus, pancreatitis, and xanthopsia have occurred with thiazides alone.

Supplied: Bottles and Single Unit Packages of 100 capsules.

CONTENTS

CLINICAL STUDIES

459 Seattle Heart Watch: Initial Clinical, Circulatory and Electrocardiographic Responses to Maximal Exercise

ROBERT A. BRUCE, GEORGE O. GEY, Jr., MANUEL N. COOPER, LLOYD D. FISHER and DONALD R. PETERSON

Frequency of future cardiac events (acute myocardial infarction and sudden death) after maximal exercise testing in 1,275 healthy men varied with age and risk assessment and in 1,057 patients with cardiovascular disease varied with diagnosis and natural history of disease. Computer-averaged S–T segment depressions were more consistent and reliable predictors than visual interpretations. In one patient testing caused postexertional cardiac arrest that responded promptly to defibrillation.

470 Electrocardiogram in Acute Pericarditis. Distributions of Morphologic and Axial Changes by Stages

DAVID H. SPODICK

Of 50 patients with uncomplicated acute pericarditis 48 showed classic stage 1 S–T segment deviations and stage 3 T wave inversions developed in 32. In the absence of stage 1 changes the electrocardiogram is ancillary to other evidence in diagnosing acute pericarditis, such as definite pericardial friction, inflammatory pericardial effusion or cardiac tamponade. Characteristic electrocardiographic lead and vector orientation changes are analyzed in these subjects.

475 Posterior Wall Velocity: An Unreliable Index of Total Left Ventricular Performance in Patients with Coronary Artery Disease

PHILIP LUDBROOK, JOEL S. KARLINER, ARNOLD LONDON, KIRK L. PETERSON, GEORGE R. LEOPOLD and ROBERT A. O'ROURKE

Echocardiographic determination of endocardial and epicardial posterior wall velocities in 48 patients admitted for diagnostic cardiac catheterization and coronary angiography correlated poorly with externally recorded systolic time intervals and other indexes of myocardial performance derived from cineangiograms. This technique does not provide reliable assessment of the total left ventricular performance in patients with ischemic heart disease.

483 Mortality in Patients Undergoing Coronary Artery Bypass Surgery After Myocardial Infarction

JOHN T. DAWSON, ROBERT J. HALL, GRADY L. HALLMAN and DENTON A. COOLEY

These data in 1,700 patients suggest that coronary artery bypass surgery can be performed 1 to 2 months after myocardial infarction without an increase in early mortality. In patients operated on within the first 7 days after acute infarction the mortality rate (38.1 percent) was more than six times greater than in patients operated on 31 to 60 days after infarction (5.8 percent). Emergency coronary artery bypass after complicated acute myocardial infarction should be reserved for those not responding to aggressive medical therapy.

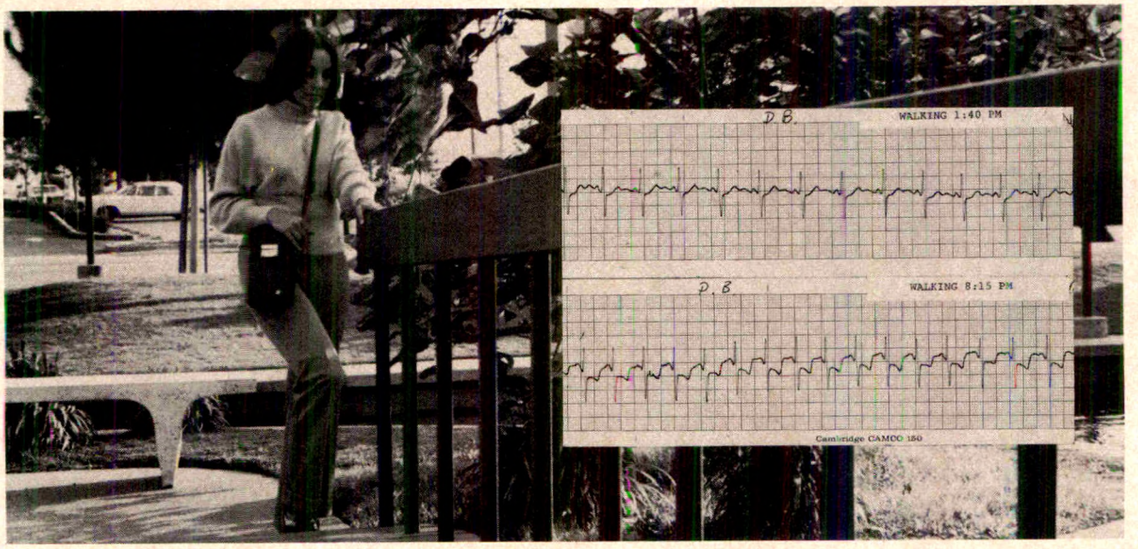
Holter DCG Monitoring Case History No. 19



A dynamic electrocardiogram was performed on a 23-year old female, who had previously complained of symptoms of rapid palpitations and chest pain. During the 10-hour recording period, the patient reported numerous symptoms, including hot flashes, chest heaviness, shortness of breath, etc.

During the first part of the tracing (see first strip), the patient reported no symptoms while walking, although minimal J-point depression was noted on the recording. However, the patient later complained of shortness of breath and chest heaviness while walking (see second strip). This time the recording showed marked ST segment depression and T-wave inversion associated with cardiac rate increase. The DCG documentation of the ischemic ST-segment shifts permitted an accurate diagnosis on this young female with hyocardial ischemia.

CONTENTS

487 Lidocaine-Induced Heart Block in Patients with Bundle Branch Block

PREM K. GUPTA, EDGAR LICHSTEIN and KUL D. CHADDA

The administration of lidocaine to 21 patients with intraventricular conduction abnormalities and ventricular premature contractions produced complete heart block distal to the His bundle potential in two patients and second degree block distal to the H deflection during atrial pacing in a third patient. These investigators advise caution in the use of lidocaine in patients with incomplete bilateral bundle branch block and consideration of a temporary pacemaker in patients with a prolonged H–V interval or known trifascicular disease.

493 Improved Intraventricular Conduction of Premature Beats After Diphenylhydantoin

JOE K. BISSETT, NEIL D. B. de SOYZA, JAMES J. KANE and MARVIN L. MURPHY

His bundle recordings and coupled atrial pacing were used to record the relative refractory period of the His-Purkinje system and the functional refractory period of the atrioventricular node in 14 patients before and after administration of diphenylhydantoin. The findings demonstrated that diphenylhydantoin significantly alters intraventricular conduction by decreasing the relative refractory period of the His-Purkinje system or reducing the H–V prolongation associated with aberrant conduction, or both.

498 Effect of Glucose-Insulin-Potassium Infusion on the Human Conduction System

LAWRENCE GOULD, C. V. REDDY and ROBERT F. GOMPRECHT

His bundle recordings in 21 patients with organic heart disease showed significant prolongation of the A–H interval after the administration of a glucose-potassium-insulin infusion. This study pinpoints potassium as the cause of the impaired conduction through the atrioventricular node and throws new light on the potential hazards of a potassium infusion.

507 Effect of Glucagon on Cardiac Conduction in Man

RAMESH C. DHINGRA, ASHFAQUE KHAN, DELON WU, PABLO DENES, J. MAURICE POUGET and KENNETH M. ROSEN

His bundle electrograms obtained before and after intravenous administration of glucagon in 4 patients with normal conduction and 22 patients with conduction disease revealed the following: Glucagon increased sinus nodal automaticity, as manifested by an increase in sinus rate and decrease of sinus nodal recovery time, and improved intraatrial conduction, as manifested by a reduction of the P–A interval and atrial functional and effective refractory periods. Glucagon had no effect on atrioventricular nodal or intraventricular conduction and did not appear to be arrhythmogenic.

EXPERIMENTAL STUDIES

513 Beneficial Electrophysiologic Effects of Nitroglycerin During Acute Myocardial Infarction

KENNETH M. KENT, ELDON R. SMITH, DAVID R. REDWOOD and STEPHEN E. EPSTEIN

Nitroglycerin enhanced the electrical stability of the heart during acute myocardial ischemia produced experimentally in open chest dogs. This beneficial electrophysiologic effect was probably related to reduction of ischemic injury and some action of nitroglycerin other than reduction in myocardial oxygen consumption mediated by decreased afterload.

Worth waiting for!

We'd like you to know there **are** valid reasons you may have experienced some delay in delivery of your new EK/5A electrocardiograph. Burdick dealers and salesmen are correctly telling you that continued heavy demand for the EK/5A and short supplies of components have brought about delays we are doing everything to overcome — without sacrificing Burdick quality.

Why is the EK/5A worth waiting for? Automatic lead coding; new patient isolation; solid-state simplicity; high safety margins on components; diagnostic accuracy and definition; reliable performance—all delivered in a smartly styled 17-lb. package!

Call your Burdick dealer **now** for a demonstration, or write **The Burdick Corporation, Milton, Wis. 53563.**

BURDICK®

CONTENTS

517 **Nitroglycerin-Induced Reduction in the Incidence of Spontaneous Ventricular Fibrillation During Coronary Occlusion in Dogs**

JEFFREY S. BORER, KENNETH M. KENT, ROBERT E. GOLDSTEIN and STEPHEN E. EPSTEIN

The effect of nitroglycerin on the incidence of ventricular fibrillation after coronary occlusion was studied in 27 open chest dogs. Twelve of the 13 control dogs died with ventricular fibrillation, whereas only 7 of 14 dogs treated with nitroglycerin died. The results indicate that nitroglycerin markedly diminishes ischemic injury, enhances ventricular electrical stability and significantly reduces the incidence of spontaneous ventricular fibrillation in an experimental model of acute myocardial infarction.

521 **Modification of Experimental Myocardial Infarct Size by Cardiac Drugs**

PRITPAL S. PURI

After coronary arterial occlusion in dogs, an intermediate zone of incomplete ischemia and partially diminished contractility was identified for the evaluation of the effects of various drugs on the extent of regionally ischemic myocardium. Isoproterenol initially augmented but later reduced contractility of this zone, whereas norepinephrine and ouabain produced consistent increases in contractility. Methoxamine increased left ventricular afterload, resulting in loss of contractility and its replacement by fiber lengthening in the intermediate zone. The data indicate that isoproterenol and methoxamine, unlike norepinephrine and ouabain, can increase the extent of noncontracting ischemic myocardium and, hence, infarct size.

529 **Pathophysiology of Tachycardia- and Bradycardia-Dependent Block in the Canine Proximal His-Purkinje System After Acute Myocardial Ischemia**

NABIL EL-SHERIF, BENJAMIN J. SCHERLAG, RALPH LAZARRA and PHILIP SAMET

In 18 dogs after acute myocardial ischemia produced by ligation of the anterior septal artery, differential localization of metabolites producing characteristic changes in the electrophysiologic properties of two groups of Purkinje fibers appeared to be responsible for the initial phase of tachycardia- and bradycardia-dependent block in the proximal His-Purkinje system. No relation was found between enhanced automaticity of pacemaker cells and bradycardia-dependent conduction disturbances.

METHODS

541 **Blood Flow Velocity Measured at the Mitral Valve of Man**

KENNETH B. DESSER and ALBERTO BENCHIMOL

The phasic mitral valve blood flow velocity pattern measured with the Doppler ultrasonic flowmeter catheter in 30 conscious human subjects consists of a large pandiastolic wave followed by a smaller systolic component. Deep inspiration decreases the peak mitral valve flow velocity; expiration increases it. A variety of other physiologic and abnormal states were studied.

REPORTS ON THERAPY

546 **Large Dose Furosemide Therapy for Hypertension. Long-Term Use in 22 Patients**

WILLIAM J. MROCZEK, MICHAEL DAVIDOV and FRANK A. FINNERTY, Jr.

This retrospective study of 22 hypertensive patients demonstrated that the combination of orally administered furosemide and standard antihypertensive therapy controlled high blood pressure better than other diuretic antihypertensive combinations previously used in these subjects. Large doses of furosemide may exert an additional antihypertensive effect, over and beyond the prevention of sodium retention and extracellular fluid volume expansion.

Beat after beat...day after day

CARDIOQUIN tablets

(quinidine polygalacturonate)

To convert...to MAINTAIN normal sinus rhythm

After conversion of cardiac arrhythmias—whether with CARDIOQUIN Tablets or some other current method—only low b.i.d. or t.i.d. dosage of this unique polygalacturonate salt of quinidine is required in most cases to maintain normal sinus rhythm.

Well-tolerated, CARDIOQUIN Tablets are particularly suited for maintenance therapy, since the polygalacturonic acid serves as a buffering moiety. It protects the mucosa of the stomach and permits dependable absorption of the quinidine.*

*Aviado, D. M., *Krantz and Carr's Pharmacologic Principles of Medical Practice*, ed. 8, Baltimore, Williams and Wilkins Co., 1972, p. 456.

BRIEF SUMMARY—INDICATIONS: CARDIOQUIN Tablets (quinidine polygalacturonate) are indicated in the treatment of: premature atrial and ventricular contractions; paroxysmal atrial tachycardia; paroxysmal AV junctional rhythm; atrial flutter; paroxysmal atrial fibrillation; established atrial fibrillation when therapy is appropriate; paroxysmal ventricular tachycardia when not associated with complete heartblock; maintenance therapy after electrical conversion of atrial fibrillation and/or flutter. CONTRAINDICATIONS: Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine. WARNING: In the treatment of atrial flutter reversion to sinus rhythm may be preceded by a progressive reduction in the degree of AV block to a 1:1 ratio and resulting extremely rapid ventricular rate. COMPOSITION: Each CARDIOQUIN Tablet (quinidine polygalacturonate 275 mg.) is equivalent in quinidine content to 3 grains quinidine sulfate. DOSAGE AND ADMINISTRATION: Dosage must be adjusted to individual needs, both for conversion and maintenance. An initial dose of 1 to 3 tablets may be used to terminate arrhythmias, and may be repeated in 3-4 hours. If normal sinus rhythm is not restored after 3 or 4 equal doses, the dose may be increased by ½ to 1 tablet (137.5 to 275 mg.) and administered three to four times before any further dosage increase. For maintenance, one tablet may be used two to three times a day; generally one tablet morning and night will be adequate. SUPPLIED: Uncoated, scored tablets in bottles of 50.

HISTORICAL MILESTONES

550 Experiments on the Mitral Valve (Stricker, 1883)

SAUL JARCHO

These late 19th century experiments by Stricker on the mitral valve in dogs demonstrate an advanced knowledge of physiology that permitted quantitative study of the functions of the individual chambers of the heart and clinical correlation with similar conditions in man.

CASE REPORTS

553 Paroxysmal Atrioventricular Block Related to Phase 4 Bilateral Bundle Branch Block

GIANNI CORRADO, RAÚL J. LEVI, GERARDO J. NAU and MAURICIO B. ROSENBAUM

This case of paroxysmal atrioventricular block in a 78 year old woman with Stokes-Adams seizures represents the first reported instance of enhanced diastolic depolarization occurring in both bundle branches simultaneously and giving rise to phase 4 bilateral bundle branch block.

557 Aneurysm of the Left Atrium

THOMAS J. HOUGEN, DONALD G. MULDER, MICHAEL T. GYEPES and ARTHUR J. MOSS

A congenital left atrial aneurysm, presenting in a 13 year old girl with an apical systolic murmur, supraventricular tachycardia and an abnormal chest roentgenogram, was successfully resected under cardiopulmonary bypass.

562 Acute Dissecting Aortic Aneurysm Resulting from Retrograde Brachial Arterial Catheterization. Successful Operative Intervention

HARRY A. WELLONS, Jr. and RAJINDAR SINGH

Degenerative medial disease of the aorta appears to be a prerequisite for the development of the type I aortic dissection that complicated a routine retrograde catheterization of the right brachial artery in a 55 year old man. The possibility of this complication should be kept in mind since prompt diagnosis and immediate operation can prevent a fatal outcome.

566 Successful Total Repair of Interrupted Aortic Arch Associated with Ventricular Septal Defect and Large Patent Ductus Arteriosus

JACQUES G. LOSMAN, HYMIE S. JOFFE, WALTER BECK and CHRISTIAAN BARNARD

In an 8 year old boy with an interrupted aortic arch associated with a ventricular septal defect and a large patent ductus arteriosus, the anomalies were totally corrected in one surgical procedure. The case provides another illustration of the significance of new pediatric surgical techniques in the prognosis for patients with congenital cardiac defects.

Continued on page A19

On Reliability and a Pound of Flesh

The life's blood of an electrocardiograph is the chart that flows through it.

Assurance that the recording is totally reliable depends, in part, on the quality of the chart itself.

Charts, as provided by the instrument maker, afford this assurance to a maxima ... because they are designed as an integral part of the instrument.

Charts, as provided by others, are imitations at best. They may save a few pennies, but not without risk of shedding a "drop of reliability".

This message was prepared in the interest of better instrument performance by ...

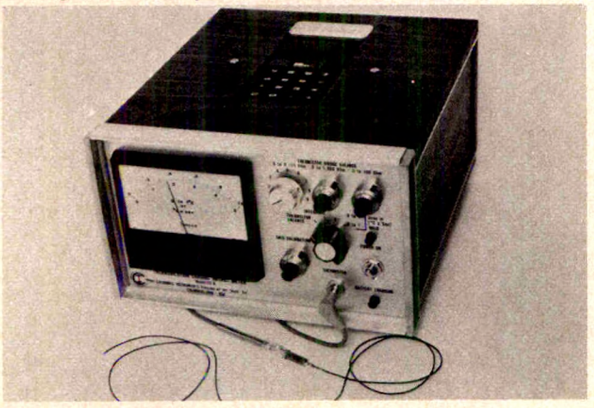
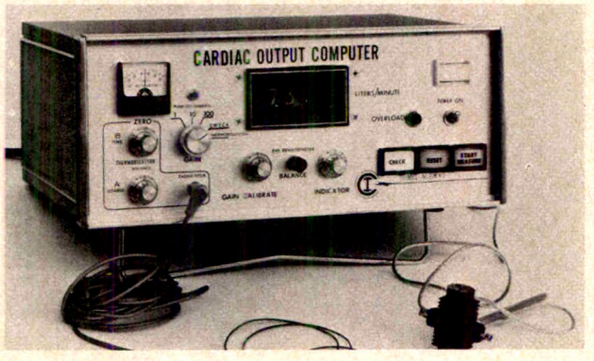
THERMODILUTION

Using room temperature indicator!



THERMODILUTION CARDIAC OUTPUT METER AND INTEGRATOR

- An intermediate instrument between the simple bridge and full scale computer.
- Battery operated—no shock hazards. Rechargeable.
- Will work with any thermistor catheter on the market; including Swan-Ganz balloon flow-directed catheter.
- Equipped with a recorder output.
- Provides information on the area under the dilution curve. (Extrapolates the dilution curve!)
- Price: $1,540.00



THERMO AND DYE DILUTION CARDIAC OUTPUT COMPUTER

- Equipped with Thermodilution and/or Dye Dilution Densitometer
- Easy calibration, automatic zeroing.
- Remote control by foot switch.
- Digital readout in L/min.
- Recorder outputs.

Pronestyl® Capsules/Injection

(Procainamide Hydrochloride)

Contraindications: In patients with myasthenia gravis and where a hypersensitivity to procainamide and related drugs exists. Should not be given to patients with complete atrioventricular heart block. Contraindicated in cases of high-degree A-V block unless an electrical pacemaker is operative.

Administration: Oral administration is preferred. When parenteral therapy is necessary, intramuscular administration is the method of choice. Intravenous use should be limited to extreme emergencies, be administered as a dilute infusion, and the patient be monitored electrocardiographically whenever practicable throughout the infusion. The intravenous dose should not exceed 1 g. Administer at a rate not exceeding 25 to 50 mg. per minute.

Should procainamide therapy be continued for any appreciable period, electrocardiograms should be made occasionally to determine its further need.

Precautions: Evidence of untoward myocardial response should be carefully watched for in all patients. In the presence of myocardial damage with atrial fibrillation or flutter, the ventricular rate may increase suddenly as the atrial rate is slowed; adequate digitalization reduces but does not abolish this danger. Ventricular tachysystole is particularly hazardous.

The dislodgement of mural thrombi producing an embolic episode may occur in correcting atrial fibrillation due to the forceful contractions of the atrium.

Extreme caution is required in attempting to adjust the heart rate when ventricular tachycardia has occurred during an occlusive coronary episode or where the use of procainamide may result in additional depression of conduction and ventricular asystole or fibrillation as in A-V block, bundle branch block, or severe digitalis intoxication.

Parenteral administration should be monitored electrocardiographically whenever practicable. Parenteral administration should be discontinued at once if electrocardiograms give evidence of impending heart block. This complication should be kept in mind when treating ventricular arrhythmias (especially parenterally) in patients with severe organic heart disease and ventricular tachycardia who may also have complete heart block. Since asystole may result if the ventricular rate is significantly slowed without attainment of regular atrioventricular conduction, procainamide should be stopped and the patient re-evaluated.

In the presence of both liver and kidney damage, normal dosage may produce symptoms of overdosage—principally ventricular tachycardia and severe hypotension.

A syndrome resembling lupus erythematosus has been reported with maintenance procainamide therapy. Common symptoms are polyarthralgia, arthritis and pleuritic pain. Fever, myalgia, skin lesions, pleural effusion and pericarditis may also occur. Rare cases of thrombocytopenia or Coombs-positive hemolytic anemia, possibly related to this syndrome, have been reported. Measure anti-nuclear antibody titers at regular intervals in patients on procainamide for extended periods of time or in whom symptoms suggestive of lupus-like reaction appear; discontinue drug in event of rising titer or clinical symptoms of LE. Steroid therapy may be effective if discontinuation of procainamide does not cause remission of symptoms. If the syndrome develops in a patient with recurrent life-threatening arrhythmias not otherwise controllable, steroid-suppressive therapy may be used concomitantly with procainamide.

Adverse Reactions: Because procainamide is a peripheral vasodilator, it may produce a hypotensive response, sometimes precipitous when given intravenously. Blood pressure should be measured almost continuously during the infusion which should be temporarily discontinued if the fall exceeds 15 mm. Hg. The hypotensive response is less likely to occur from intramuscular injection and is rare following oral administration. Serious disturbances of cardiac rhythm such as ventricular asystole or fibrillation are also more common with I.V. administration.

Large oral doses may sometimes produce anorexia, nausea, urticaria, and/or pruritus.

Reactions consisting of fever and chills; soreness of mouth, throat, or gums; and symptoms of upper respiratory tract infection have been reported. Agranulocytosis has been occasionally reported following prolonged use of the drug, and deaths have occurred. Therefore, routine blood counts are advisable during maintenance therapy. If any of the above symptoms should occur and leukocyte counts indicate cellular depression, procainamide therapy should be discontinued and appropriate treatment should be instituted immediately. Diarrhea, weakness, mental depression, giddiness, psychosis with hallucinations, hypersensitivity reactions such as angioneurotic edema and maculopapular rash, and bitter taste have been reported.

The package insert should be read carefully to become familiar with the recommended oral and parenteral dosage for the indicated conditions.

How Supplied: Pronestyl Capsules (Procainamide Hydrochloride Capsules U.S.P.) providing 250 mg. and 500 mg. are available in bottles of 100 and 1000 and Unimatic* Single Dose packaging in cartons of 100. Capsules providing 375 mg. are available in bottles of 100. Pronestyl Injection (Procainamide Hydrochloride Injection U.S.P.) providing a 10% sterile aqueous solution (100 mg./cc.) with 0.9% (w/v) benzyl alcohol is available in 10 cc. vials.

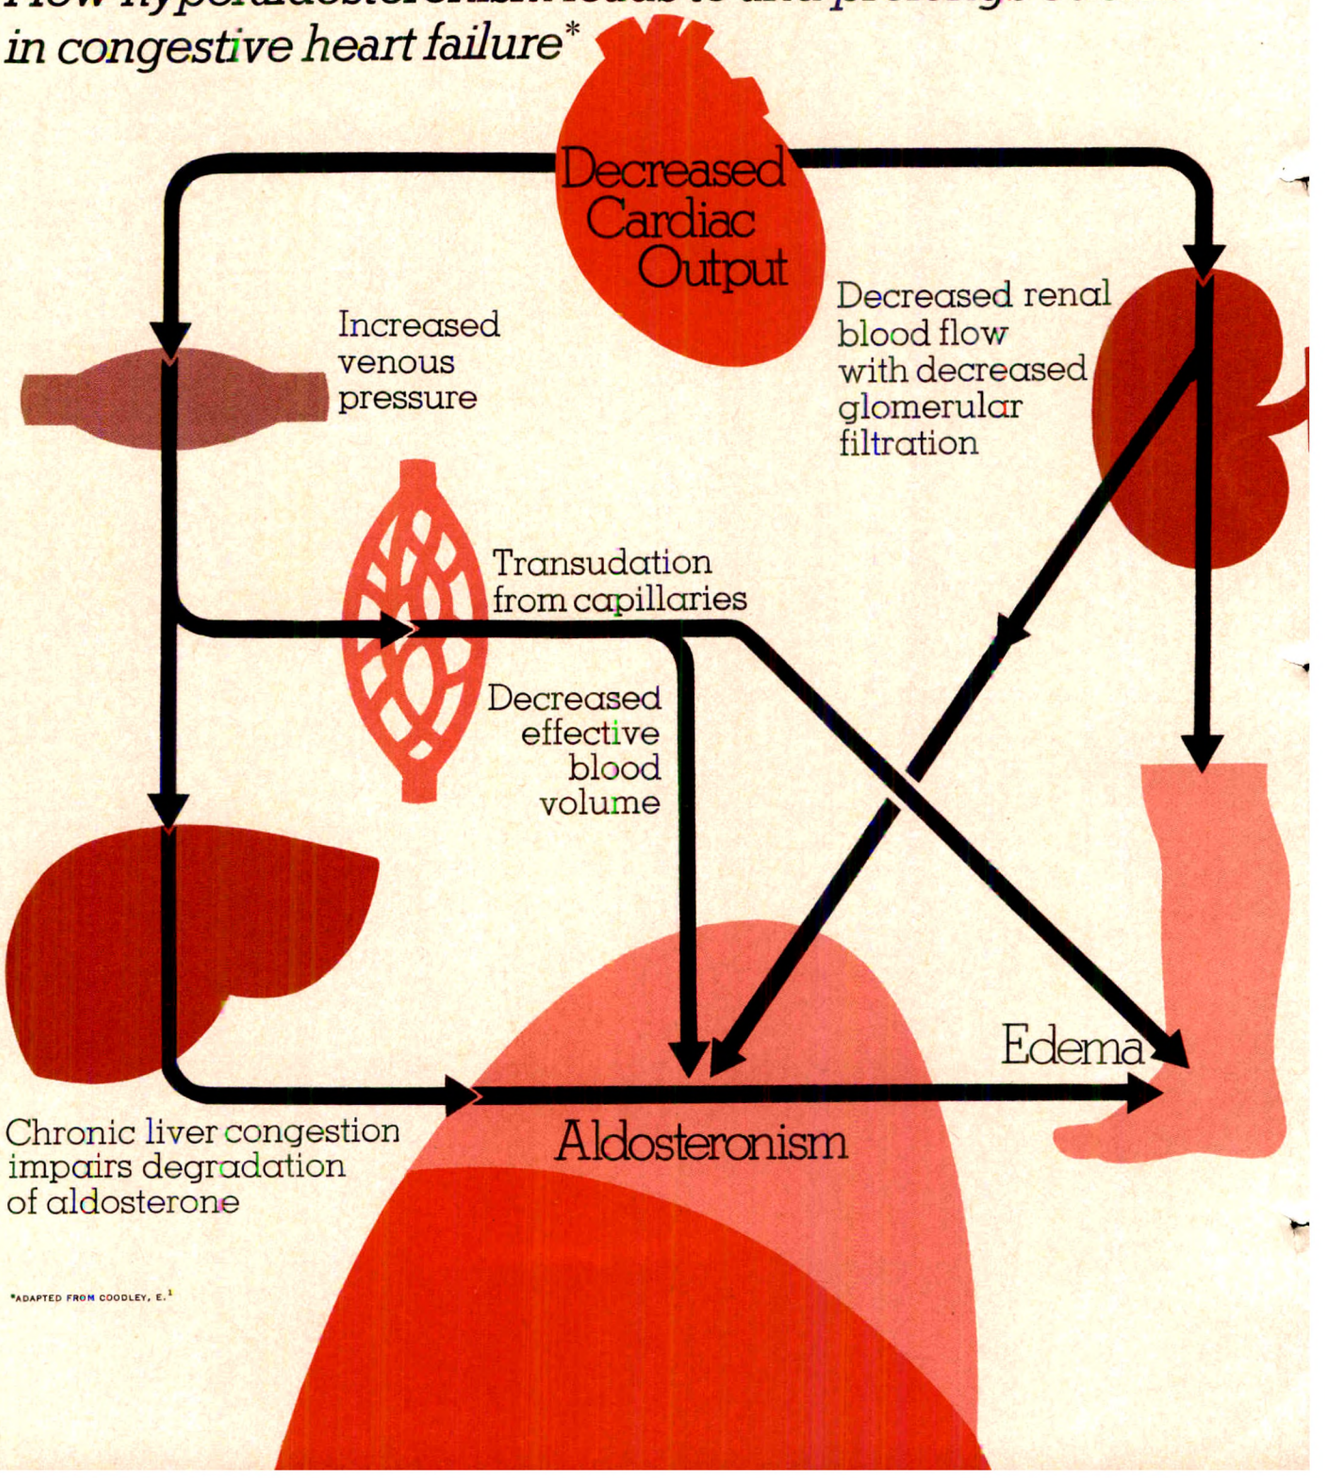
In congestive heart failure...

secondary aldosteronism

*How hyperaldosteronism leads to and prolongs edema in congestive heart failure**



*ADAPTED FROM COODLEY, E.[1]

is a primary factor

To "switch off" the aldosterone factor in congestive heart failure

Aldactone®

brand of

spironolactone 25-mg. tablets

the only specific aldosterone antagonist... basic in all diuretic therapy

Three ways to use Aldactone in congestive heart failure

1. As the only diuretic

- Often sufficient alone.
- Produces gradual, sustained diuresis by blocking aldosterone action in the distal renal tubule.
- Avoids potassium loss.

2. As the basic daily diuretic with an "add-on" alternate-day-diuretic ("A.D.D." schedule)

- Can be administered daily as basic therapy with the additional agent (furosemide or ethacrynic acid) given every second or third day.
- Aldactone plus "A.D.D." schedule minimizes potassium deficiency and potentiates effect of "add-on" diuretic.[2]
- Avoids acute volume depletion and aldosterone rebound.[2]

3. As a daily diuretic in combination with a daily dose of a thiazide

- Permits daily additive diuretic effect while maintaining potassium balance.

Indications—Essential hypertension; edema or ascites of congestive heart failure, cirrhosis of the liver and the nephrotic syndrome; idiopathic edema. Some patients with malignant effusions may benefit from Aldactone (spironolactone), particularly when given with a thiazide diuretic.

Contraindications—Acute renal insufficiency, rapidly progressing impairment of renal function, anuria and hyperkalemia.

Warnings—Potassium supplementation may cause hyperkalemia and is not indicated unless a glucocorticoid is also given. Discontinue potassium supplementation if hyperkalemia develops. **Usage of any drug in women of childbearing age requires that the potential benefits of the drug be weighed against its possible hazards to the mother and fetus.**

Precautions—Patients should be checked carefully since electrolyte imbalance may occur. Although usually insignificant, hyperkalemia may be serious when renal impairment exists; deaths have occurred. Hyponatremia, manifested by dryness of the mouth, thirst, lethargy and drowsiness, together with a low serum sodium may be caused or aggravated, especially when Aldactone is combined with other diuretics. Elevation of BUN may occur, especially when pretreatment hyperazotemia exists. Mild acidosis may occur. Reduce the dosage of other antihypertensive drugs, particularly the ganglionic blocking agents, by at least 50 percent when adding Aldactone since it may potentiate their action.

Adverse Reactions—Drowsiness, lethargy, headache, diarrhea and other gastrointestinal symptoms, maculopapular or erythematous cutaneous eruptions, urticaria, mental confusion, drug fever, ataxia, gynecomastia, inability to achieve or maintain erection, mild androgenic effects, including hirsutism, irregular menses and deepening voice. Adverse reactions are infrequent and usually reversible.

Dosage and Administration—For **essential hypertension** in **adults** the daily dosage is 50 to 100 mg. in divided doses. Aldactone may be combined with a thiazide diuretic if necessary. Continue treatment for two weeks or longer since an adequate response may not occur sooner. Adjust subsequent dosage according to response of patient.

For edema, ascites or **effusions** in **adults** initial daily dosage is 100 mg. in divided doses. Continue medication for at least five days to determine diuretic response; add a thiazide or organic mercurial if adequate diuretic response has not occurred. Aldactone dosage should not be changed when other therapy is added. A daily dosage of Aldactone considerably greater than 75 mg. may be given if necessary.

A glucocorticoid, such as 15 to 20 mg. of prednisone daily, may be desirable for patients with extremely resistant edema which does not respond adequately to Aldactone and a conventional diuretic. Observe the usual precautions applicable to glucocorticoid therapy; supplemental potassium will usually be necessary. Such patients frequently have an associated hyponatremia—restriction of fluid intake to 1 liter per day or administration of mannitol or urea may be necessary (these measures are contraindicated in patients with uremia or severely impaired renal function). Mannitol is contraindicated in patients with congestive heart failure, and urea is contraindicated with a history or signs of hepatic coma unless the patient is receiving antibiotics orally to "sterilize" the gastrointestinal tract.

Glucocorticoids should probably be given first to patients with nephrosis since Aldactone, although useful for diuresis, will not directly affect the basic pathologic process.

For **children** the daily dosage should provide 1.5 mg. of Aldactone per pound of body weight.

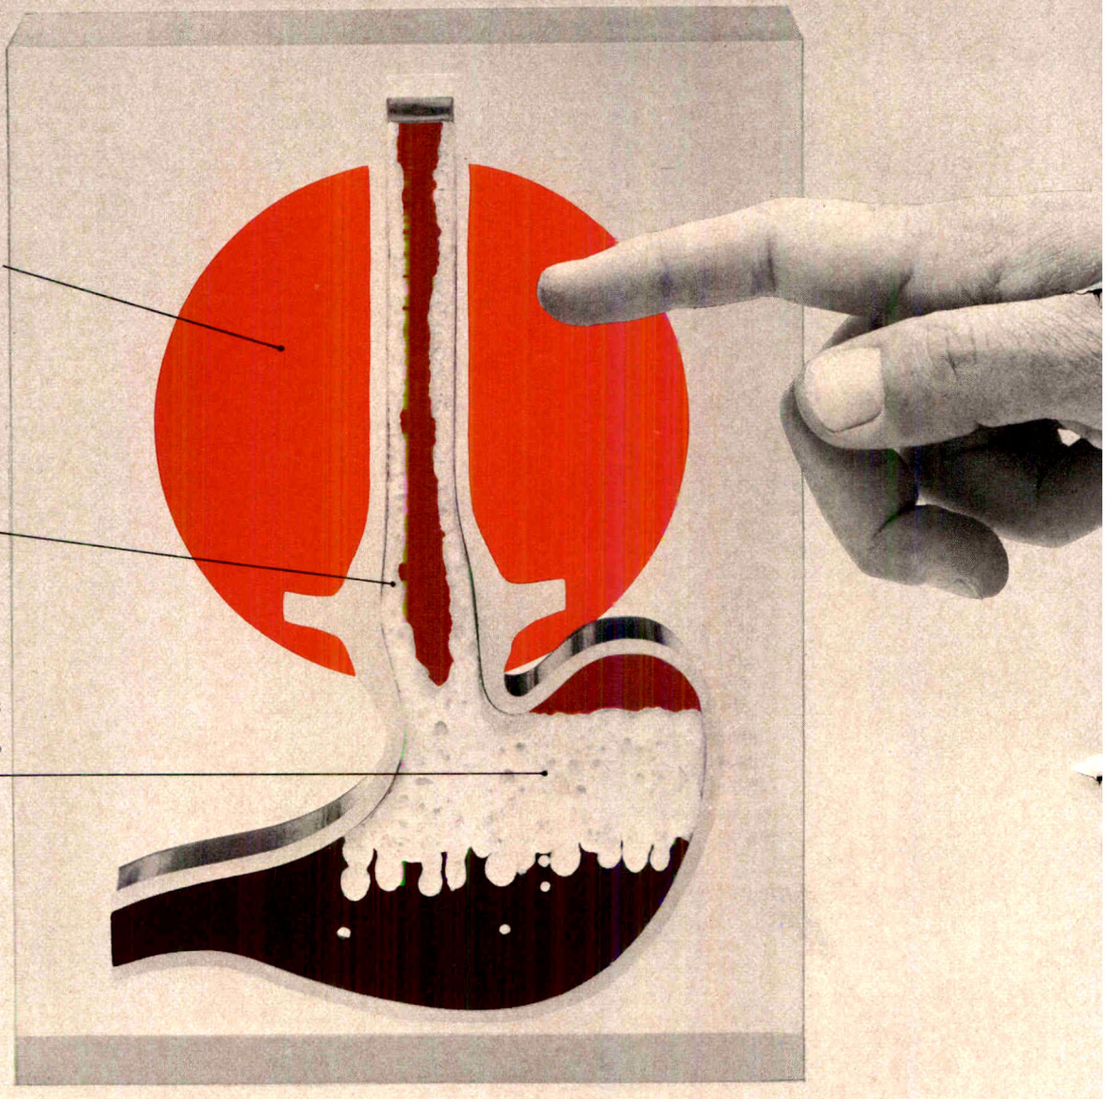
"This is the real Heartburn Zone. This is where GAVISCON® works!"

The Real Heartburn Zone
When gastric juice refluxes into the esophagus, stomach contents irritate sensitive nerve endings in esophageal mucosa to produce the pain of heartburn.

Gaviscon Coats
The Gaviscon foam coating clings to esophageal mucosa for pinpoint neutralization of gastric contents which might reflux from the stomach.

Gaviscon Floats
In the cardia and fundus of the stomach, GAVISCON® FOAMTAB® tablets form a soft, viscous layer of floating antacid foam that precedes gastric contents refluxing into the esophagus.



GAVISCON®

FOAMTAB®

(Alginic acid, 200 mg; aluminum hydroxide dried gel, 80 mg; magnesium trisilicate, 20 mg; sodium bicarbonate, 70 mg)
CHEWABLE ANTACID TABLETS for relief of heartburn accompanying hiatal hernia, gastroesophageal reflux, and esophagitis.

precision quality control...
- assured tablet content uniformity*

predictable patient response...
- proven biologic availability*

Contraindications: There are no absolute contraindications to digitalis. However, in ventricular paroxysmal tachycardia or ventricular fibrillation, it should be used *only* in refractory cases not induced by digitalis intoxication and if heart failure has developed.

Precautions: If the patient has been given digoxin during the previous week or any other less rapidly excreted drug of the digitalis group during the previous two weeks, the dose of Lanoxin brand Digoxin must be reduced accordingly. Because of impaired renal function and excretion in elderly patients, they frequently require lower than recommended doses.

Potassium loss in patients sensitizes the heart to digitalis intoxication even with recommended doses. The diuretic agents as well as electrolyte manipulations by the physician are major causes of potassium depletion in cardiac patients. Under these conditions, it may be necessary to reduce the usual dosages of Lanoxin brand Digoxin during digitalization and maintenance.

Digoxin is usually ineffective in cases of cardiac failure due to mechanical causes which are independent of myocardial diseases, e.g., cardiac tamponade, or to disorders not primarily of cardiac origin, as severe anemia. Despite a variable or poor response to digoxin in the presence of active rheumatic carditis, the development of cardiac failure is an indication for its use.

Effects of Overdosage and Treatment: The symptoms of overdosage with digoxin are quite similar to those occurring with other digitalis preparations. The most common toxic manifestations are anorexia, nausea, vomiting and various cardiac arrhythmias, including ventricular extrasystoles and paroxysmal supraventricular tachycardia or fibrillation with A-V block. In general, the gastrointestinal manifestations of toxicity with digoxin precede the cardiac arrhythmias occurring from overdosage. Furthermore, because of the rapid dissipation of digoxin, manifestations of toxicity are of short duration, usually lasting from a few hours to one or two days.

If necessary, potassium chloride may be administered as an intravenous infusion containing (adult dosage) 40 milliequivalents in 500 cc. of 5% dextrose in water, given over the course of 1 hour and repeated, if required, until a total of 120 milliequivalents have been given (1 mEq. KCl = 74.5 mg.). Electrocardiographic monitoring should be conducted and the infusion halted immediately upon the appearance of peaking of the T-waves. For children, the intravenous infusion dosage of potassium chloride would be 5 to 10 milliequivalents in 100 cc. of 5% dextrose in water given over the course of 1 hour, repeated if required, to a total of 15 to 30 milliequivalents. For more serious intoxication with abnormal cardiac rhythms, potassium chloride may be given orally in divided doses totalling 4 to 6 grams per day (adults) or 1 to 2 grams (children) provided renal failure is not present.

LANOXIN® digoxin TABLETS. **0.125 mg.** (yellow) in bottles of 100 and 1,000. **0.25 mg.** (white) scored, in bottles of 100, 500, 1,000 and 5,000; also Unit Dose Pack, strips of 10 tablets, 10 boxes of 100 tablets (1,000). **0.5 mg.** (green) scored, in bottles of 100 and 1,000.

You expect a lot from a pacemaker with a 36 month full replacement warranty.

And you get a lot from the IDP-54:

An implantable R-wave-inhibited pacemaker for intracardial and myocardial stimulation for a low, constant stimulation threshold.*

Low energy consuming circuitry and the new Mallory cell producing up to 4 to 5 years operating life.

36 month full replacement warranty.

Suitability for initial implant or implantation in patients with existing implanted electrode systems.

* The implantation of an R-wave-inhibited pacemaker has been well proven in the following cases: intermittent AV block with predominant sinus rhythm, recurrent bradycardia and second implantation to replace a fixed rate pacemaker with virtual return to sinus rhythm.

Get to know Biotronik, the pacemakers known for quality.

HEMODYNAMICS OF ANGINA PECTORIS* — PATIENTS RESTING AND EXERCISING, BEFORE AND AFTER ISORDIL® SUBLINGUAL

(isosorbide dinitrate)

BEFORE MEDICATION		AFTER 5 mg. ISORDIL SUBLINGUAL (isosorbide dinitrate)
	PULMONARY ARTERY (MEAN PRESSURE)		TOTAL PULMONARY RESISTANCE		CARDIAC INDEX		BRACHIAL ARTERY (MEAN PRESSURE)		TOTAL SYSTEMIC RESISTANCE	
IN ANGINA PECTORIS*

- to abort or terminate acute anginal attacks
- to reduce the frequency and severity of anginal episodes often caused by unavoidable everyday stress

ISORDIL® SUBLINGUAL

(ISOSORBIDE DINITRATE)

SUBLINGUAL TABLETS: 2.5 mg. and 5 mg.

***Indications:** Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indication as follows:
"Probably" effective: When taken by the sublingual route, Isordil Sublingual is indicated for the treatment of acute anginal attacks and for prophylaxis in situations likely to provoke such attacks.
Final classification of the less-than-effective indications requires further investigation.

Contraindication: Idiosyncrasy to this drug.

Warnings: Data supporting the use of nitrites during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

Precautions: Tolerance to this drug and cross-tolerance to other nitrites and nitrates may occur.

Adverse Reactions: Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents. An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

Consult direction circular before prescribing.

May we send you reprints, detailed information and/or professional samples?

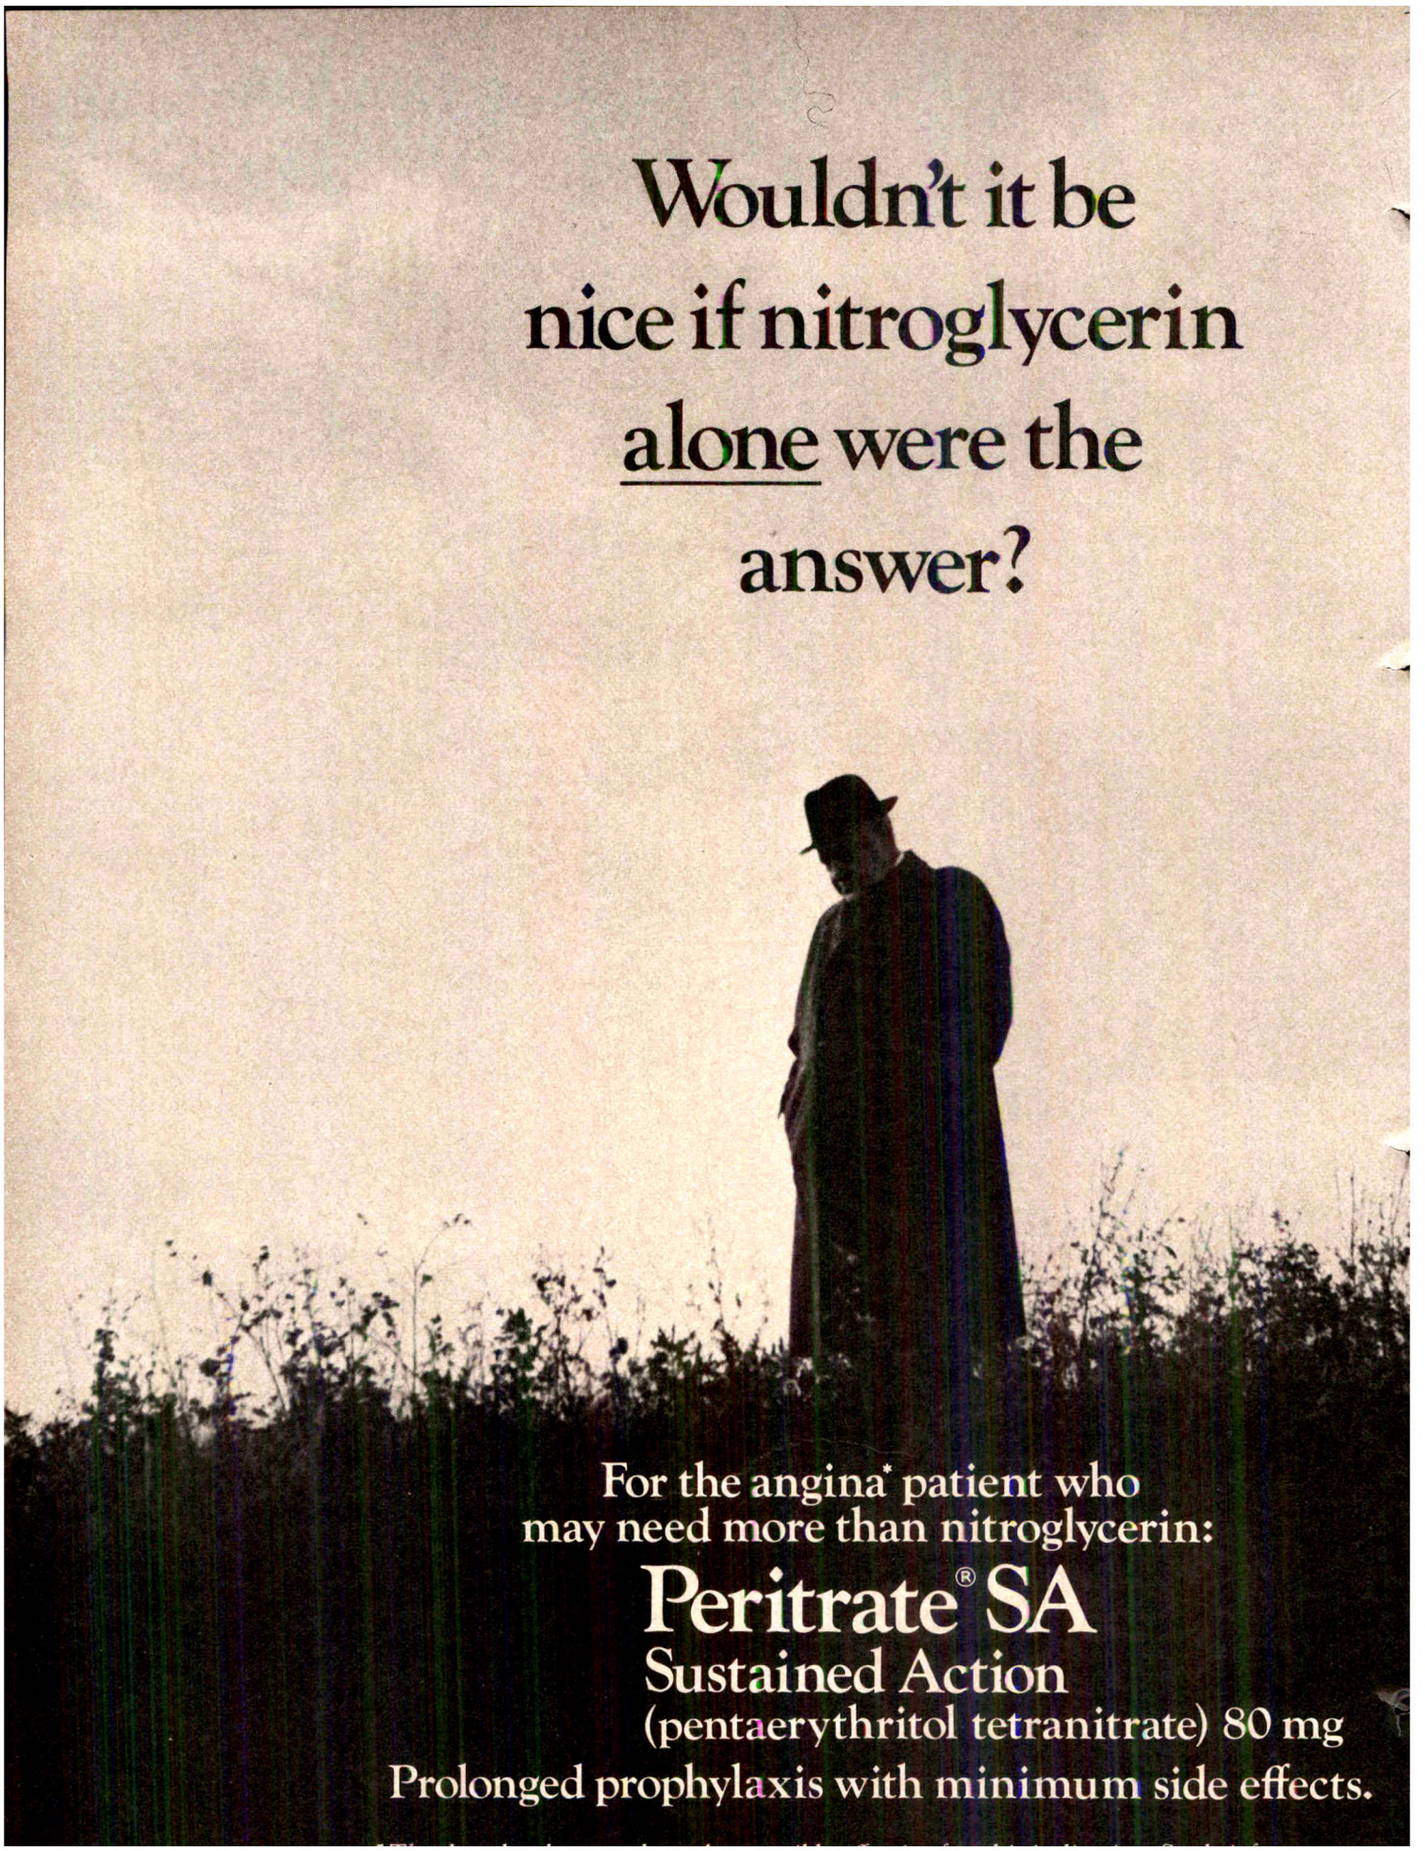
DEDICATED TO IMPROVING THE QUALITY OF LIFE, THROUGH MEDICINE

Adapted from: Kasparian H, Najmi M, Likoff W: Laboratory Evaluation of Coronary Artery Disease. Scientific Exhibit, AMA Convention, Chicago, Ill, June 1966.



Wouldn't it be
nice if nitroglycerin
alone were the
answer?
For the angina* patient who
may need more than nitroglycerin:
Peritrate® SA
Sustained Action
(pentaerythritol tetranitrate) 80 mg
Prolonged prophylaxis with minimum side effects.

Peritrate® SA

Sustained Action (pentaerythritol tetranitrate) 80 mg

CAUTION: Federal law prohibits dispensing without prescription.

Each tablet of Peritrate SA Sustained Action contains: pentaerythritol tetranitrate 80 mg (20 mg in immediate release layer and 60 mg in sustained release base). Peritrate® (pentaerythritol tetranitrate) is a nitric acid ester of a tetrahydric alcohol (pentaerythritol).

Indications: Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

"Possibly" effective: Peritrate (pentaerythritol tetranitrate), is indicated for the relief of angina pectoris (pain associated with coronary artery disease). It is not intended to abort the acute anginal episode but it is widely regarded as useful in the prophylactic treatment of angina pectoris.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg is contraindicated in patients who have a history of sensitivity to the drug.

Warning: Data supporting the use of Peritrate (pentaerythritol tetranitrate) during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents.

Precautions: Should be used with caution in patients who have glaucoma. Tolerance to this drug, and cross-tolerance to other nitrites and nitrates may occur.

Adverse Reactions: Side effects reported to date have been predominantly related to rash (which requires discontinuation of medication) and headache and gastrointestinal distress, which are usually mild and transient with continuation of medication. In some cases severe persistent headaches may occur.

In addition, the following adverse reactions to nitrates such as pentaerythritol tetranitrate have been reported in the literature:

(a) Cutaneous vasodilatation with flushing.
(b) Transient episodes of dizziness and weakness, as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop.
(c) An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur, even with the usual therapeutic doses. Alcohol may enhance this effect.

Dosage: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg (b.i.d. on an empty stomach), 1 tablet immediately on arising and 1 tablet 12 hours later.

Supplied: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg, double layer, biconvex, dark green/light green tablets in bottles of 100 and 1000.

Additional Dosage Forms: Peritrate 20 mg—light green, scored tablets; Peritrate 10 mg—light green, unscored tablets. Bottles of 100 and 1000. Full information is available on request.

A New Book! Goldberger

THE TREATMENT OF CARDIAC EMERGENCIES

An unprecedented source for information on cardiac emergencies, this new volume emphasizes practical treatment and techniques designed to utilize available resources in the wide variety of settings where cardiac emergencies occur. Etiology, equipment, diagnosis, treatment and pharmacology of cardiac emergencies—all are concisely covered. A time-saving table of emergency treatments is included.

By EMANUEL GOLDBERGER, M.D., F.A.C.P.; chapter 13 by MYRON W. WHEAT, Jr., M.D. March, 1974. Approx. 424 pages, 7" x 10", 231 illustrations. About $14.00.

New 4th Edition! Stephenson

CARDIAC ARREST AND RESUSCITATION

This new edition begins with a combined discussion of etiology and prevention, then thoroughly examines modern treatment methods. New material on cardiogenic shock, arrhythmias, ventricular fibrillation, and pediatric resuscitation relate the latest corrective measures.

By HUGH E. STEPHENSON, Jr., M.D., F.A.C.S.; with 28 contributors. April, 1974. 4th edition, approx. 886 pages, 7" x 10", 379 illustrations in 262 figures. About $37.50.

A New Book! Meaney-Lalli-Alfidi

COMPLICATIONS AND LEGAL IMPLICATIONS OF RADIOLOGIC SPECIAL PROCEDURES

This new volume focuses on possible complications involved with special radiographic procedures. It discusses each of the most common procedures in detail, delineating how to prevent complications and manage them should they occur. Legal implications are clearly presented.

By THOMAS F. MEANEY, M.D.; ANTHONY F. LALLI, M.D.; and RALPH J. ALFIDI, M.D.; with 15 contributors. May, 1973. 207 pages plus FM I-XII, 6¾" x 9¾", 51 illustrations. Price, $18.50.

DONTI™ The Pulmonary Performance Analyzer that makes every second count

Pulmonary testing is an important adjunct in the clinical handling of cardiac problems. In the few seconds required for a patient to perform a forced exhalation, the DONTI™ Pulmonary Performance Analyzer records and instantaneously displays a complete battery of sensitive spirometric parameters:

- Forced vital capacity
- FEV_1
- FEV_3
- Peak flow
- $FEV_{1\%}$
- $FEV_{3\%}$

With 10 more seconds of patient participation, the DONTI™ Pulmonary Performance Analyzer measures and expresses maximum voluntary ventilation (MVV) in liters per minute.

The DONTI™ Pulmonary Function Recorder:

- Produces simultaneously a meaningful record for patient histories.
- Provides a basis for easily determining $FEF_{200\text{-}1200}$ and $FEF_{25\%\text{-}75\%}$.

"The functional integration of the circulatory and respiratory systems makes it inevitable that disturbances in one will profoundly affect the other . . . lung complications constitute an important aspect of the diagnostic and therapeutic approaches to cardiac disease."[1]

In surgical handling of cardiac patients, the importance of preoperative pulmonary function testing has been noted. "Pulmonary complications developed after surgical operations in 70% of patients who had chronic lung disease; but in only 3% of those who had normal findings on pulmonary function tests and no respiratory symptoms."[2]

The compact Donti Pulmonary Performance Analyzer and Recorder can be used in the office or at bedside. Its electronic system simplifies the mechanical aspects of testing and allows the clinician to focus on the patient and test interpretation — with no diversion to preparing the instrument or to time-consuming calculations.

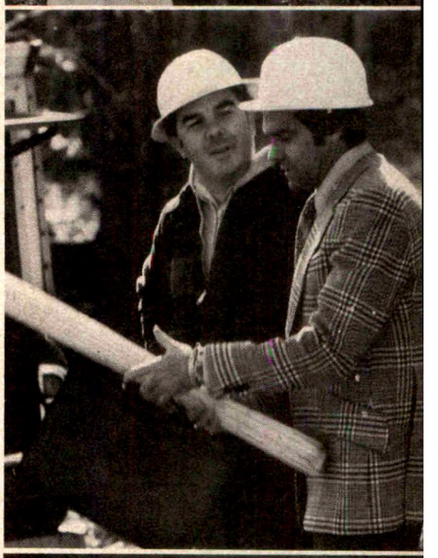
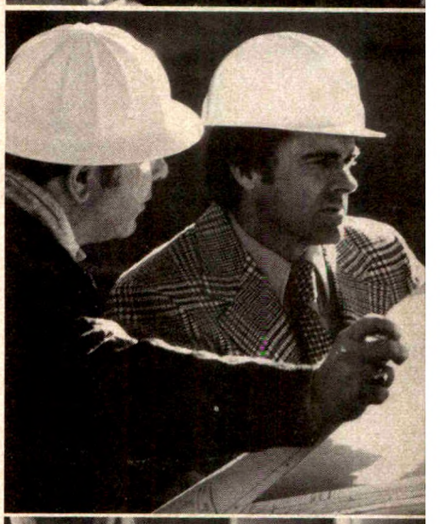
NEW FROM AYERST

the "healthy" hypertensive





It may be years before he experiences a single symptom of hypertension. But left untreated, even mild to moderate elevations of blood pressure may quietly strip years from an otherwise healthy and active life. Early control with DIUCARDIN may help forestall damage to healthy target organs.

DIUCARDIN provides approximately the same diuretic potency as hydrochlorothiazide at maximal therapeutic dosage. With DIUCARDIN, the onset of diuresis is gradual and may be maintained for twelve hours or more with a single dose.[1,2] The antihypertensive effect of DIUCARDIN is usually maintained in long term use. For many patients on DIUCARDIN, a convenient once-a-day dosage may suffice.

Based on efficacy *and* economy, DIUCARDIN provides a good beginning for many hypertensive patients. New DIUCARDIN 50 mg. Tablets. For mild to moderate hypertension and adjunctive therapy for many types of edema. Ayerst®

controlled early on

Diucardin® TABLETS

(hydroflumethiazide)

diuretic/antihypertensive

(See prescribing information on next page.)

NEW FROM AYERST

For the "healthy" hypertensive, early control with

Diucardin® TABLETS (hydroflumethiazide)

diuretic/antihypertensive

BRIEF SUMMARY

(For full prescribing information, see package circular.)

ACTIONS: The primary action of the thiazide diuretics is to produce diuresis by increasing the renal excretion of sodium and chloride. They inhibit the mechanism for tubular reabsorption of sodium and chloride by direct action on the distal segment. At maximal therapeutic dosage all thiazides are approximately equal in their diuretic potency.

The mechanism(s) of the antihypertensive action of the thiazides has not been elucidated.

INDICATIONS: **Hypertension:** DIUCARDIN alone may provide adequate control in mild or moderate hypertension. In severe hypertension or in cases of mild or moderate hypertension which do not respond adequately, DIUCARDIN may be used in conjunction with other antihypertensive agents.

DIUCARDIN alone or in conjunction with other antihypertensive agents is indicated for control of hypertension in pregnancy. (See WARNINGS)

Edema: DIUCARDIN is indicated as adjunctive therapy in edema associated with congestive heart failure, hepatic cirrhosis, and corticosteroid and estrogen therapy.

DIUCARDIN is indicated in severe edema during pregnancy. (See WARNINGS)

DIUCARDIN is indicated in the treatment of edema due to various forms of renal dysfunction, *e.g.* nephrotic syndrome, acute glomerulonephritis, and chronic renal failure.

CONTRAINDICATIONS: Anuria, oliguria. Hypersensitivity to DIUCARDIN or other sulfonamide derivatives.

The routine use of diuretics in an otherwise healthy pregnant woman with or without mild edema is contraindicated and possibly hazardous.

WARNINGS: Use with caution in severe renal disease since thiazides may precipitate azotemia. Effects due to accumulation of the drug may occur in patients with impaired renal function.

Use with caution in patients with impaired hepatic function or progressive liver disease since minor changes of fluid and electrolyte balance may precipitate hepatic coma.

Use with caution when hydroflumethiazide is administered in conjunction with other antihypertensive agents. Lowering of dosage of these agents is usually indicated. Thiazides potentiate ganglionic or peripheral adrenergic blocking drugs.

Sensitivity reactions may occur in patients with a history of allergy or bronchial asthma.

The possibility of exacerbation or activation of systemic lupus erythematosus has been reported.

Usage in Pregnancy and During Lactation: Thiazides cross the placental barrier and also appear in breast milk. Consequently, they may cause fetal or neonatal hyperbilirubinemia, thrombocytopenia, altered carbohydrate metabolism and other adverse reactions. Therefore, the potential benefits of thiazide administration in women of childbearing age must be weighed against the possible hazards to the fetus or child.

PRECAUTIONS: Tests should be made at appropriate intervals to detect possible electrolyte imbalance, *i.e.* hypokalemia, hyponatremia, and hypochloremic alkalosis. All patients taking thiazides should be observed for signs and symptoms of electrolyte or fluid imbalance, namely dryness of mouth, thirst, weakness, lethargy, drowsiness, restlessness, muscle pains or cramps, muscular fatigue, hypotension, oliguria, tachycardia, and gastrointestinal disturbances such as nausea and vomiting. Serum and urine electrolyte determinations are particularly important if the patient is vomiting excessively or receiving parenteral fluids.

If hypokalemia should develop, dietary potassium supplementation or the use of dilute potassium solutions should be tried. Small bowel lesions have been reported following the administration of enteric coated, concentrated preparations of potassium salts.

Dilutional hyponatremia may occur in edematous patients during hot weather. Water restriction rather than administration of salt is appropriate except in rare cases when hyponatremia is life-threatening. In actual salt depletion, appropriate replacement should be given.

Hypochloremia is generally mild and usually does not require specific treatment except under extraordinary circumstances, as in renal or liver disease.

The possibility of development of electrolyte or fluid imbalance is increased by brisk diuresis, severe liver disease, or concomitant administration of medications such as digitalis, ACTH, and corticosteroids.

Adequate oral intake of electrolytes should be maintained to minimize the possibility of electrolyte imbalance.

If a progressive increase in serum nitrogen occurs, a careful appraisal of the patient's condition should be made to determine whether diuretic therapy should be continued.

Because of the possibility of hypokalemia developing, patients taking digitalis should be followed carefully since a decrease in body potassium may necessitate lowering digitalis dosage.

Plasma uric acid levels may be increased and could, in susceptible patients, precipitate an attack of gout.

Thiazides alter carbohydrate metabolism. Patients who have diabetes mellitus or are suspected of being prediabetic should be followed closely since hyperglycemia and glycosuria may occur. Dosage adjustment of antidiabetic agents is frequently indicated.

Thiazides may decrease serum PBI without signs of thyroid disturbance.

Thiazides act to decrease the response of the peripheral arterial system to catecholamines and to enhance the effects of curare and its derivatives. Caution should be exercised in administering general anesthesia or curare derivatives to patients taking thiazides.

The antihypertensive effect of thiazides may be enhanced following sympathectomy.

ADVERSE REACTIONS: **Gastrointestinal:** anorexia, gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, acute pancreatitis. **Central Nervous System:** dizziness, vertigo, headache, paresthesias, xanthopsia, restlessness.

Hematologic: leukopenia, thrombocytopenia, agranulocytosis, aplastic anemia.

Allergic: purpura, photosensitivity, rash, urticaria, necrotizing angiitis, exfoliative dermatitis, glomerulonephritis, intrahepatic cholestatic hepatitis.

Cardiovascular: orthostatic hypotension (may be aggravated by alcohol, barbiturates, or narcotics).

Musculoskeletal: muscle cramps, weakness.

Clinical Laboratory Test Findings: electrolyte imbalance, elevation of serum nitrogen, elevation of plasma uric acid, hyperglycemia and glycosuria, decreased serum PBI levels.

DOSAGE AND ADMINISTRATION: **Usual adult dosage:** 50-100 mg. per day.

The dosage regimen should be individualized to obtain the maximum effect at the lowest dosage level. Dosage regimens using 25 mg. DIUCARDIN (hydroflumethiazide) may be adequate in some cases. Dosage should not exceed 200 mg. per day.

HOW SUPPLIED: DIUCARDIN—No. 702—Each scored tablet contains 50 mg. hydroflumethiazide, in bottles of 100 and 1,000.

The Silent Threat

"Thrombotic phenomena now occupy first place as a complicating factor, if not the cause, of mortality as determined in all autopsy series in the United States today. Thrombotic disease has become an increasingly important cause of disability and death as infectious diseases have responded to chemotherapy and as public health measures have become increasingly effective."

Contributing to the seriousness of the problem is the fact that "At present there is no satisfactory technique for the recognition in man of the incipient or active thrombotic state."[1] There are, however, a number of factors which are known to predispose to thrombus formation and potentially fatal embolism. Recognition of these factors, plus the application of adequate prophylactic and therapeutic measures, could contribute significantly toward decreasing the morbidity and mortality caused by 'the silent threat.'

The population at risk

Although such modern techniques as isotopic lung scanning, the radioactive fibrinogen uptake test and the Doppler ultrasound flow detector show promise of permitting early detection of thrombus formation, it is generally agreed that these methods are not completely accurate as diagnostic tools, nor are they practical for large-scale patient screening. As a result, most physicians rely on the presence of known predisposing factors as a means of identifying patients who are especially prone to venous thrombosis and pulmonary emboli.

The high risk groups

As one authority has noted, these high risk "...groups include severely injured patients, particularly those over age 50 who have fractures of the pelvis, hip, or lower extremities; those undergoing elective cup arthroplasty or pelvic surgery; those immobilized or completely bedridden; those with a previous history of venous thrombosis or pulmonary embolism; those with severe obesity or congestive heart failure, or any combination of the above categories."[2]

Myocardial infarction: a special high risk category

Patients with acute myocardial infarction comprise another high risk group, especially if they have "...large transmural infarctions, previous infarction or angina, severe hypotension or shock, congestive heart failure, chronic atrial fibrillation, or past history of venous thrombosis or embolism."[2]

Therapy to lessen the risk

In patients with conditions known to predispose them to thrombosis and potentially fatal pulmonary embolism—the high risk groups—the use of anticoagulant therapy can be of significant benefit. As one investigator recently remarked: "If [the physician] believes that the risk of embolism is high he should use the only proved form of prevention, anticoagulation."[3]

With special regard to pulmonary embolism, it has been noted that "...a pulmonary infarct proves the existence of intravenous thrombosis and should be considered as a warning of possible further emboli. It is generally accepted that diagnosis of pulmonary infarction justifies the immediate application of anticoagulant therapy. Heparin is usually used initially, then oral anticoagulants (most commonly warfarin). The length of such therapy is often arbitrary, averaging four to six weeks, but depends on the extent and chronicity of the venous disease, whenever these can be determined."[4]

Myocardial infarction: a special case for longer term therapy

Following acute myocardial infarction patients are especially prone to such thromboembolic complications as mural and venous thrombosis and pulmonary and systemic emboli. The increased risk is due to reduced cardiac output, reduced arterial perfusion of the limbs, hypercoagulability (in the presence of cardiac ischemia), and venous pooling in the lower limbs—all of which may induce venous stasis leading to potentially fatal thrombus formation and embolization.

Because of the great risk of thromboembolic complications after myocardial infarction, anticoagulant therapy is widely recommended. As noted in a recent study, "...an excellent case can be made for the use of anticoagulants for the prevention of thromboembolic complications [following acute myocardial infarction]."[5]

With regard to duration of therapy, although there is no consensus, it is generally agreed that anticoagulants should be given for as long as observable benefits persist. In a study of 735 myocardial infarction patients treated with COUMADIN or another coumarin derivative: "Results indicate that anticoagulant therapy reduces the death rate significantly during the first three years after an acute myocardial infarction. However, survival rates converge after the third year, and by the fifth year there is no difference in survival of treated and untreated groups. Therapy appeared to be more effective in patients who had experienced more than one infarction. The incidence of recurrent infarction and congestive heart failure was less in the group treated with anticoagulants."[6]

Another investigator expressed his opinion on the duration of therapy by remarking that "...male patients on anticoagulants during the acute phase of myocardial infarction can logically be kept on them for 2 or 3 years when feasible. Such treatment can be recommended especially to men under age 55 and to men who have had a previous history of angina pectoris, myocardial infarction, or both, since they are the ones most likely to benefit."[2]

COUMADIN®
(crystalline sodium warfarin*)

*present as crystalline sodium warfarin isopropanol clathrate

Please refer to brief summary of prescribing information on last page of this advertisement.

COUMADIN (crystalline sodium warfarin) BRIEF SUMMARY

EFFECTIVENESS: Coumadin® (crystalline sodium warfarin) is indicated for the prophylaxis and treatment of venous thrombosis and its extension, the treatment of atrial fibrillation with embolization, the prophylaxis and treatment of pulmonary embolism, and as an adjunct in the treatment of coronary occlusion.

CONTRAINDICATIONS: Hemorrhagic blood dyscrasias. Recent or contemplated surgery of: (1) central nervous system; (2) eye; (3) traumatic surgery resulting in large open surfaces. **Bleeding tendencies associated with active ulceration or overt bleeding of:** (1) gastrointestinal, genitourinary or respiratory tracts; (2) cerebrovascular hemorrhage; (3) aneurysms—cerebral, dissecting aorta; (4) pericardial effusions; (5) subacute bacterial endocarditis. **Threatened abortion,** eclampsia and preeclampsia. **Inadequate laboratory facilities,** or lack of patient cooperation. **Miscellaneous:** polyarthritis, vitamin C deficiency, major regional block anesthesia.

WARNINGS: Administration of anticoagulants in the following conditions will be based upon clinical judgment in which the risk of hemorrhage due to anticoagulants is weighed against the risk of thrombosis or embolization in untreated cases. The following may be associated with increased risk of hemorrhage: **Pregnancy**—oral anticoagulants pass through the placental barrier, and the danger of hemorrhage to the fetus exists even to the point of fatal hemorrhage *in utero*, even in the accepted therapeutic range of maternal prothrombin level. Close observation and laboratory control are essential. **Lactation**—coumarins may pass into the milk of mothers and cause a prothrombinopenic state in the nursing infant. **Prolonged dietary deficiency** (cachexia, vitamin K). **Severe to moderate hepatic or renal insufficiency. Infectious diseases or disturbances of intestinal flora**—sprue, antibiotic therapy. **Severe trauma** of head, bones or muscles associated with extreme raw surfaces. **Surgery** resulting in large exposed raw surfaces. **Indwelling catheters. Spinal puncture. Severe to moderate hypertension. Miscellaneous:** polycythemia vera, vasculitis, severe diabetes, menometrorrhagia, allergic and anaphylactic disorders.

Abrupt cessation of anticoagulant therapy is not generally recommended; taper dose gradually over three to four weeks.

PRECAUTIONS: Periodic determination of prothrombin time is essential.

Numerous factors, alone or in combination, including travel, changes in diet, environment, physical state and medication may influence response of the patient to anticoagulants. It is generally good practice to monitor the patient's response with additional prothrombin time determinations whenever other medications are initiated, discontinued or taken haphazardly. The following factors are listed for your reference; however, other factors may also affect the prothrombin response.

The following factors, alone or in combination, may be responsible for increased prothrombin time response:

ENDOGENOUS FACTORS: Carcinoma; collagen disease; congestive heart failure; diarrhea; elevated temperature; hepatic disorders—infectious hepatitis, jaundice; poor nutritional state; vitamin K deficiency—steatorrhea.

EXOGENOUS FACTORS: Alcohol†; allopurinal; anabolic steroids; antibiotics; bromelains; chloral hydrate†; chlorpropamide; chymotrypsin; cinchophen; clofibrate; Coumadin® (crystalline sodium warfarin) overdosage; dextran; dextrothyroxine; diazoxide; dietary deficiencies; diuretics†; disulfiram; drugs affecting blood elements; ethacrynic acid; glucagon; hepatotoxic drugs; indomethacin; inhalation anesthetics; mefenamic acid; methylphenidate; monoamine oxidase inhibitors; nalidixic acid; oxyphenbutazone; phenylbutazone; phenyramidol; prolonged hot weather; prolonged narcotics; quinidine; quinine; salicylates (in excess of 1 Gm./day); sulfinpyrazone; sulfonamides, long acting; thyroid drugs; tolbutamide; triclofos sodium; unreliable prothrombin time determinations.

†Increased and decreased prothrombin time responses have been reported.

The following factors, alone or in combination, may be responsible for decreased prothrombin time response:

ENDOGENOUS FACTORS: Diabetes mellitus; edema; hereditary resistance to coumarin therapy; hyperlipemia; hypothyroidism.

EXOGENOUS FACTORS: Adrenocortical steroids; alcohol†; antacids; antihistamines; barbiturates; chloral hydrate†; chlordiazepoxide; cholestyramine; Coumadin® (crystalline sodium warfarin) underdosage; diet high in vitamin K (vegetables, fish, fish oil, onions); diuretics†; ethchlorvynol; glutethimide; griseofulvin; haloperidol; meprobamate; oral contraceptives; paraldehyde; primidone; rifampin; unreliable prothrombin time determinations; vitamin C.

†Increased and decreased prothrombin time responses have been reported.

A patient may be exposed to a combination of the above factors, some of which may increase and some decrease his sensitivity to Coumadin. Because the net effect on his prothrombin time response may be unpredictable under these circumstances, more frequent laboratory monitoring is advisable.

ADVERSE REACTIONS: Potential side effects of Coumadin® (crystalline sodium warfarin) include: 1. Minor or major hemorrhage from any tissue or organ—which is an extension of the physiologic activity of prothrombinopenia. Bleeding during anticoagulant therapy does not always correlate with prothrombin activity. (See TREATMENT FOR OVERDOSAGE.) Bleeding which occurs when the prothrombin time is within the therapeutic range warrants diagnostic investigation since it may unmask a previously unsuspected lesion, e.g. tumor, ulcer etc. 2. Side effects other than hemorrhage are infrequent and consist of alopecia, urticaria, dermatitis, fever, nausea, diarrhea, hypersensitivity reactions and an extremely rare reaction consisting of hemorrhagic infarction and necrosis of the skin.

TREATMENT FOR OVERDOSAGE: Excessive prothrombinopenia, with or without bleeding, is readily controlled by discontinuing Coumadin® (crystalline sodium warfarin), and if necessary, the oral or parenteral administration of vitamin K_1. The appearance of microscopic hematuria, melena, petechiae or oozing from nicks made while shaving are early manifestations of hypoprothrombinemia beyond a safe and satisfactory level.

In excessive prothrombinopenia with mild or no bleeding, omission of one or more doses of Coumadin® (crystalline sodium warfarin) may suffice; and if necessary, small doses of vitamin K_1 (Mephyton®*) orally, 2.5 mg., will usually correct the problem.

If minor bleeding persists, or progresses to frank bleeding, vitamin K_1 (AquaMephyton®*) in doses of 10 to 25 mg. may be given parenterally. (Please note recommendations accompanying vitamin K preparations prior to use.) Fresh whole blood transfusions should be considered in cases of severe bleeding or prothrombinopenic states unresponsive to vitamin K_1.

Resumption of Coumadin® (crystalline sodium warfarin) administration reverses the effect of vitamin K_1, and a therapeutic hypoprothrombinemia level is readily obtained.

For complete prescribing information, including dosage and laboratory control, see package circular.

SUPPLIED: Tablets: Coumadin® (crystalline sodium warfarin) for oral use, single scored, imprinted numerically with potency as follows: 2 mg. lavender, 2½ mg. orange, 5 mg. peach, 7½ mg. yellow, 10 mg. white, 25 mg. red. In bottles of 100 and 1000. Also available in Hospital Unit-Dose blister package of 100. **Injection:** Available as single injection units of amorphous sodium warfarin lyophilized for intravenous or intramuscular use in a box of 6 units, 50 mg.: Unit consists of 1 vial, 50 mg.; sodium chloride, 10 mg.; thimerosal, 0.2 mg. accompanied by a 2 ml. ampul Sterile Water for Injection. 75 mg.: Unit consists of 1 vial, 75 mg.; sodium chloride, 15 mg.; thimerosal, 0.3 mg. accompanied by a 3 ml. ampul Sterile Water for Injection.

Sterile Water for Injection contains no antimicrobial or other substance, and it is not suitable for intravascular injection without first having been made approximately isotonic by the addition of a suitable solute. Use only for reconstitution of the lyophilized product.

Vitatron Medical offer you 100 % pacemaker analysability

The new generation of Vitatron Medical pacemakers are completely analysable during implantation.

The new digital pacemaker analyzer MPA 1 allows post-operative determination off all important pacemaker parameters such as electrode impedance in ohms and stimulation threshold in mA.

A regular review of the data will determine the run down of a pacemaker's lifetime well in advance.

Use of Vitatron Medical VCA pacemakers eliminates the need for elective pacemaker replacement.

The Vitatron Medical analysis system enables a near 100% utilization of the pacemaker lifetime, reducing replacement to an absolute minimum.

Do it right the first time with the Mark 16/35 Automatic Film Processor.

If you want fast black-and-white film processing, you have to sacrifice quality. Right?

Wrong.

The Mark 16/35 automatically processes all 16mm and 35mm B/W films, cine fluorography (diagnostic cardiology), to 50 feet per minute. And you still get all the clarity and tonal reproduction of theater-quality motion pictures.

The Mark 16/35 is constructed of 316L stainless steel inside and out for years of maintenance-free operation.

Fully adjustable controls let you use standard or hot developing solutions. Once the magazine is loaded (with up to 1250 feet of film,) all processing is done in normal room light. Anyone can become an expert film processor with an hour's practice. It's that easy.

So take the first step to true quality control. Contact us or your nearest Oscar Fisher dealer.

TRACK
a new
approach
in angina
pectoris...

Inderal®

Brand of

propranolol hydrochloride

beyond conventional measures and nitroglycerin

INDERAL, through a new mechanism, provides a unique approach in the management of patients with moderate to severe angina pectoris unresponsive to weight control, cessation of smoking, rest, sublingual nitroglycerin, and avoidance of precipitating factors. INDERAL should not be used in patients in whom anginal attacks occur only with considerable effort or infrequent precipitating circumstances.

decrease in anginal attacks and need for nitroglycerin

In 29[1-29] of 30[1-30] controlled clinical trials, INDERAL was found to reduce the incidence of anginal pain and the consumption of nitroglycerin. In 24[1-9,11-15,17,18,20-24,26,27,30] of these studies, it was possible to determine the proportion of patients responding to treatment; approximately 75 percent of the patients had less pain and used less nitroglycerin when taking INDERAL than when taking a placebo. Of the 29 studies reporting effectiveness with INDERAL, results were deemed statistically significant in 19,[1-19] not statistically significant in 2,[20,21] and the statistical significance was not given in 8.[22-29] In these and 3 other studies,[31-33] the effectiveness of INDERAL was demonstrated both clinically and by objective laboratory measurements. One study[30] reported propranolol not effective. Altogether, these clinical studies[1-33] covered 746 patients.

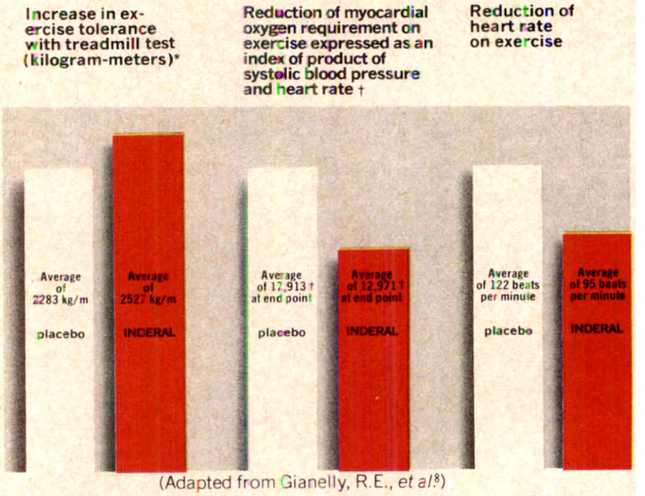
improved exercise tolerance

In 17 controlled trials dealing with exercise tolerance, INDERAL was found to be effective in 14[2,8,10,12,13,15,16,18,22,23,25,27,28,32] and not in 3.[3,29,30] In 8[2,8,10,12,15,16,18,32] of these, the improvement was statistically significant, in 6[13,22,23,25,27,28] the significance was not given.

objective proof of effectiveness

clinical results with 160 mg. Inderal (propranolol hydrochloride) daily in 19 patients

In a double-blind study, the effect of INDERAL on exercise tolerance was examined by Gianelly and associates.[8] It was concluded that in responsive patients,INDERAL, by reducing cardiac work, tends to bring into balance myocardial oxygen supply and need, and increases exercise tolerance.



(Adapted from Gianelly, R.E., *et al*[8])

*Incomplete data on one patient reduced the number to 18 for this aspect of the study.

In a double-blind crossover study of 19 patients with a typical history of angina and a positive Master 2-step test, the effects of INDERAL on exercise tolerance were correlated with cardiovascular physiologic effects. The patients, ranging in age from 38 to 65 years, received either placebo or 160 mg. INDERAL daily in 4 divided doses for 4 weeks. Exercise tolerance was assessed using a treadmill.

in the management of moderate to severe angina pectoris

works to decrease myocardial oxygen demand and prevent oxygen deficit in responsive patients

When physical or psychological stress increases beta-adrenergic stimulation of the heart, oxygen demand may exceed capacity for oxygen delivery in a coronary circulation compromised by atherosclerosis.

INDERAL (propranolol hydrochloride)—through its beta-adrenergic blocking action—provides a unique approach. By specifically competing with catecholamines for available myocardial beta-receptor sites, INDERAL can reduce sympathetically induced increases in heart rate, systolic blood pressure, and velocity of contraction during exercise or stress—and thus decrease the oxygen requirements of the heart. On the other hand, propranolol may increase oxygen requirements by increasing left ventricular fiber length, end diastolic pressure, and systolic ejection period.

If the net physiologic effect of beta-adrenergic blockade in angina is advantageous, it would be expected to manifest itself during exercise by delayed onset of pain due to the decreased oxygen requirement.

for maximum effect, dosage should be titrated and individualized

The average optimum dosage of INDERAL appears to be 160 mg. per day, although individuals may respond at any dosage level. Starting with 10-20 mg. 3 or 4 times daily, before meals and at bedtime, dosage should be gradually increased at 3 to 7 day intervals until optimum response is obtained. Doses higher than the average optimum dosage of 160 mg. may be required; however, the value and safety of dosage exceeding 320 mg. per day have not been established.

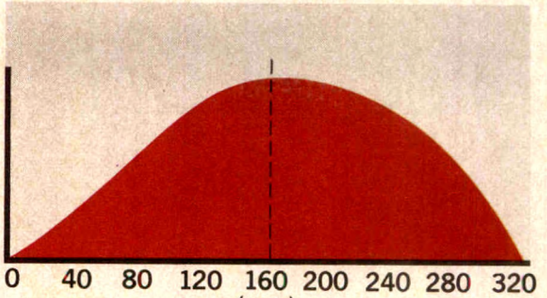
If treatment is to be discontinued, it is recommended that withdrawal be gradual over a period of several weeks. (See PRECAUTIONS.)

Special caution should be observed in patients with heart block or a history of congestive heart failure. (See CONTRAINDICATIONS and WARNINGS.)

Good medical practice dictates that INDERAL should not be continued unless there is reduced pain or increased work capacity. Treatment should be carefully monitored.

INDERAL will not interfere with the cardiac action of sublingual nitroglycerin, or cardiotonic agents such as digitalis.

average optimum daily dosage is 160 mg.



Clinical experience as reported in controlled studies has shown that the average optimum dosage appears to be 160 mg. per day. However, dosage must be individualized as some patients may obtain maximum response at a dosage level lower than 160 mg. daily, and others may require a dosage up to 320 mg. daily. The value and safety of daily doses of more than 320 mg. have not been established. (See DOSAGE AND ADMINISTRATION and OVERDOSAGE OR EXAGGERATED RESPONSE)

USE OF **INDERAL® /ANGINA PECTORIS**

BRIEF SUMMARY

(For full prescribing information, see package circular.)

Inderal®

Brand of propranolol hydrochloride

A beta-adrenergic blocking agent

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

ACTIONS: INDERAL is a beta-adrenergic receptor blocking drug, possessing no other autonomic nervous system activity. It specifically competes with beta-adrenergic receptor stimulating agents for available beta receptor sites. When access to beta receptor sites is blocked by INDERAL, the chronotropic, inotropic, and vasodilator responses to beta-adrenergic stimulation are decreased proportionately.

In dosages greater than required for beta blockade, INDERAL also exerts a quinidine-like or anesthetic-like membrane action which affects the cardiac action potential and depresses cardiac function.

Propranolol is almost completely absorbed from the gastrointestinal tract, but a portion is immediately bound by the liver. Peak effect occurs in one to one and one-half hours. The biologic half-life is approximately two to three hours. There is no simple correlation between dose or plasma level and therapeutic effect, and the dose-sensitivity range as observed in clinical practice is wide. The principal reason for this is that sympathetic tone varies widely between individuals. Since there is no reliable test to estimate sympathetic tone or to determine whether total beta blockade has been achieved, proper dosage requires titration.

Beta receptor blockade is useful in conditions in which, because of pathologic or functional changes, sympathetic activity is excessive or inappropriate and detrimental to the patient. But there are also situations in which sympathetic stimulation is vital. For example, in patients with severely damaged hearts, adequate ventricular function is maintained by virtue of sympathetic drive which should be preserved. In the presence of AV block, beta blockade may prevent the necessary facilitating effect of sympathetic activity on conduction. Beta blockade results in bronchial constriction by interfering with adrenergic bronchodilator activity which should be preserved in patients subject to bronchospasm.

The proper objective of beta blockade therapy is to decrease adverse sympathetic stimulation but not to the degree that may impair necessary sympathetic support or vital functional balances.

Propranolol exerts its antiarrhythmic effects in concentrations associated with beta-adrenergic blockade and this appears to be its principal antiarrhythmic mechanism of action. The membrane effect also plays a role, particularly, some authorities believe, in digitalis-induced arrhythmias. Beta-adrenergic blockade is of unique importance in the management of arrhythmias due to increased levels of circulating catecholamines or enhanced sensitivity of the heart to catecholamines (arrhythmias associated with pheochromocytoma, thyro-

toxicosis, exercise).

Propranolol may reduce the oxygen requirement of the heart at any given level of effort by blocking catecholamine-induced increases in heart rate, systolic blood pressure, and the velocity and extent of myocardial contraction. On the other hand, propranolol may increase oxygen requirements by increasing left ventricular fiber length, end diastolic pressure, and systolic ejection period.

If the net physiologic effect of beta-adrenergic blockade in angina is advantageous, it would be expected to manifest itself during exercise by delayed onset of pain due to decreased oxygen requirement.

INDICATIONS: *Angina Pectoris Due to Coronary Atherosclerosis.* The initial treatment of angina pectoris involves weight control, rest, cessation of smoking, use of sublingual nitroglycerin, and avoidance of precipitating circumstances. INDERAL (propranolol hydrochloride) is indicated in selected patients with moderate to severe angina pectoris who have not responded to these conventional measures. Propranolol should not be used in patients with angina which occurs only with considerable effort or with infrequent precipatating factors.

INDERAL exerts both favorable and unfavorable effects, the preponderance of which may be beneficial. (See ACTIONS Section.) INDERAL should not be continued unless there is reduced pain or increased work capacity.

Because of the potential for adverse results, treatment should be carefully monitored. The patient should also be reevaluated periodically since the dosage requirement and the need to continue INDERAL may be altered by clinical exacerbations or remissions. (See DOSAGE AND ADMINISTRATION.)

Additional studies of the effects of INDERAL in angina pectoris patients are in progress to better evaluate and define the proper role of INDERAL in this condition.

CONTRAINDICATIONS: INDERAL is contraindicated in: 1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS: CARDIAC FAILURE: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and inhibition with beta-blockade always carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. INDERAL acts selectively without abolishing the inotropic action of digitalis on the heart muscle (*i.e.* that of supporting the strength of myocardial contractions). However, the inotropic action of digitalis may be reduced by INDERAL's opposite inotropic effect. The effect of INDERAL and digitalis are additive in depressing AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, continued depression of the myocardium over a period of time can, in some cases, lead to cardiac failure. In rare instances, this has been observed during INDERAL therapy. Therefore, at the first sign or symptom of impending cardiac failure, patients should be fully digitalized, and the response observed closely: (a) if cardiac failure continues, INDERAL therapy must be immediately withdrawn; (b) if tachyarrhythmia is being controlled, patients should be maintained on combined dosage and the patient closely followed until threat of cardiac failure is over.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term use have not been adequately appraised. Special consideration should be given to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of continuing hyperthyroidism or complications and give a false impression of improvement. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg. propranolol.

IN PATIENTS DURING ANESTHESIA with agents that require catecholamine release for maintenance of adequate cardiac function, beta blockade will impair the desired inotropic effect. Therefore, INDERAL (propranolol hydrochloride) should be titrated carefully when administered for arrhythmias occurring during anesthesia.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta blockade impairs the ability of the heart to respond to reflex stimuli. For this reason, with the exception of pheochromocytoma, INDERAL should be withdrawn 48 hours prior to surgery, at which time all chemical and physiologic effects are gone according to available evidence. However, in case of emergency surgery, since INDERAL is a competitive inhibitor of beta receptor agonists, its effects can be reversed by administration of such agents, *e.g.* isoproterenol or levarterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.* CHRONIC BRONCHITIS, EMPHYSEMA), INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Because of its beta-adrenergic blocking activity, INDERAL may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia. Especially important with labile diabetics.

USE IN PREGNANCY: The safe use of INDERAL in human pregnancy has not been established. Use of any drug in pregnancy or women of childbearing potential requires that the possible risk to mother and/or fetus be weighed against the expected therapeutic benefit.

PRECAUTIONS: Patients receiving catecholamine depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine blocking action of this drug may then produce an excessive reduction of the resting sympathetic nervous activity. Occasionally, the pharmacologic activity of INDERAL may produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

When discontinuance of chronically administered INDERAL is planned, the dosage should be gradually reduced over a period of several weeks and the patient should continue to be carefully monitored. There have been reports of myocardial infarction occurring in angina pectoris patients following *abrupt* discontinuation of INDERAL therapy.

As with any new drug given over prolonged periods, laboratory parameters should be observed at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function.

ADVERSE REACTIONS: *Cardiovascular:* bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura

Central Nervous System: lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics

Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation

Allergic: pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress

Respiratory: bronchospasm

Hematologic: agranulocytosis, non-thrombocytopenic purpura, thrombocytopenic purpura

Miscellaneous: reversible alopecia

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase

DOSAGE AND ADMINISTRATION: The oral route of administration is preferred.

ORAL

ANGINA PECTORIS—*Dosage must be individualized.* Starting with 10-20 mg. three or four times daily, before meals and at bedtime, dosage should be gradually increased at three to seven day intervals until optimum response is obtained. Although individual patients may respond at any dosage level, the average optimum dosage appears to be 160 mg. per day. The value and safety of dosage exceeding 320 mg. per day have not been established.

If treatment is to be discontinued, reduce dosage gradually over a period of several weeks. (See PRECAUTIONS.)

PEDIATRIC DOSAGE

At this time the data on the use of the drug in this age group are too limited to permit adequate directions for use.

OVERDOSAGE OR EXAGGERATED RESPONSE: IN THE EVENT OF OVERDOSAGE OR EXAGGERATED RESPONSE, THE FOLLOWING MEASURES SHOULD BE EMPLOYED:

BRADYCARDIA—ADMINISTER ATROPINE (0.25 to 1.0 mg.): IF THERE IS NO RESPONSE TO VAGAL BLOCKADE, ADMINISTER ISOPROTERENOL CAUTIOUSLY

CARDIAC FAILURE—DIGITALIZATION AND DIURETICS

HYPOTENSION—VASOPRESSORS, *e.g.* LEVARTERENOL OR EPINEPHRINE (THERE IS EVIDENCE THAT EPINEPHRINE IS THE DRUG OF CHOICE.)

BRONCHOSPASM—ADMINISTER ISOPROTERENOL AND AMINOPHYLLINE

HOW SUPPLIED

INDERAL
(propranolol hydrochloride)

TABLETS

No. 461—Each tablet contains 10 mg. of propranolol hydrochloride, in bottles of 100 and 1,000.

No. 464—Each tablet contains 40 mg. of propranolol hydrochloride, in bottles of 100 and 1,000.

INJECTABLE

No. 3265—Each cc. contains 1 mg. of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as: 1 cc. ampuls in boxes of 10.

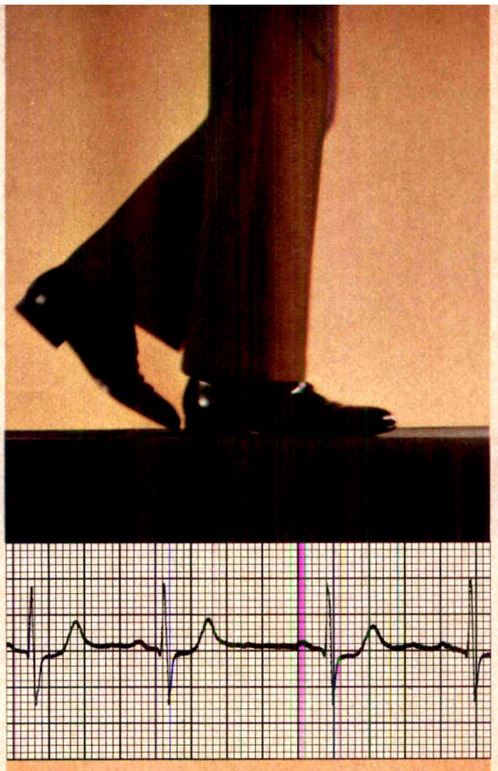
Standing, at rest, V-5, HR-74. American's Stress Test Electrode supplies immediate base line stability. Testing with a narrow, drift free base line can begin as soon as the self-adhering, silver/silver chloride electrodes have been applied to the patient and connections made to your monitoring equipment.

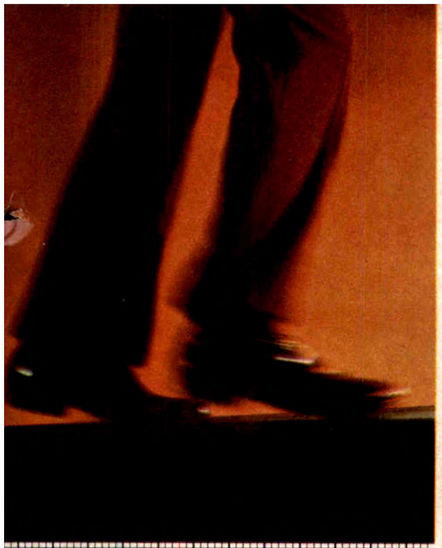


4th Minute at 2 mph, 0% Grade, V-5, HR-75. Base line stability is maintained because of the electrode's gel retaining cup and impregnated foam pad which is slightly oversize to assure positive, continuous pressure at the electrode-skin surface. The results: immediate onset and virtual elimination of base line instability and motion artifact.

4th Minute at 3 mph (8th minute test), 0% Grade, V-5, HR-83. (The patient's ECG indicates 1 mm of S-T depression.) Fully shielded cable and leadwire provide an effective barrier to the electrical interference that might otherwise mask small amounts of S-T depression.

Finally.

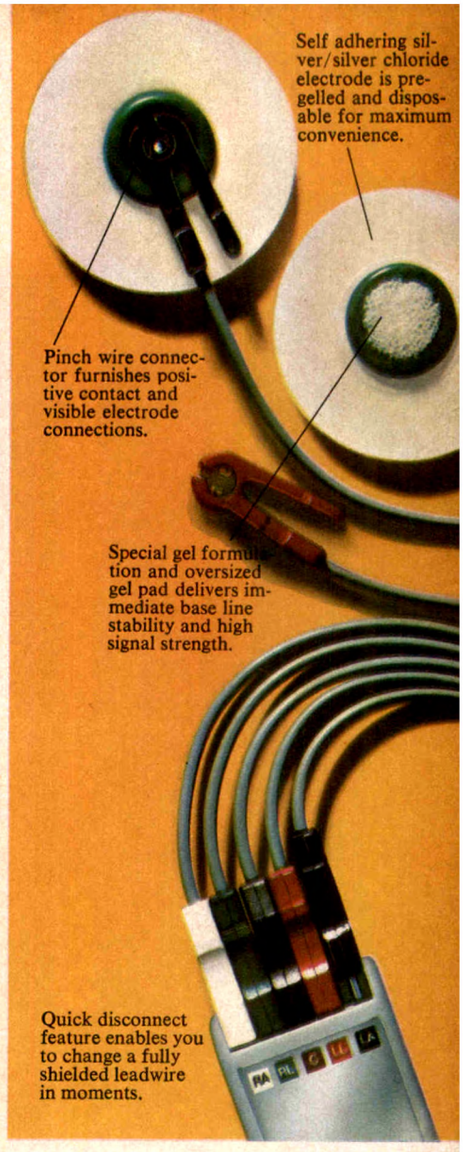
An electrode/cable system specifically designed for stress testing.



th Minute at 3 mph (12th minute f test), 5% Grade, V-5, HR-117. S-T depression increases to 2.5 mm.) Even at high work loads, the Ameri-an Stress Test Electrode and fully hielded cable system delivers a stable ase line and noise-free signal.

4th Minute at 3 mph (16th minute of test), 7.5% Grade, V-5, HR-135. (S-T depression drops to 2.0 mm.) Long test procedures* seldom affect the electrode's contact with a patient's skin; trace quality remains high, even with patients who perspire heavily.

* Because of this electrode's special gel formulation, application periods of longer than four hours are not recommended.



Compare the stress test electrocardiograms you have been getting with those reproduced above.* There's a reason for the unusually high quality of the ECG traces shown: The patient was being monitored with American's new Stress Test Electrode and fully shielded cable system.

If you've been diagnosing from stress test electrocardiograms that display wide or unstable base lines, severe motion artifact or possible hidden S-T depression, please contact us. We think we can help.

*Examples shown were produced under clinical conditions during an actual stress test procedure using the American Stress Test Electrode system.

Available through

AMERICAN HOSPITAL SUPPLY

Div. of American Hospital Supply Corp • General Offices, 1450 Waukegan Road, McGaw Park, Illinois 60085

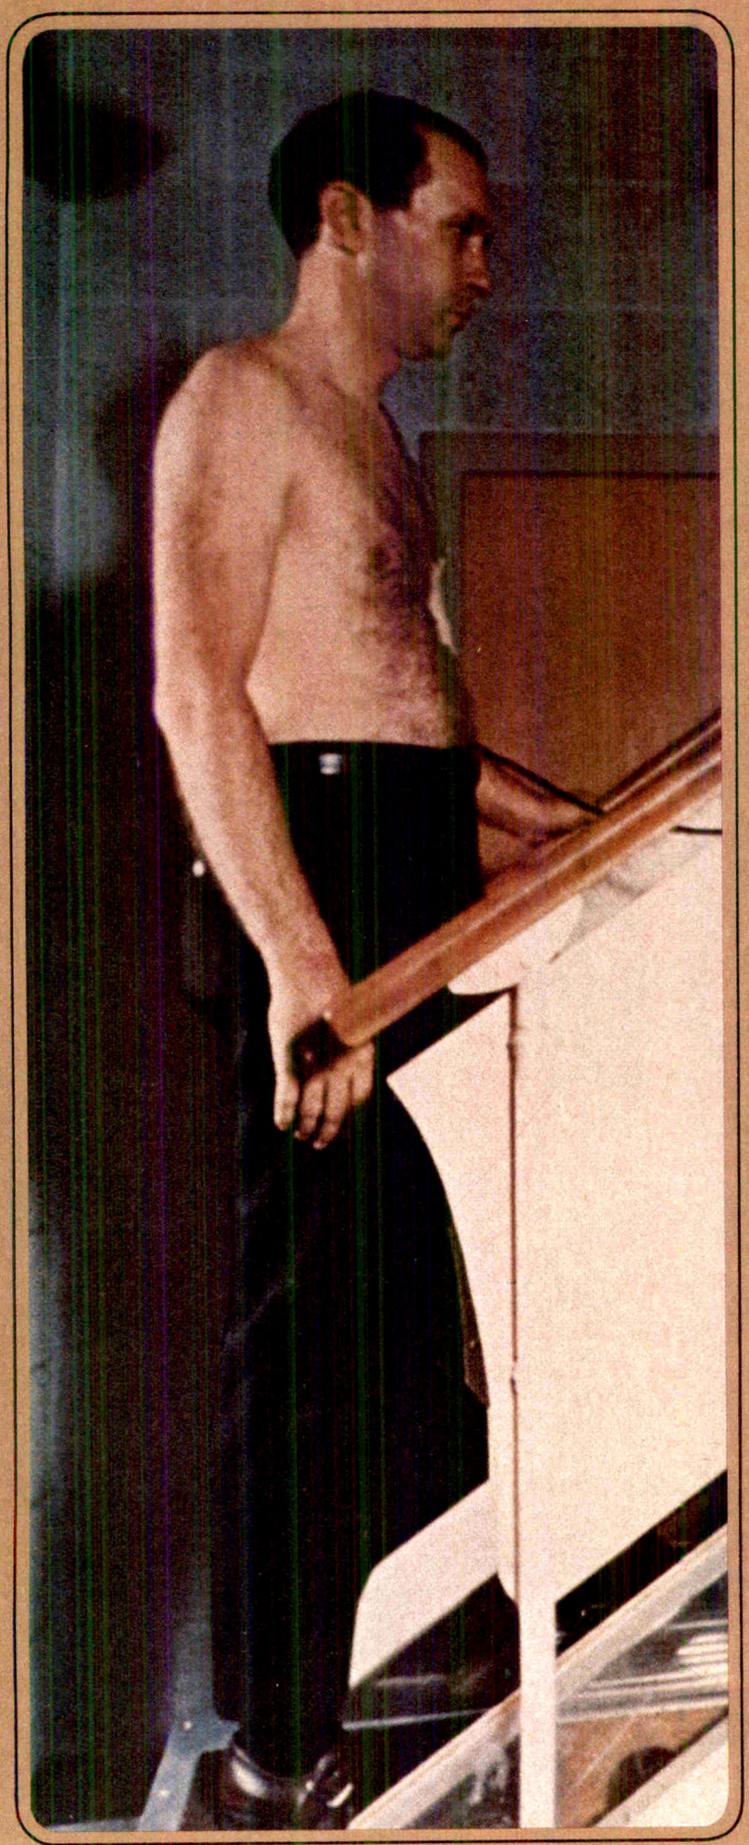
The Stress Test Electrode is protected by NDM Corporation by the following U.S. Patents: 3,696,807; 3,701,346; 3,713,435.

AMERICAN HOSPITAL SUPPLY®

We invite you to try the only electrode/cable system designed to match the "no compromise" nature of exercise stress testing. The fully shielded patient cable is adaptable to your present monitoring equipment, regardless of its make.

Please contact your American Hospital Supply or NDM representative and ask for:

- A complete demonstration of this system's benefits.
- A no obligation clinical trial. American will supply electrodes, fully shielded cables and fully shielded, quick disconnect leadwires adaptable to your present monitoring equipment during the trial period.
- A total inservice for your staff.
- Information about our nationwide technical support program.



tolerance to exercise improved for angina patients

INDICATIONS: For the prophylaxis and long-term management of patients with frequent or recurrent anginal pain and reduced exercise tolerance associated with angina pectoris, rather than for the treatment of the acute attack of angina pectoris, since its onset of action is somewhat slower than that of nitroglycerin.

PRECAUTIONS: As with other effective nitrites, some fall in blood pressure may occur with large doses. Caution should be observed in patients with a history of recent cerebral hemorrhage, because of the vasodilatation which occurs in the area. Although therapy permits more normal activity, the patient should not be allowed to misinterpret freedom from anginal attacks as a signal to drop all restrictions.

SIDE EFFECTS: No serious side effects have been reported. As with nitroglycerin or other effective nitrites, temporary vascular headache may occur during the first few days of therapy. This can be controlled by temporary dosage reduction in order to allow adjustment of the cerebral hemodynamics to the initial marked cerebral vasodilatation. These headaches usually disappear within one week of continuous therapy but may be minimized by the administration of analgesics such as Empirin® Compound.

Mild gastrointestinal disturbances occur occasionally with larger doses and may be controlled by reducing the dose temporarily.

SUPPLIED: 10 mg. chewable tablets. Bottles of 100. Also 5, 10 and 15 mg. scored tablets in bottles of 100. 10 mg. scored tablets also supplied in bottles of 1000.

Also available: Cardilate-P brand Erythrityl Tetranitrate with Phenobarbital (Warning: may be habit-forming).

Cardilate®

CLINICAL STUDIES

Seattle Heart Watch: Initial Clinical, Circulatory and Electrocardiographic Responses to Maximal Exercise

ROBERT A. BRUCE, MD, FACC
GEORGE O. GEY, Jr., MB
MANUEL N. COOPER, MD
LLOYD D. FISHER, PhD
DONALD R. PETERSON, MD

Seattle, Washington

A network of 15 maximal exercise testing facilities in four teaching hospitals, 10 private offices and clinics and an industrial medical department was organized in July 1971 to study prospectively the antecedents of myocardial infarction and sudden cardiac death. Within 18 months 2,332 men were tested: 1,275 healthy "normal" subjects, 97 with prior myocardial infarction, 306 with angina pectoris, 193 with hypertension and 461 with various mutually exclusive combinations of these diagnoses; among these clinical groups were five patients who had had a prior episode of ventricular fibrillation. Historical, physical and laboratory data were recorded on self-teaching printed forms, with normal, borderline and abnormal responses arranged in three columns. Classification with respect to "unlikely," "questionable" or "likely" risk of future cardiac events was assessed from the highest tally of items in these columns. Analysis showed computer-averaged S–T segment responses were more consistent and reliable predictors than visual interpretations.

Cardiac manifestations in healthy men varied with age and risk assessment, and in patients with cardiovascular disease varied with diagnosis and natural history of disease. Many significant differences provided insights into mechanisms of impaired cardiac function in relation to type of clinical disease. Testing was responsible for one postexertional cardiac arrest. Recovery was effected promptly by defibrillation; there was no mortality.

From the Division of Cardiology, Departments of Medicine, Biostatistics and Epidemiology, University of Washington, and Boeing Medical Department, Seattle, Wash. This study was supported by Contract 71-2474 and Program Project Grant HL-13517 from the National Heart and Lung Institute, National Institutes of Health, Bethesda, Md. and an award from the Max Baer Fund of the Fraternal Order of Eagles. Manuscript accepted September 26, 1973.

The methods and initial results of maximal exercise testing received the "Third Award for Excellence" from the Board of Governors when exhibited at the 22nd Annual Scientific Session of the American College of Cardiology in San Francisco, February 15–17, 1973.

Address for reprints: Robert A. Bruce, MD, Department of Medicine, Division of Cardiology, University of Washington, Seattle, Wash. 98195.

"Candidates for future development of premature coronary heart disease can now be identified with a degree of probability unsurpassed for most other diseases, and equaled for a few." [1]

Effective prevention of cardiovascular morbidity and mortality in middle age requires earlier detection of hypertension and coronary artery disease. Once persons at risk are identified, clinical examination may indicate appropriate intervention to minimize the risk and to delay the occurrence of cardiovascular morbidity and mortality. Whereas examination at rest is sufficient to identify persons with consistently increased blood pressure, it is inadequate for early detec-

tion of coronary artery disease. Identification of risk factors such as hypertension, hyperlipidemia and cigarette smoking may be helpful,[1] but such factors are often absent in patients who experience myocardial infarction or sudden cardiac death.[2]* Epidemiologic studies indicate that postexertional S–T segment depression after moderate exercise is the most powerful predictor of future coronary events and is independent of the other risk factors, at least in men from the United States.[3] Preliminary comparative studies of postexertional S–T segment depression in healthy men observed repeatedly for 8 years indicate that, compared with the conventional double Master two-step test, the multistage treadmill test of maximal exercise is three times more accurate in predicting future coronary events.[4,5]

The Seattle Heart Watch was organized in 1971 as a prospective area practice study in order to elucidate the antecedents of acute myocardial infarction and sudden cardiac death.† The program comprises six units of study supported by a contract from the National Heart and Lung Institute and directed by Dr. Harold T. Dodge.

This report describes the organization and initial findings of only the exercise unit of the Seattle Heart Watch, which has two major purposes. The first is to define quantitatively the impairment of functional aerobic capacity and to identify some of the responsible cardiovascular mechanisms in each person tested. The second purpose is to test the experimental hypothesis that the risk of future cardiac events in a specific person may be predicted more accurately by use of maximal exercise testing than by assessment of risk factors identified by examining persons at rest. Differences in circulatory responses to maximal exercise with aging and with coronary disease have been described by Kasser and Bruce,[6] and representative limits of cardiovascular performance[7] and the assessment of functional aerobic impairment[8] have been reported elsewhere. This current study indicates the feasibility of applying these principles and these methods to an area practice in which a common protocol is used in several locations and electrocardiographic responses to exercise are relayed by dataphone to a central computer for quantitative analysis. Initial findings are described, and the feasibility of assessing subsequent morbidity and mortality is postulated. Validation of results must, of course, await the accumulation of adequate data on persons who have been followed up longitudinally for years.

Material and Methods

Case material: Subjects participating in this study include a group of ostensibly healthy executives and supervisors of the Boeing Company who have annual physical examinations and who have volunteered for this type of exercise testing. Other healthy persons from the Seattle area are being enrolled when they undergo a routine physical examination by their private physician. Also enrolled are patients classified in "clinical" groups as follows: (1) those with new or recent cardiovascular symptoms reporting to their physician for an initial diagnosis; (2) those known to have advancing symptoms of coronary artery disease who are being considered for surgical treatment of stable angina pectoris or other complications of coronary artery disease; and (3) a small number who previously have been resuscitated from sudden cardiac arrest, whether or not it was associated with myocardial infarction.

In the first 18 months of this study 2,332 men and 225 women were enrolled and their data entered into a computer file. For the purposes of this report, only the results from the men are presented, organized according to preliminary clinical classification (before exercise testing) into eight mutually exclusive groups. The number of men in each diagnostic category is listed in Table I together with the number of those who were previously resuscitated from sudden cardiac arrest* or who were studied by coronary arteriography.

Protocol: Many physicians and cardiologists were invited to participate in the organization of this prospective study. Each agreed to use the standardized protocol for the multistage test of maximal exercise,[7] provide a treadmill, electrocardiograph and defibrillator (for reasons of safety), submit bipolar precordial electrocardiographic signals by dataphone, and record data on standardized forms and submit them to the central laboratory. Each physician signed an agreement to follow these principles and to make no additional charge to his patients for extra computer analysis and data processing. The National Heart and Lung Institute contract supports the rental charges for dataphones and the costs of private telephone lines, computer processing, registration and the additional medical and nursing staff required for exercise testing of healthy persons in industry. A form used to obtain informed consent also gives each subject the physician's initial clinical appraisal of the presence of heart disease before exercise testing is performed. The diagnostic alternatives are termed "inapparent," "possible," "probable" or "definite" heart disease, to which are added any clinical notations as to major manifestations of disease and current treatment. This signed consent form documents each participant's enrollment into the Seattle Heart Watch and includes his consent to future follow-up studies. The experimental design, protocol, data forms and especially the informed consent statement were extensively reviewed and approved by the Biomedical Sciences Review Committee of the University of Washington. Testing laboratories have been established in four teaching hospitals, 10 private offices and

* In such cases they may be considered 'false negatives' and defined as "100 percent minus reported sensitivity of one or more predictive variables," that is, the relative importance of false negative findings, given the occurrence of a cardiovascular event. For increased serum cholesterol in men aged 40 to 59 years, this value is 73 percent; for either or both a systolic blood pressure of 160 mm Hg or a diastolic pressure of 95 mm Hg or more, it is 82 percent; for both increased cholesterol and blood pressure it is 89 percent, but for either or both it is 32 percent; for two or three risk factors it is 77 percent; for three risk factors 66 to 72 percent in different age groups and population studies; and for four risk factors 86 percent (Tables 2 to 5 and 7 to 10, Reference 2).

† By design, selection and sampling, the Seattle Heart Watch does not represent an epidemiologic study of a defined population. However, the principle of automatic, periodic follow-up surveillance is adapted from conventional epidemiologic practices.

* The number of men who underwent successful defibrillation by Medic I and were subsequently enrolled into Seattle Heart Watch after exercise testing are included in the subtotals for the various clinical classifications.

clinics in Seattle and the Boeing Medical Department (Renton plant).

Exercise data collected from all 15 participating groups are reported on standardized printed forms.* Physiologic data, such as change in heart rate from rest to maximal exertion, are scored by predetermined tolerance limits from a prior study of healthy middle-aged persons.[6] Data are arranged in three columns to facilitate assessment of risk, with normal responses (previously identified from other studies)* printed on the left side, abnormal responses on the right, and questionable responses in the center. Numerical data are recorded by a technician, and clinical items are checked by the supervising physician who monitors the

* Copies available on request to Dr. Bruce.

* Tolerance limits were defined from the best straight line fit to a cumulative percentage distribution of curves (smoothed by computer) of each continuous variable; they represented a close approximation (varying with any skewness of the distribution) to the mean ± 1.5 standard deviations and ranged from 81 to 90 percent of the normal samples for men and women.

For all means and distributions, $P < 0.001$ (in relation to means of continuous variables for healthy men and for distributions of discrete variables for all men in eight columns of clinical classifications) except where indicated either $P < 0.01$ or not significant (NS).

*Mutally exclusive categories, except that of five patients with sudden cardiac arrest and successful defibrillation, one had hypertension, two others had recovered from prior myocardial infarction, and two had no history of prior heart disease.

†Not significant.

‡$P < 0.01$.

AP = angina pectoris; Healthy = inapparent heart disease before testing and unlikely to be at risk after testing, in order to select those who most closely approximate "normal" subjects. HT = hypertensive; PMI = postmyocardial infarction.

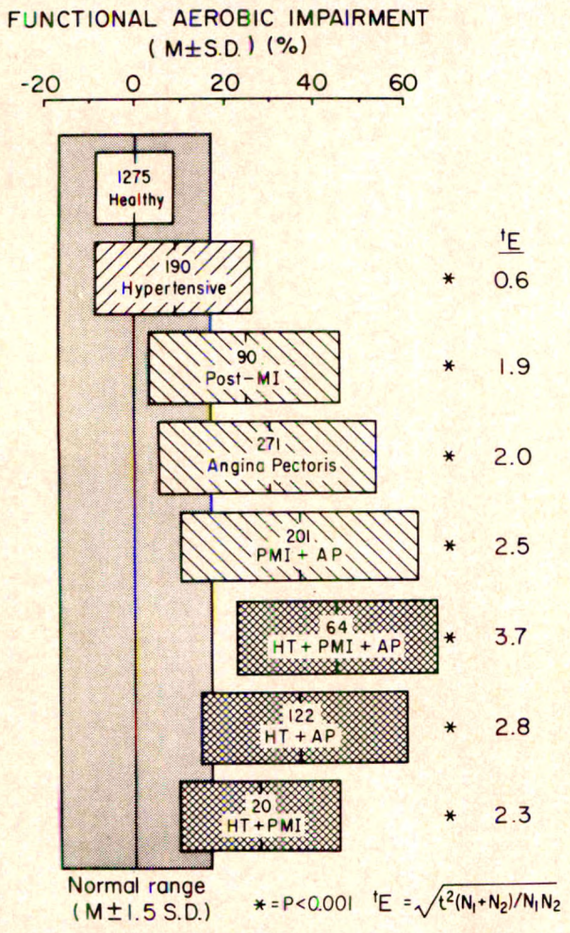

FIGURE 1. Variations in functional aerobic impairment (see text for definition) in relation to clinical classifications of men. E estimates the difference between means, relative to spread of distributions of the variable, in two populations, that is, clinical classification vs. healthy men. AP = angina pectoris; HT = hypertension; M = mean; PMI and Post-MI = postmyocardial infarction; S.D. = standard deviation. Numbers in boxes indicate number of men in each group.

patient during and immediately after testing. Use of the forms provides an extensive analytical profile of exercise performance in a brief time, and the technique can be a self-teaching method for physicians and assistants.

The degree of risk revealed by response to exercise is estimated from the largest sum of items recorded in the three columns. When the sums of normal (left) and abnormal (center and right) items are identical, the risk is arbitrarily considered "questionable."

The possible mechanisms of future cardiac events—angina or infarction from myocardial ischemia versus sudden cardiac death from arrhythmia—are also identified whenever feasible, primarily from the clinical interpretation of the electrocardiographic responses. In addition, the possibility of heart failure is predicted from subnormal circulatory responses consistent with left ventricular power failure. Similarly, evidence of a major atrioventricular conduction disorder—not as yet observed in these men—would be considered an indicator of possible development of complete atrioventricular heart block.

Because of differences in age and habitual physical activity among these men, neither duration of exercise nor the maximal oxygen uptake (which can be reasonably estimated from duration by a regression equation[8]) provided an adequate appraisal of the physiologic aerobic capacity of the individual subject. This was achieved, however, by derivation of functional aerobic impairment using the appropriate nomogram for sex and cardiovascular diagnosis.[8] Studies of other healthy middle-aged persons showed that the normal range of the means ±1.5 standard deviations was −20 to +20 percent (mean of 0 percent) (Fig. 1).

Results of computer analysis of ST_B responses (mean of 16 voltage readings from 50 to 69 msec after nadir of S), based upon averaged 100 beat samples at rest, during each work load, and for each of 5 minutes of recovery, as described previously,[9,10] are added after the clinical assessment. A separate classification table based upon clinical risk assessment (column assignment) and computer analysis (row assignment) defines the performance of each person tested, and is entered into the follow-up surveillance registry. Copies of these records are distributed to the computer center and to collaborating physicians after results of computer analysis have been obtained and checked for completeness and accuracy to ensure quality control.

Because of technical faults in individual calibration, transmission, recording or off-line processing of electrocardiographic signals, quantitative computer analysis of S–T segment responses is available for only 2,082 of the 2,332 men studied (89 percent). The variables recorded* from preliminary clinical examination, exercise testing and electrocardiographic analysis are stored on magnetic discs and tapes, using an improved comprehensive software package, "Conversational Computer Statistical System" developed by Kronmal et al.[11] The significance of differences in distributions of discrete variables is ascertained by the chi-square statistic,[12] significance between means for each continuous variable for men in the different clinical groups is appraised by using Student's unpaired t test.

Results

Clinical Findings Before Exercise Testing

Only the salient characteristics of healthy men, three groups of patients with a single clinical diagnosis, and four with various combinations of clinical diagnoses are presented in Table I.† The average age of the 1,275 healthy men was 44.5 years (standard deviation ± 7.4), whereas that of the three groups of men with a diagnosis of one cardiovascular abnormality was significantly greater (P <0.001)—50.3 years (± 8.3) for the 97 with prior myocardial infarction, 51.2 years (± 8.4) for the 306 men with angina pectoris and 49.3 years (± 8.7) for the 193 men with hypertension. Heights of most of the clinical patients were significantly lower, whereas weights were lower in patients with coronary artery disease, but higher in hypertensive‡ patients.

Distributions of mutually exclusive classifications of clinical certainty of heart disease, designated by the individual examining physician "inapparent," "possible," "probable" or "definite" on the basis of

* When observations have been missing, only the number actually recorded is shown: thus prevalence rates may be slightly underestimated.

† Other data on frequency of clinical characteristics and resting electrocardiographic abnormalities together with details of exercise responses are available on request to American Documentation Institute, 2000 P St. N.W., Washington, D.C.

‡ As classified by criteria used by the examining physicians.

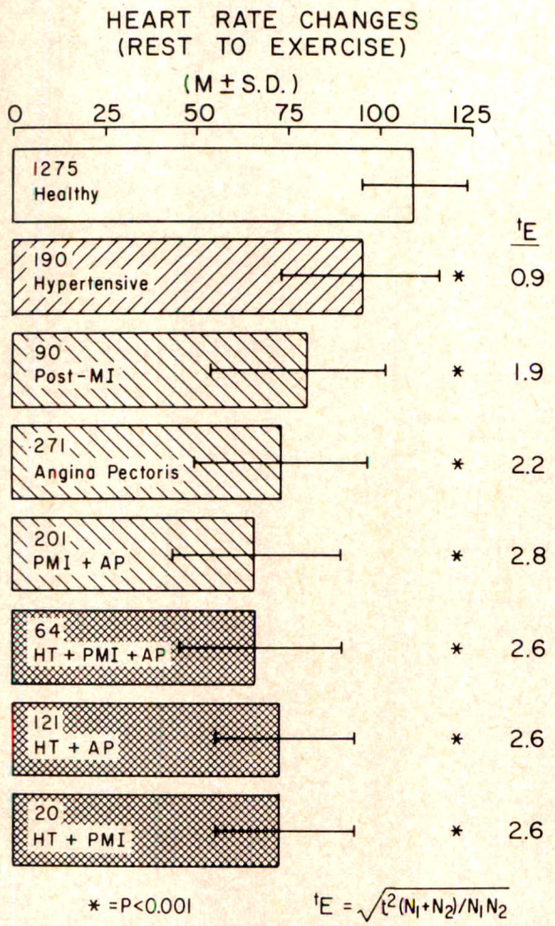

FIGURE 2. Variations in changes in heart rate from rest to maximal exercise as indexes of chronotropic reserve. Variations in N in subgroups reflect missing data in a few instances. Abbreviations as in Figure 1.

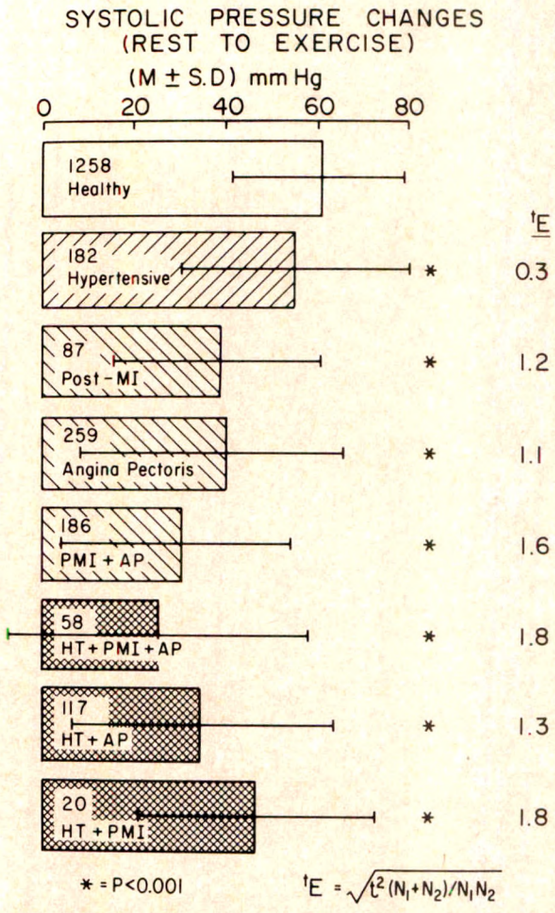

FIGURE 3. Variations in changes in systolic pressure, from rest to exercise, as indexes of inotropic reserves. Abbreviations as in Figure 1.

the history, physical examination, resting electrocardiogram and risk factors, are also shown in Table I. By definition and selection, all healthy men were classified as having "inapparent" heart disease;* 46 percent of the patients with "hypertension" and fewer than 5 percent with prior myocardial infarction or with angina were so classified. Whereas 41 percent of the hypertensive men were considered to have "possible" heart disease, no more than 25 percent in the two categories of patients with coronary heart disease were similarly classified. Conversely, the frequency of "probable" disease was less than 5 percent in the hypertensive patients and much greater in the groups with coronary heart disease. Fewer than 10 percent of the hypertensive subjects, about 33 percent of patients with angina, and 80 percent of those with prior myocardial infarction were considered to have "definite" heart disease before testing. Statistically, these distributions were extremely significant ($\chi^2 = 2802$, 21 d.f.).

Resting pressure of the healthy men averaged 123 ± 13 mm Hg systolic (standard deviation) and 77 ± 10 mm Hg diastolic. Since corresponding values for hypertensive subjects were significantly ($P < 0.001$) but only moderately higher—141 ± 16 and 90 ± 11 mm Hg, respectively—many either had "mild" hypertension or were receiving effective medical treatment. Resting pressures, particularly diastolic, in the patients with angina were very slightly greater than those of the healthy men. At rest, the patients with hypertension, recent myocardial infarction and angina had a modest prevalence of either supraventricular or ventricular premature beats.

Clinical, Circulatory and Electrocardiographic Responses to Maximal Exercise Testing

The predominant limiting symptoms at maximal exercise in healthy men were pronounced weakness of the legs (71 percent) and fatigue (25 percent).*

* Use of the term "inapparent" recognizes that if some of the men were to die of accidental or other causes, autopsy might reveal minor to moderate coronary vascular lesions although clinically they are asymptomatic, have negative findings on physical examination and exhibit no abnormalities on the resting 12 lead electrocardiogram.

* Tabulations of frequency of symptoms, signs and electrocardiographic data before exercise testing as well as during and immediately after maximal exercise are available on request to Dr. Bruce.

These symptoms were noted less frequently in hypertensive patients (50 percent) and in patients with angina (46 percent), in whom dyspnea (50 percent) and chest discomfort, tightness or pain (61 percent) were more frequent reasons for terminating exercise. Duration of maximal exertion shortened progressively with increasing evidence of cardiac disease, particularly in men with combinations of two or three diseases.

Functional aerobic impairment: The normal value derived from observed minutes of exercise in relation to age, sex and activity status, using the nomogram, was 0.6 ± 11 percent (standard deviation) (Fig. 2). The range was −16 to +17 percent, or less than that previously reported. With increasing severity of cardiovascular disease, the mean functional aerobic impairment shifted to 9 ± 19 percent, 25 ± 21 percent and 30 ± 24 percent in the patients with hypertension, prior myocardial infarction and angina, respectively (Fig. 1).

The major cardiac components of functional aerobic impairment were identified from simple measurements of circulatory and electrocardiographic responses. The chronotropic reserve of the heart, that is, the change from the resting heart rate to the highest rate observed with maximal exercise, averaged 109 ± 14 beats (standard deviation) in healthy men, 95 ± 22 in men with hypertension, 80 ± 22 in men with previous myocardial infarction, and 73 ± 24 in men with angina (Fig. 2). Similarly, an index of inotropic reserve of the left ventricle was derived from the change from resting systolic pressure to the highest pressure recorded either at or immediately after (if unable to obtain it at maximal effort) maximal exercise.* The average change in systolic pressure was 62 ± 19 mm Hg in healthy men, 56 ± 24 mm Hg in hypertensive men, 38 ± 23 mm Hg in men with previous myocardial infarction, and 40 ± 26 mm Hg in men with angina (Fig. 3). Variations in systemic peripheral resistance were indicated by small but significant changes in diastolic pressure. Both healthy men and hypertensive men showed a slight reduction in mean diastolic pressure at maximal exercise compared with their pressures at rest (Table II). Hypertensive subjects, of course, had higher diastolic pressures than healthy men. In patients with either previous myocardial infarction or angina, the level of dia-

* This is an index, since the physiologic decrease in systemic vascular resistance with strenuous exercise underestimates the actual increment in pressure.

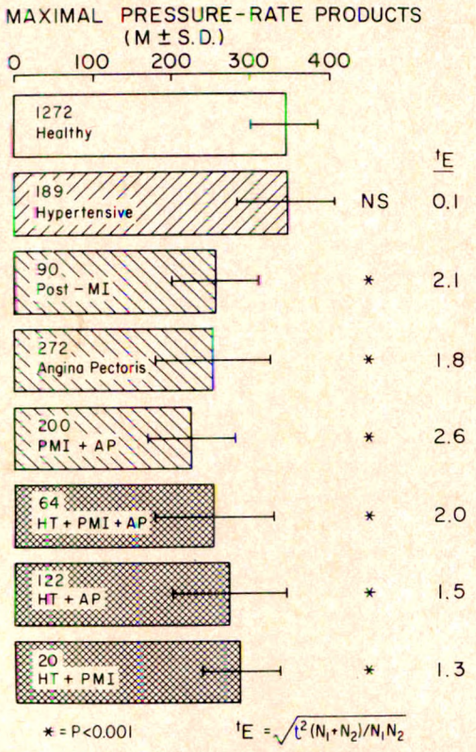

FIGURE 4. Variations in the maximal pressure-rate products as indexes of myocardial oxygen utilization. Abbreviations as in Figure 1.

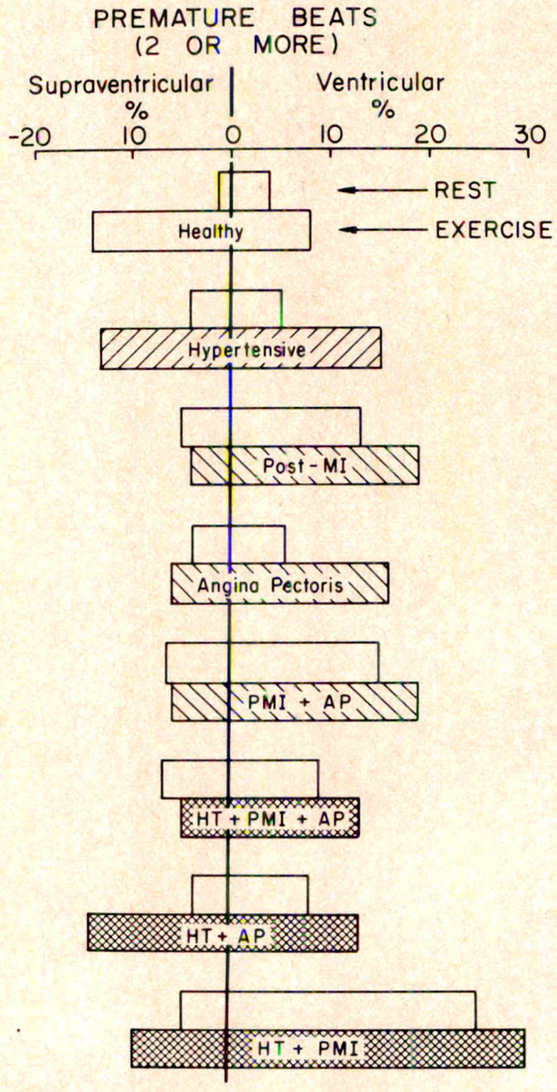

FIGURE 5. Variations in the frequencies of two or more premature beats, as indexes of arrhythmia with maximal exercise, compared with those at rest. Abbreviations as in Figure 1.

stolic pressure at rest was slightly elevated and rose with maximal exertion, indicating further arterial vasoconstriction to compensate for inadequate cardiac output.[13]

Possible differences in aerobic metabolism of the myocardium in these groups were appraised from the pressure-rate product, which is an index of myocardial oxygen uptake.[14] (Systolic rather than mean systemic arterial pressure was used, but since normal standards were obtained by the same methods, the effects of cardiovascular disease could be appraised.) Healthy men and hypertensive men had maximal values for pressure-rate product/100 of 343 ± 43 (standard deviation) and 346 ± 61, respectively (Fig. 4). Corresponding values in men with previous myocardial infarction and angina were significantly lower: 255 ± 58 and 252 ± 71, presumably because of the restrictive effects of coronary vascular disease on oxygen supply.

Arrhythmia and S–T segment displacement: Other mechanisms of cardiac impairment are revealed by arrhythmia or S–T segment displacement in the precordial electrocardiogram. All groups, including the healthy men, showed an increase in either supraventricular or ventricular premature beats (two or more) with maximal exercise (Fig. 5); the greatest number of these beats was exhibited by the hypertensive patients. More than a fourth of the healthy men (28.3 percent) had S–T segment depression of 1 mm or more (Fig. 6) for at least 60 msec of the S–T segment in the initial recovery period (by clinical interpretation), but in three fifths of these the depression was "upsloping" into the prominent upright T wave (59 percent) rather than "horizontal" or "down-

sloping" into a low or inverted T wave, the pattern usually considered by others to characterize an abnormal "ischemic" response to submaximal exercise. The majority of the hypertensive men showed these responses in a similar proportion of "upsloping" and "horizontal or downsloping" patterns. Patients with prior myocardial infarction or angina had a greater frequency of S–T segment deviation (43 and 63 percent, respectively), and more of these patients, especially those with angina, had horizontal or downsloping S–T segment depression. These changes were often evolutionary and persistent for a few minutes of recovery. Treatment with digoxin caused an accentuated S–T segment depression in very few of the patients with angina or prior infarction.

Only about 2 percent of all patients with cardiovascular disease and 0.5 percent of the healthy men exhibited S–T segment elevation with exercise (Fig. 6). In other studies S–T segment elevation was frequently associated with significantly larger left ventricular end-diastolic and end-systolic volumes, greater end-diastolic pressure and lower ejection fraction at rest.[15] About 40 percent of the patients with angina showed a "false negative" response, that is, S–T segment depression of less than 1 mm after maximal exercise. Computer analysis and display against heart rate showed abnormal hysteresis pathways during recovery as noted in previous studies.[4]

Of the 1,315 men apparently healthy before testing, 1,275 (97.2 percent) were classified after testing as "unlikely" and 40 (3 percent) as either "questionably" or "likely" to be at risk of future cardiac events. More than 15 percent of the hypertensive men, 49 percent of those with myocardial infarction and 59 percent of those with angina were similarly classified as "questionably" or "likely" to be at risk (Table II). Most of the risk assessment items were obtained from the clinical symptoms, signs and circulatory responses; the electrocardiographic items were of major importance in suggesting the possible mechanisms of future events, that is, angina or infarction from ischemia versus sudden cardiac death from arrhythmia.

Relation of Maximal Exercise to Target Heart Rates and Motivation

Since the type and protocol for multistage exercise testing are identical to those adopted by Sheffield,[16] it is of interest to ascertain the relation of maximal exercise, as the end point of exercise testing, to the age- and activity-adjusted target heart rates used by others. Less than 15 percent of the men in our study attained the prescribed heart rate (Fig. 7). From 3.7 percent active to 15.3 percent sedentary healthy men and from 44.7 percent active to 70.7 percent sedentary patients with cardiovascular disease could not attain the prescribed target heart rates advocated by Sheffield. Of greater interest, from 70.7 percent of sedentary to 94.2 percent of active healthy men, and 23.9 percent of sedentary to 54.3 percent of active patients with cardiovascular disease exceeded these arbitrary empirical limits.

When reexamined in relation to motivation, only 35 men (1.6 percent) were coded by the testing physicians as poorly motivated to perform exercise. Regardless of motivation, from 0 to 11 percent precisely attained the prescribed target heart rates. Whereas 14.2 percent active and 38.3 percent sedentary but well motivated men could not attain these limits, 36.4 percent of active and 12.5 percent of sedentary but poorly motivated men actually exceeded them. These observations indicate the unreliability of target heart rates in assessing functional capacity, either in health or in cardiovascular disease, and the importance of classifying habitual physical activity status when evaluating cardiovascular function.

Relation of Computer Analysis to Clinical Interpretation of S–T Segment Depression

In 1,636 tests (70.2 percent) satisfactory computer analyses of 100 beat electrocardiographic samples were available for comparison with clinical interpretation (by various physicians) of S–T segment depression in the initial recovery period after exercise. When the rigid conventional criterion of 1 mm horizontal or downsloping segmental depression for 0.1 mv or more was considered the diagnostic clinical criterion and computed ST_B voltages exceeded normal tolerance limits for two or more periods of observation, agreement was 85 percent, with only 10.8 per-

cent false positive and 4.1 percent false negative results (χ^2 = 567, 1 d.f.). When the more common upsloping segmental depression was also included, and only one computed ST_B voltage exceeded normal limits, agreement fell to 78.6 percent, with 12.8 percent false positive and 8.6 percent false negative results (χ^2 = 497, 1 d.f.).

The prevalence rate of horizontal or downsloping S–T segment depression was 16.8 percent in healthy men and only 18.9 percent in patients with prior myocardial infarction. Inclusion of upsloping depression increased the prevalence rate of S–T segment depression to 28.1 percent in healthy men and to 56.9 percent in patients with both hypertension and angina. The prevalence rates of abnormally depressed ST_B voltages by computer analysis ranged from a low of 33.7 percent in healthy men to 100 percent in the patients with hypertension and angina. In that the computer analysis provides greater frequency of abnormal responses, it is considered more reliable, because of the much larger sample for each determination and the uniform consistency in the application of rigid criteria for differentiation.

Complications of Maximal Exercise Testing

Only three types of complications were encountered; in 12 men an ataxic gait developed, and 6 men had three or more consecutive ventricular premature beats. Because both complications require stopping the test for reasons of safety, the prevalence rate of these potential hazards was only 0.8 percent. The gait disturbance was just as likely to occur in healthy men as in men with cardiovascular disease (χ^2 = 13, 7 d.f., not significant). Ventricular irritability was more likely to occur in patients with cardiovascular disease (χ^2 = 82, 7 d.f., $P < 0.001$). Only one patient had ventricular fibrillation during recovery from exercise; this hypertensive patient with angina underwent successful defibrillation and myocardial infarction did not develop. There have been no fatalities.*

Discussion

Feasibility, value and safety of study: The principles and methods of this prospective area practice study, making use of testing facilities in several hospitals, private offices, clinics and an industrial medical department, all linked by dataphones to a computer for analysis of electrocardiographic responses to maximal exercise, are workable. On the basis of the 2,332 men tested within the first 18 months and the rapid increase in the number of persons enrolled each month, the program is acceptable to patients and physicians alike.† Morbidity severe enough to require hospitalization has been only 0.1 percent, and there has been no mortality to date; thus, the procedure is safe under these circumstances when the precautionary principles and standardized protocol are followed.

The initial findings on examination and testing indicate that it is a productive study. It provides a more informative appraisal of the history of exertional symptoms and a more meaningful examination of the ambulatory patient with coronary artery disease than has heretofore been possible by noninvasive techniques. These results are due to determination of functional limits and observation of several cardiac mechanisms of impaired function.

The organization of pertinent data readily leads to further education of the supervising physicians and their assistants and provides a definable basis for risk assessment for future cardiac events. The assessment can be performed reliably, objectively and with documentation within 5 minutes, which is the usual time allowed for the patient to recover from the stress of maximal exertion. This evaluation is also compared with that of a totally independent computer analysis of the electrocardiographic responses. In addition, the study provides an opportunity to standardize criteria for evaluation and to facilitate an effective approach to quality control. Analysis of a large number of variables stored in the computer file is expedited by an advanced computer hardware/software system.

Assessment of cardiovascular function: Despite similarity of age and clinical diagnosis of the patients studied, there are highly significant functional differences in the assessed severity of cardiovascular disease, depending upon whether the patients report for examination in private offices or in teaching hospitals. Contrary to expectations of physicians unfamiliar with maximal exercise testing, few patients have been inappropriately motivated to perform.

The value of using target heart rates[16] as a uniform end point of exercise can be seriously questioned. The importance of habitual level of physical activity

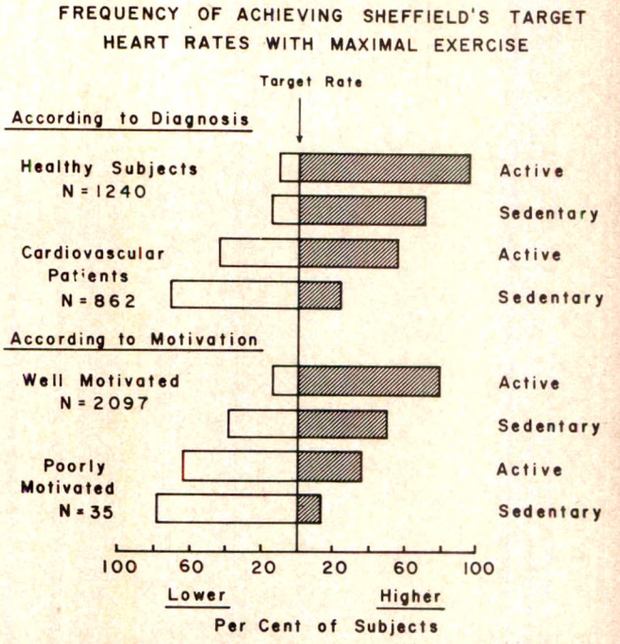

FIGURE 7. Variations in numbers of persons who either failed to attain or exceeded the age- and activity-adjusted target heart rates recommended as desirable end points for exercise testing by the same protocol as used in this laboratory for many years. See text for comments.

* Even though a few patients died suddenly during coronary arteriography or in cardiac surgery at a later date.

† One year later the enrollment had increased to 6,620 persons.

should not be disregarded in assessing cardiovascular function. Neither should it be neglected in predicting longitudinal changes with aging[18] or effect of cardiovascular disease on survival.[19]

Cardiac mechanisms of functional impairment may be appraised with respect to chronotropic and inotropic reserves of the left ventricle, index of myocardial aerobic metabolism, arrhythmias and symptomatic or unsymptomatic myocardial ischemia. Even the effects of aging on these variables may be differentiated from the effects of ischemic heart disease.[6]

Just as there are significant gradients in degree of functional aerobic impairment, there are similar gradients in the cardiovascular components of disease in a cross-sectional comparison of the clinical diagnostic classifications. For example, hypertension without apparent heart disease exerts much less restriction of cardiovascular function than either the anginal syndrome or postmyocardial infarction categories of coronary artery disease. For the few available ambulatory survivors of infarction who also exhibit manifestations of angina and hypertension, functional impairment is greater than for patients in the other six clinical categories studied. Conversely, when hypertension complicates either angina or infarction (but not both together) there is less functional impairment and postexertional myocardial ischemia. Does the greater perfusing pressure compensate, in part, for significant stenotic or occlusive lesions of the sclerotic coronary arteries, or both?

Functional effects of various types of therapeutic interventions have been reported previously in relation to the effects of medical treatment with nitroglycerin,[19] surgical treatment with saphenous vein grafting,[20] and physical training of patients with coronary artery disease.[21] Other aspects will require collection and analysis of more data to achieve adequate evaluation. These include the reproducibility of findings when there is no change in the clinical condition, as well as changes that occur with time as disease progresses in its natural history. Variations in maximal exercise performance in relation to the natural history of hypertensive disease[22] and divergent effects of antihypertensive therapy in the early phases of the natural history[23] have also been reported.

Predictive value of study: The most important question regarding validity of predictions must await the enrollment of a larger number of healthy subjects and patients with cardiovascular disease, as well as an adequate period of follow-up observation. In an earlier, pilot study on 211 healthy men followed up for 8 years, the sensitivity and predictive risk ratio of postexertional S–T segment depression were two to three times greater with this multistage test of maximal exercise than that observed in the same men with the double Master two-step test.[4] Already follow-up data on the first 1,000 men in the Seattle Heart Watch indicate that evaluation of the relative predictive value of several variables will be feasible.

Electrocardiogram in Acute Pericarditis

Distributions of Morphologic and Axial Changes by Stages

DAVID H. SPODICK, MD, FACC

Boston, Massachusetts

Among 50 patients with uncomplicated acute pericarditis, 48 showed classic stage 1 S–T segment deviations; stage 3 T wave inversions developed in 32 patients. Electrocardiographic changes during the transitional stages 2 and 4 were recorded in 23 and 32 patients, respectively. Stage 1 orientation of the S–T segment frontal plane mean vector (ÂS–T) corresponded closely to ÂT and ÂQRS. Precordial S–T segment elevations occurred with increasing frequency from leads V_1 to V_6. Subsequent T wave inversions produced a wide dispersion of ÂT in stage 3 between −50° and +100°; precordial T waves were always inverted in leads V_5 and V_6. Forty-one patients had P–R segment shifts; in 93 percent ÂP–R was concentrated between −120° and −150°, directly opposite to ÂP. ÂS–T was oriented to the left and anterior and inferior, representing the generalized subepicardial ventricular myocarditis of acute pericarditis. ÂP–R was oriented to the right and posterior and superior, representing the corresponding generalized atrial injury. The wide dispersion of ÂT in stage 3 is consistent with inhomogeneity of the ventricular recovery process after injury.

The electrocardiogram in the majority of patients with acute pericarditis[1–3] classically evolves in a sequence of four stages[4] based on S–T and T wave changes, part or all of which can be virtually diagnostic in the absence of other evidence of pericarditis[3] (Fig. 1 and 2). The typical sequence is outlined in Table I. The ubiquitous S–T segment deviations of stage 1 and subsequent T wave inversions in stage 3 are the electrocardiographic hallmarks of acute pericarditis. Stage 2 is an unstable continuum between stages 1 and 3. In stage 4 the widespread T wave abnormalities of stage 3 undergo more or less complete restitution toward the configuration of the prepericarditis tracing. P–R segment deviations,[3] appearing in stage 1 or 2, or in both (occasionally in stage 3), are almost as characteristic as the classic S–T segment deviations[3,5,6] and are not due to changes in heart rate.[5] One or another stage may be missing depending on the frequency of electrocardiographic monitoring in relation to the tempo of the inflammatory process.[1,3]

Diagnosis of acute pericarditis by electrocardiogram alone is fairly certain if the S–T segment deviations of stage 1 are recorded (Fig. 1 and 2), whether or not those of any other stages can be documented. The generalized T wave inversions of stage 3 are highly suggestive of the diagnosis, yet are indistinguishable from various patterns representing biventricular "strain" and diffuse myocardial injury. Thus, in the absence of stage 1 S–T changes, the electrocardiogram is ancillary to other evidence in diagnosing acute pericarditis, such as identification of unmistakable pericardial friction (Fig. 3)[7] or definite evidence of an inflammatory pericardial effusion or cardiac tamponade.[8] The aim of this investigation was to characterize by lead and by vector orientation the distributions of electrocardiographic changes in patients with uncomplicated acute pericarditis and more or less classic electrocardiographic evolution.

TABLE I

Four-Stage ("Typical") Electrocardiographic Evolution of Acute Pericarditis

Stage	Leads of "Epicardial" Derivation			Leads Reflecting "Endocardial" Potential		
	S–T Segment	T Waves	P–R Segment	S–T Segment	T Waves	P–R Segment
1	Elevated	Upright	Depressed or isoelectric	Depressed	Inverted	Elevated or isoelectric
2 Early	Isoelectric	Upright	Isoelectric or depressed	Isoelectric	Inverted	Isoelectric or elevated
Late	Isoelectric	Low to flat to inverted	Isoelectric or depressed	Isoelectric	Shallow to flat to upright	Isoelectric or elevated
3	Isoelectric	Inverted	Isoelectric	Isoelectric	Upright	Isoelectric
4	Isoelectric	Upright	Isoelectric	Isoelectric	Inverted	Isoelectric

Material and Methods

The subjects were 50 patients with clinically acute pericarditis and no evidence of heart disease. Etiologic assignment of pericarditis was as follows: "Idiopathic pericarditis" (syndrome) or "pericarditis of uncertain origin" (17 cases); associated with neoplasia (12 cases); viral, including 1 during hepatitis (10 cases); possible bacterial (2 cases); connective tissue diseases (9 cases). All patients had definite electrocardiographic changes, but the diagnosis of acute pericarditis could be made independently of the electrocardiogram. For this study acute pericarditis was considered present (irrespective of symptoms) on detection of a pericardial rub or fresh effusion, or both. Forty-four patients had a pericardial rub (Fig. 3), two had an effusion and four had both. Twelve lead electrocardiograms were analyzed for sequential S–T segment, T wave and P–R segment changes. The T–P interval was the base line for P–R and S–T segment measurements. Directional changes were noted for each lead, and frontal plane mean vectors (Â) were plotted on the hexaxial scale. Since this was a retrospective study, numerical and percentage distributions of electrocardiographic changes were considered to demonstrate significant trends rather than precise prevalence rates of particular events. It was recognized that one or more stages might be absent because of late arrival or early discharge of the patient or rapid evolution of the inflammatory process.

Results

Axial orientations are summarized in Table II in terms of percentage distributions for each change. The statistical base varied with the number of subjects demonstrating each stage as follows: Stage 1 was present in 48 patients, stage 2 in 23, stage 3 in 32 and stage 4 in 37. (Stage 2, always an unstable transitional phase of S–T and T wave changes [Table I], was analyzed for P–R segment changes only.)

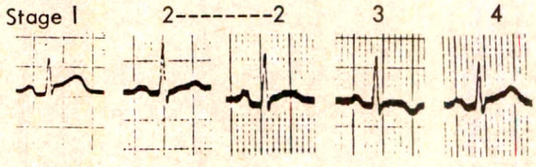

FIGURE 1. Classic four stage evolution of electrocardiogram in acute pericarditis according to S–T and T wave changes. Stage 2 is transitional with J points on the base line before T waves begin to flatten. T wave inversion characterizes stage 3. Stage 4 represents electrocardiographic resolution. Note the P–R segment depression, particularly in late stage 2 **(middle panel).**

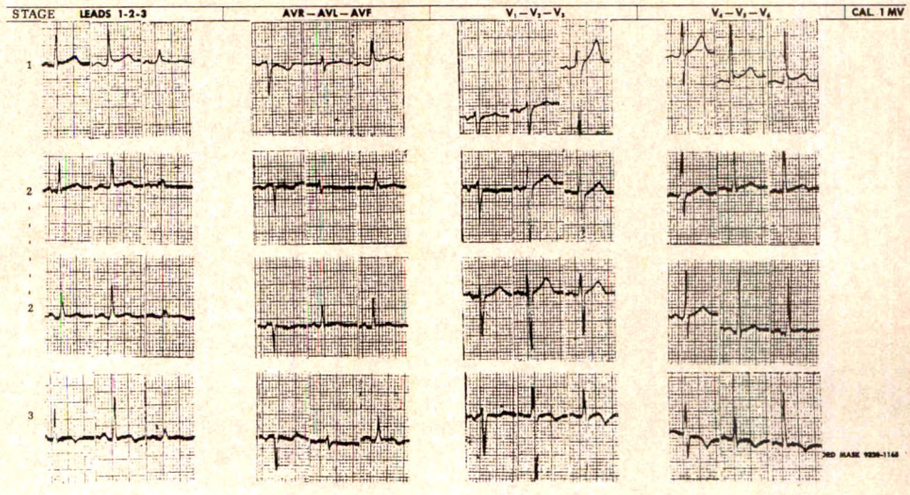

FIGURE 2. Electrocardiographic stages 1, 2 and 3 diagnostic of acute pericarditis. In stage 1, S–T segment elevation occurs in most leads of "epicardial" derivation. Note the isoelectric S–T segment in lead aVL (ÂS–T = +60°) and in leads V_1 and V_2. Late in stage 2 (third tracing from the top) P–R segment depressions occur, best seen in leads I, II, aVL, aVF and V_4 to V_6.

Heart rate: The heart rate ranged between 68 and 136 beats/min in stage 1 and between 63 and 125 beats/min in stage 2, nearly always permitting accurate delineation of waves and segments. In a single case (heart rate 136 beats/min) the proximity of the P and T waves obliterated the T–P segment so that the electrocardiogram was scored "negative" for S–T and P–R deviations.

S–T segment deviations: The numerical distribution of ÂS–T in 48 patients is shown in Figure 4. The percentage distribution (Table II) shows that 80 percent of frontal plane mean S–T vectors were oriented in the intermediate axis range lying between +30° and +60°, corresponding to 65 percent of T and 56 percent of QRS vectors. On either side of this range, horizontal (14 percent) and vertical (6 percent) ÂS–T also corresponded generally to the distributions of ÂT and ÂQRS. Precordial S–T segment deviations were seen in 47 of these 48 patients and are additionally broken down in Table III according to frontal plane QRS axis orientations. (An analysis of variance of these figures showed no trend for the distribution of precordial S–T deviations to correspond to frontal plane axes.) For the entire series, 46 of 47

patients had S–T segment elevations in leads V_5 and V_6. In lead V_1 only 8 had S–T elevations, whereas 14 had S–T depressions, and in 25 patients the S–T segment was isoelectric.

T wave changes. In stage 1 the normal mean frontal T wave vectors were concordant with the QRS vector (Table II). In stage 3 the T wave vectors had shifted as a whole to a large range with a wide dispersion between −50° and +100°, (an arc of 210°) away from the normal stage 1 ÂT orientations (Table II and Fig. 5). There was some concentration (37 percent of cases) of T wave vectors in the sector between −130° and −150°. Precordial T wave changes generally followed the lead by lead pattern of S–T deviations shown in Table II, with T wave inversions corresponding to earlier S–T elevations. The inverted T waves increased in frequency from lead V_1 to lead V_6. In nine patients (28 percent) the T wave was inverted in all precordial leads. In all cases (100 percent) T waves became completely or partially inverted in leads V_5 and V_6. Thus, both S–T and T wave changes were most frequent in the left precordial leads.

P–R segment changes: P–R segment shifts (Fig. 1 to 3) appeared in 40 patients in stage 1 or 2, or both, and in 1 patient in stage 3 only. Table II and Figure 6 show that 38 (93 percent) of the frontal plane P–R vectors in these patients were oriented in the sector between −120° and −150°, approximately directly opposite to the corresponding P wave vectors (ÂP), 88 percent of which were in the sector between +40° and +60°. Thirty-two (80 percent) of the P–R vectors were oriented 180° ± 10° from ÂP. The P–R segment was always negative in leads aVF and II and always positive in lead aVR. In precordial leads V_2 to V_6, P–R segments were always negative (38 to 40 patients, depending on lead) or isoelectric (1 to 3 patients). In 37 patients this was also true of lead V_1, but in the remaining 4 the P–R segment in lead V_1 was elevated. It was never elevated in leads V_2 to V_6.

Discussion

Subepicardial injury vectors: Forty-eight of 50 patients showed the generalized S–T segment deviations of stage 1. (In the remaining two patients the electrocardiogram was first seen during stage 2 with return to the base line of the S–T junction and subsequent T wave changes.) The S–T vectors were oriented concordantly with the mean QRS vector in most cases (Table II), the majority being in the intermediate axis range, as would be expected in a population without heart disease. Figure 4 shows both the nu-

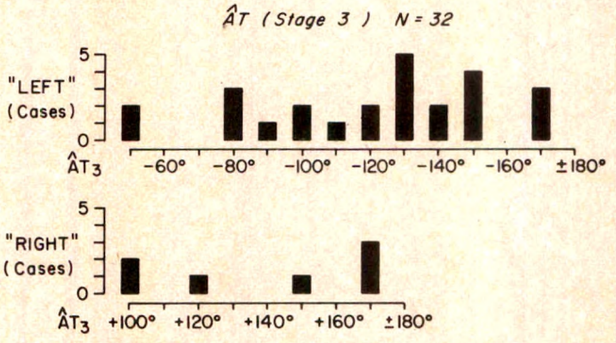

FIGURE 5. Distribution of T wave vector (ÂT) in stage 3. There is no range of predilection although most cases are oriented to the left on the hexaxial scale (see text).

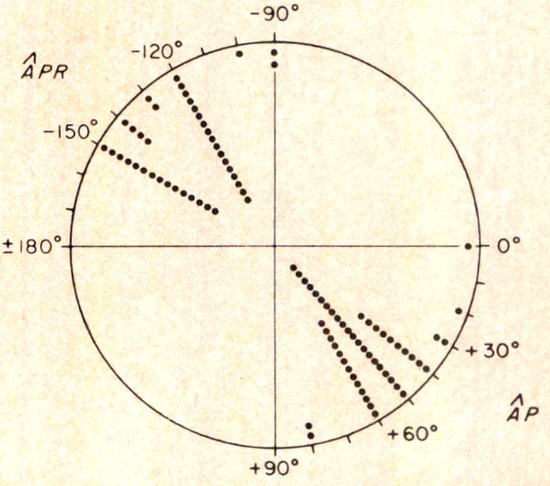

FIGURE 6. Mean frontal plane P–R segment vector orientation (ÂP–R) plotted with corresponding mean P wave vectors (ÂP) on the hexaxial scale to the nearest 10°. ÂP–R tended to be oriented to the right and superiorly and was approximately 180° opposite to ÂP, corresponding to the expected spatial orientation of atrial T wave vectors. (Although ÂP–R may be considered "left" on the hexaxial reference scale, this orientation is spatially rightward.)

merical distribution of frontal plane S–T vectors and the direction of the S–T segment deviations in each of the corresponding limb leads. Thus the S–T segment was always positive in lead II and negative in lead aVR; in lead III it was negative or positive depending on whether the QRS axis was, respectively, horizontal or vertical. The reverse was true of lead aVL. Such S–T orientations concordant with the QRS and T vectors (Table II) are consistent with a vector of generalized subepicardial injury oriented predominantly leftward and inferior in the frontal plane, that is, mainly toward the cardiac apex.[1–4] The precordial S–T segment deviations (Table III) yielded a mean horizontal plane S–T vector oriented leftward and anterior, consistent with the same concept. Thus, the net spatial ÂS–T was to the left and inferior and anterior.

In contrast to the more or less concentrated S–T vectors of acute injury, the T wave changes in stage 3 yielded a very wide range of orientation for ÂT (Fig. 5 and Table II), consistent with wider dispersion (inhomogeneity) of the ventricular repolarization process after the subepicardial injury.

Atrial injury vector: Because of the appearance of the P–R vector in more than 80 percent of the patients studied (41 of 50), P–R segment deviation must be considered almost as characteristic of acute pericarditis as the classic S–T segment shift. ÂP–R was always oriented to the right and superiorly (Fig. 6). Since no patient had P wave abnormalities, P–R segment deviations probably represent subepicardial atrial injury. ÂP–R tended to be close to 180° away from ÂP (Table II); that is, it followed the expected orientation of the atrial T wave.[9,10] Thus, the electrocardiographic registration of atrial injury in acute pericarditis is analogous to that of the stage 1 ventricular subepicardial injury in that each follows the orientation of its respective normal recovery (T) wave. Since most atrial tissue lies posteriorly, to the right, and relatively cephalad of the ventricles, the orientation of a vector of generalized atrial injury (ÂP–R) would be expected to be to the right and superior (as shown by the frontal plane ÂP) and also posterior. The predominant P–R segment depressions across the precordium document the posterior component. Because of these P–R segment deviations, it is of practical importance in acute pericarditis to consider the T–P segment to be the electrocardiographic base line to avoid mistaking P–R segment depression for S–T segment elevation.

Posterior Wall Velocity: An Unreliable Index of Total Left Ventricular Performance in Patients with Coronary Artery Disease

Posterior wall velocity determined by use of echocardiography has been proposed as an index of total left ventricular performance in patients with ischemic heart disease. Accordingly, in 9 normal subjects and 39 patients with angiographically documented coronary artery disease, we compared mean endocardial posterior wall velocity determined by echocardiography with echocardiographic and biplane cineangiographic calculations of ejection fraction and the mean rate of circumferential fiber shortening (mean V_{CF}), and with externally recorded systolic time intervals. All studies were performed on the same day in each patient. Mean endocardial posterior wall velocity averaged 4.6 cm/sec (range 2.9 to 8.7) and correlated poorly with echocardiographic ejection fraction ($r = 0.47$), cineangiographic ejection fraction ($r = 0.26$), cineangiographic mean V_{CF} ($r = 0.47$), the ratio of preejection period to left ventricular ejection time ($r = -0.35$) and the preejection period corrected for heart rate ($r = -0.30$). Substitution of maximal for mean endocardial posterior wall velocity did not improve the separation of normal from depressed left ventricular performance. Epicardial posterior wall velocity, a measurement more easily obtainable than endocardial posterior wall velocity, also did not correlate well with systolic time intervals or with ejection fraction or mean V_{CF} derived from the echocardiogram and cineangiogram. Both endocardial and epicardial posterior wall velocity values were poorly reproducible on a day to day or a beat to beat basis. We conclude that neither endocardial nor epicardial posterior wall velocity, whether derived as a mean or a maximum, provides an accurate measure of total left ventricular performance in patients with coronary artery disease.

There has been considerable recent interest in the noninvasive estimation of left ventricular performance in man. Both echocardiography[1–4] and externally recorded systolic time intervals[5] have been proposed as methods suitable for serial atraumatic assessment of myocardial function. It has been suggested that echocardiographic measurement of left ventricular posterior wall velocity might provide a simple reproducible method for serial evaluation of total cardiac performance.[6–8] Accordingly, we compared echocardiographic estimates of posterior wall velocity with other echocardiographic indexes of left ventricular function and with externally recorded systolic time intervals and indexes of myocardial performance derived from cineangiocardiograms in patients with and without coronary artery disease.

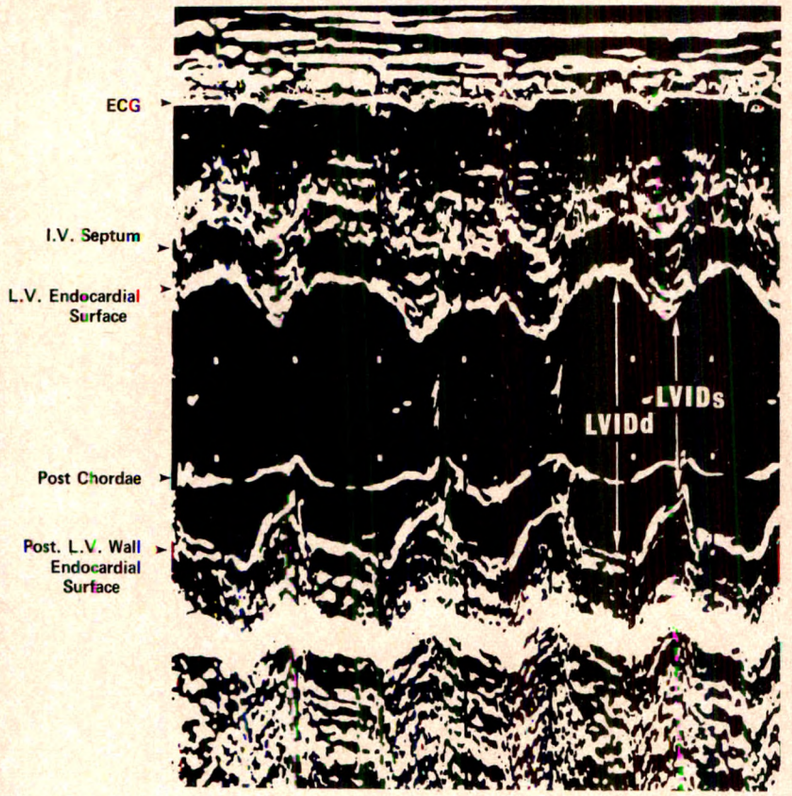

FIGURE 1. Echocardiogram showing the left ventricular (L.V.) endocardial surface of the interventricular (I.V.) septum and the left ventricular posterior (post.) wall endocardium. Careful visualization of the posterior chordae insured both accurate definition of the left ventricular endocardium and consistent localization of the ultrasound beam. Automatically incorporated into the display are the simultaneous electrocardiogram and time-distance markers. Distance is plotted on the ordinate and time on the abscissa. The left ventricular internal end-diastolic dimension (LVIDd) between endocardial surfaces was measured along a vertical line drawn through the QRS complex. The left ventricular internal end-systolic dimension (LVIDs) was defined as the smallest distance separating the endocardial surfaces of the septum and the left ventricular posterior wall. Ejection time (ET) was taken as the length of time from the peak of the QRS complex to the maximal excursion of the left ventricular posterior wall, less 50 msec for the preejection period when no appreciable fiber shortening occurs.[11,12] In each instance, posterior wall velocity was derived from the same cycles used to calculate ejection fraction and mean V_{CF}. In the case illustrated, a sinus arrhythmia was present.

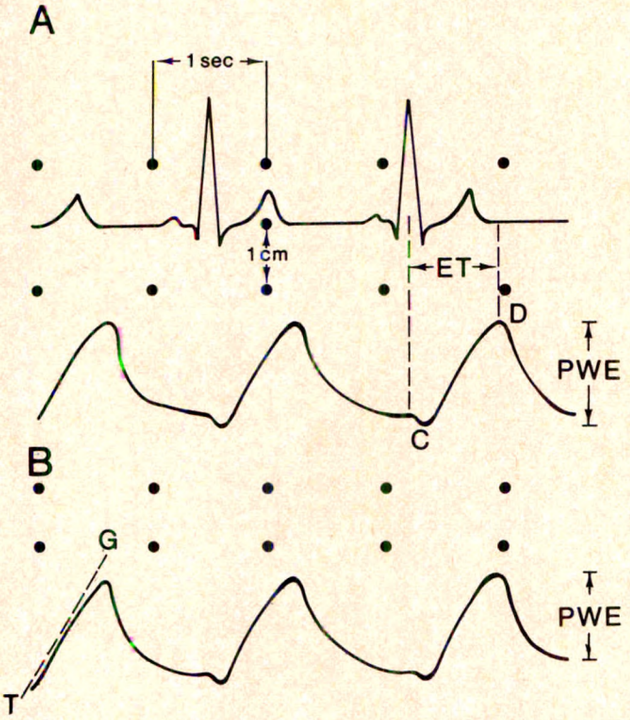

FIGURE 2. Two methods for calculating left ventricular posterior wall velocity are shown. **A,** the mean posterior wall velocity is equal to posterior wall excursion (PWE) measured from points C to D, divided by the ejection time (ET), as defined. **B,** maximal posterior wall velocity is calculated by constructing a tangent (TG) to the steepest part of the left ventricular posterior wall and expressing the slope in centimeters per second.

Methods

In 48 patients admitted for diagnostic cardiac catheterization and coronary angiography, echocardiographic estimates of posterior wall velocity and left ventricular dimensions were performed by one observer within 24 hours of catheterization. Thirty-nine of these patients had coronary artery disease; the remaining nine had no evident cardiac disease. Ten additional patients were studied daily by echocardiography for an average of 6 days in the coronary care unit; seven of these patients had documented acute myocardial infarction, and the other three had angina pectoris without overt infarction. Another nine normal subjects were also examined daily by echocardiography for an average of 3 days. All echocardiographic studies were performed with subjects in the basal fasting state, in either the supine or left lateral decubitus position.

Methods of ultrasound echocardiography have previously been described in detail.[3,9,10] A commercially available ultrasonoscope (Ekoline 20, Mark II, Smith-Kline) was used with a 2.25 megaHerz, 0.75 inch transducer that had a repetition rate of 1,000 impulses/sec. Polaroid photographs of the "time-motion" echocardiographic display were made directly from the oscilloscope (Fig. 1). Careful visualization of the "x" line representing echoes from the supporting apparatus of the mitral valve ensured both accurate definition of the left ventricular endocardium and consistent localization of the ultrasound beam. In all 48 patients a complete echocardiographic left ventricular dimensional analysis was performed using methods previously described for determination of end-diastolic and end-systolic volumes and ejection fraction, mean velocity of circumferential fiber shortening, and posterior wall velocity.[3] For the latter measure, two types of determinations were made. A mean value

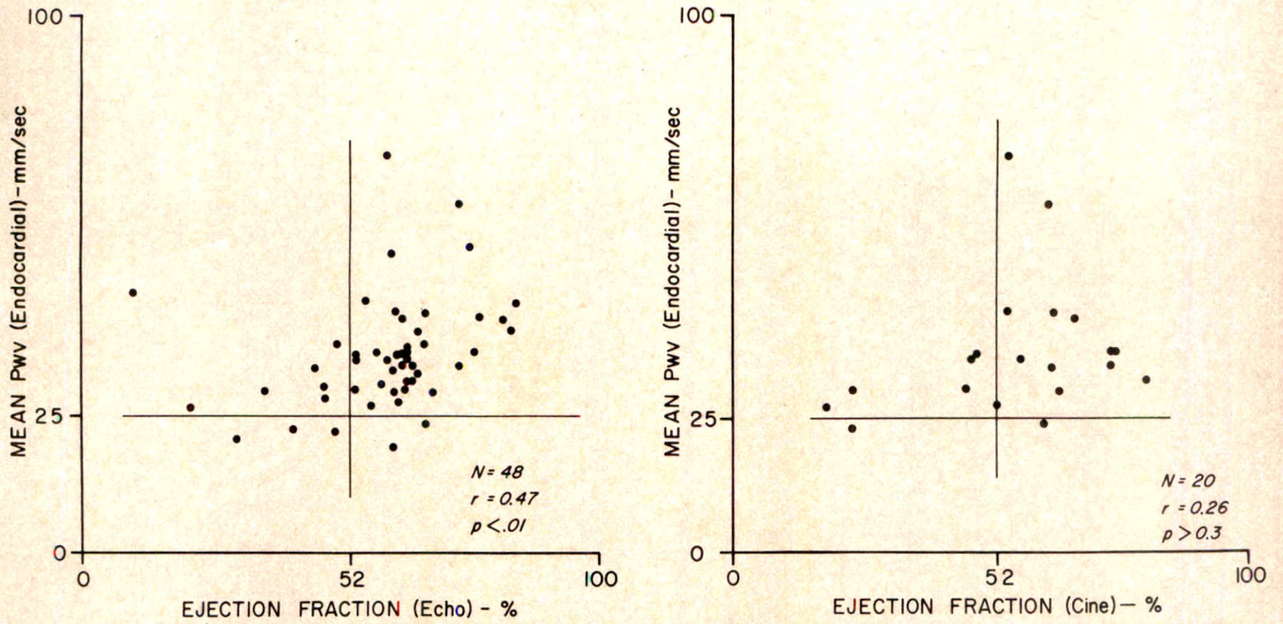

FIGURE 3. Mean endocardial posterior wall velocity (PWV) determined by echocardiography plotted against ejection fraction determined by echocardiography **(left)** and cineangiography **(right).** The **crossed lines** represent the lower limits of normal for each measurement (25 mm/sec for mean posterior wall velocity and 0.52 for ejection fraction).

for posterior wall velocity (mean PWV [cm/sec]) was calculated from the value for posterior wall excursion divided by the ejection time (less 50 msec for isovolumetric contraction, when little significant fiber shortening occurs[11] [Fig. 2]). Mean posterior wall velocity was derived at both the endocardial and epicardial surfaces. To validate the method of calculating ejection time, we compared our technique with the alternative method of measuring the duration of systole directly from the echocardiogram. For 40 of the 48 patients the correlation between results of the two techniques was excellent ($r = 0.987$, $P < 10^{-6}$). The average difference between the two determinations was 6.3 msec (range 0 to 15 msec). Neither method yielded a value consistently larger or smaller than that of the other. In the remaining eight patients, the ejection time could not be accurately determined directly from the ultrasound recording because of the initial slurring of the upstroke associated with isovolumetric systole. The left ventricular ejection time derived from the externally recorded carotid pulse tracing averaged 260.5 ± 5.0 (standard error) msec (range 178 to 338), and that obtained by the ultrasound method described averaged 259 ± 4.8 msec (range 170 to 340). There was a highly significant correlation between the two measures ($r = 0.870$, $P < 10^{-6}$). As with the previous comparison, neither method yielded a value consistently larger or smaller than that of the other.

Maximal posterior wall velocity (PWVmax [cm/sec]), calculated at both the endocardial and the epicardial surfaces, was determined from the slope of a tangent drawn to the steepest position of the anterior movement of the posterior wall echo (Fig. 2). For each determination of ejection fraction, mean velocity of basal circumferential fiber shortening (mean V_{CF}) and posterior wall velocity, five satisfactorily recorded beats were averaged. Thus, the beats from which the echocardiographic ejection fraction and mean V_{CF} were derived were from the same cycles used to calculate posterior wall velocity, thereby eliminating any bias in the comparisons among these determinations.

In the 10 patients who were studied in the coronary care unit, echocardiographic recordings were made of epicardial posterior wall movement only, since we sought to test the validity and reproducibility of the epicardial posterior wall velocity alone as an index of left ventricular performance. Recordings of the epicardial surface, which can be obtained rapidly and with minimal discomfort to the patient, were thought to be most suited to patients with documented or suspected acute myocardial infarction.

Cardiac catheterization was performed with patients in the fasting state after premedication with 100 mg of sodium pentobarbital. Left ventricular catheterization was performed by the retrograde arterial technique, and left ventricular cineangiograms were recorded at 75 frames/sec after intraventricular injection of 40 to 50 ml of 75 percent Hypaque® over 2 to 3 seconds. End-systolic and end-diastolic left ventricular volumes were estimated using the area-length method for biplane ventriculograms,[13] and the ejection fraction was calculated from these measurements.[14] Mean V_{CF} was derived from the lateral projection of the left ventriculogram by calculating the shortening of a chord drawn perpendicular to the long axis of the ventricle at one third of the distance from the midpoint of the mitral valve plane to the cardiac apex.[3,12] This chord was selected for comparison since it corresponds most closely to the plane of the ultrasound beam.[3]

Systolic time intervals were measured from simultaneous recordings of a high frequency phonocardiogram, indirect carotid arterial pulse and electrocardiogram on a multichannel recorder (Elena-Schonander Minograf) at a paper speed of 100 mm/sec, immediately after the echocardiogram. Calculations of mean intervals were derived from measurements of 10 optimally recorded cardiac cycles. Observed intervals were corrected for heart rate and sex according to the regression equations of Weissler and coworkers,[5] and expressed as indexes. The ratio of preejection period (PEP) to left ventricular ejection time (LVET) was obtained by dividing the observed PEP by the uncor-

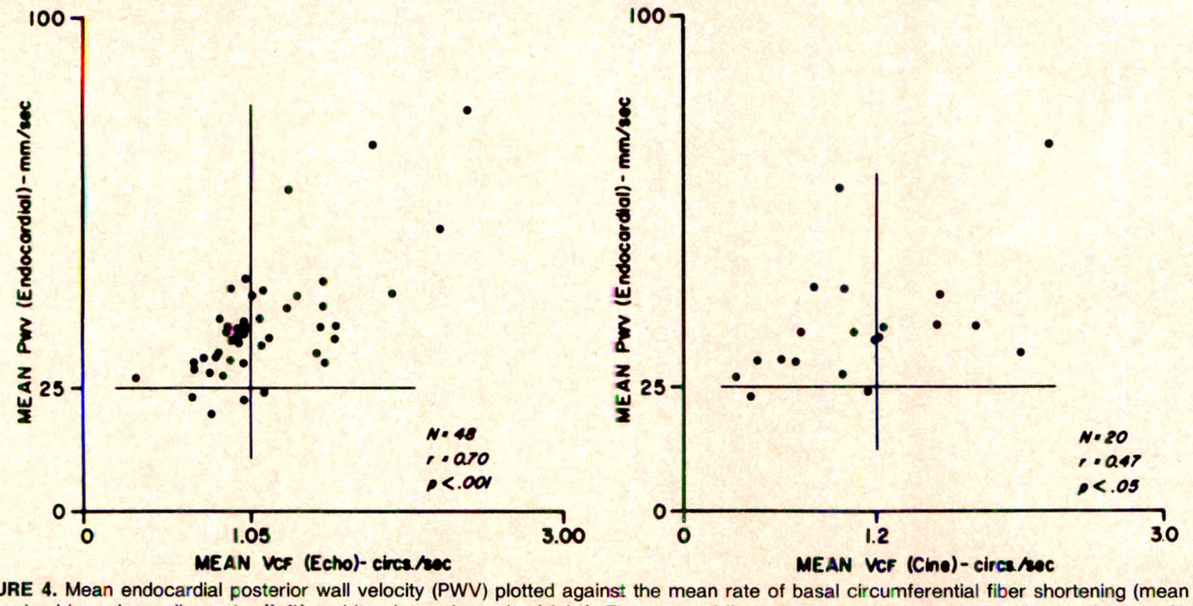

FIGURE 4. Mean endocardial posterior wall velocity (PWV) plotted against the mean rate of basal circumferential fiber shortening (mean V_{CF}) determined by echocardiography **(left)** and by cineangiography **(right).** The **crossed lines** represent the lower limits of normal for each measurement (25 mm/sec for mean posterior wall velocity, 1.05 circumferences/sec for mean V_{CF} by echocardiography and 1.20 circumferences/sec for mean V_{CF} by cineangiography).

rected LVET, since it has previously been shown that this ratio is independent of heart rate.[15]

Echocardiograms satisfactory for volume estimation and for calculation of posterior wall velocity were obtained in all 48 patients studied in the catheterization laboratory. In 20 of these patients left ventricular cineangiograms were suitable for volume and mean V_{CF} determinations; that is, there was adequate opacification of normally conducted beats that did not follow one or more premature contractions. The 10 patients studied in the coronary care unit and the 9 normal control subjects also had satisfactory echocardiograms for analysis of posterior wall velocity.

In 6 patients 16 echocardiographic dimensional analyses and determinations of systolic time intervals were performed to test observer and technique reproducibility. The average variation for echocardiographic determinations in

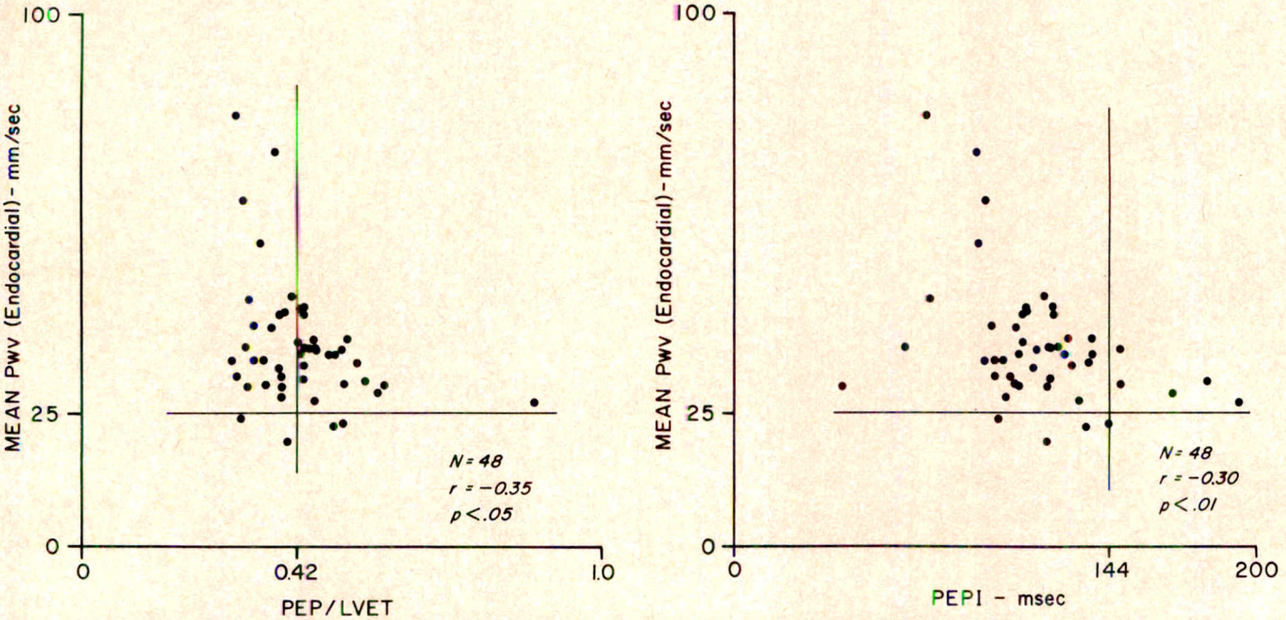

FIGURE 5. Mean endocardial posterior wall velocity (PWV) plotted against the ratio of the preejection period to the left ventricular ejection time (PEP/LVET) **(left),** and against the preejection period (PEP) corrected for heart rate (PEPI) **(right).** The **crossed lines** depict the lower limit of normal for posterior wall velocity (25 mm/sec), and the upper limit of normal for PEP/LVET (0.420) and for preejection period corrected for heart rate (144 msec).

the same patient was 3 percent for ejection fraction and 6.5 percent for mean V_{CF}; the average variation for PEP/LVET was 9 percent. These figures are in accord with previous data from our laboratory showing that mean V_{CF} was reproducible within 6 percent when determined by echocardiography[3] and cineventriculography.[12]

Results

In the 48 patients, mean endocardial posterior wall velocity averaged 3.8 cm/sec (range 2.0 to 7.4) and correlated closely with maximal endocardial posterior wall velocity (average 4.6 cm/sec; range 2.9 to 8.7). In nine patients considered to have normal left ventricular function on the basis of hemodynamic studies, mean endocardial posterior wall velocity averaged 4.2 cm/sec (range 3.0 to 4.4) and maximal endocardial posterior wall velocity averaged 5.1 cm/sec (range 3.7 to 5.6). In the 39 patients with coronary artery disease, mean posterior wall velocity averaged 3.6 cm/sec (range 2.0 to 7.4) and the average maximal posterior wall velocity was 4.3 cm/sec (range 2.1 to 7.5). Neither mean nor maximal posterior wall velocity separated normal from impaired left ventricular performance.

Posterior wall velocity vs. ejection fraction: Figure 3 shows the poor correlation between mean endocardial posterior wall velocity and ejection fraction determined by echocardiogram and cineangiocardiogram. In 7 patients with a reduced ejection fraction by echocardiogram (<0.52), mean endocardial posterior wall velocity exceeded our lower limit of normal for mean posterior wall velocity (2.5 cm/sec, a value that is 2 standard deviations below the mean value derived from 24 normal subjects in our laboratory). Similarly, in five patients with a depressed ejection fraction by cineangiogram, mean endocardial posterior wall velocity was within the normal range. Use of maximal endocardial posterior wall velocity did not improve the separation of normal from abnormal left ventricular performance.

Posterior wall velocity vs. V_{CF}: Figure 4 shows the correlation between mean endocardial posterior wall velocity and mean V_{CF} determined by echocardiogram and cineangiocardiogram. Of 25 patients with a reduced mean V_{CF} (<1.05 circumferences/sec) by echocardiogram,[3] only 3 had a depressed mean endocardial posterior wall velocity (Fig. 4, left panel). Similarly, of 12 patients whose mean V_{CF} by cineangiogram was reduced (<1.2 circumferences/sec),[12] only 2 had an abnormal value for mean posterior wall velocity (Fig. 4, right panel). Substitution of maximal for mean endocardial posterior wall velocity did not improve the separation.

Posterior wall velocity vs. PEP/LVET: Equally poor results were obtained when mean endocardial posterior wall velocity was plotted against the ratio of preejection period (PEP) to left ventricular ejection time (LVET) (Fig. 5, left panel), and the preejection period was corrected for heart rate (PEPI, Fig 5, right panel). Of 23 patients with an abnormal PEP/LVET ratio (>0.420), 21 had a normal value for mean posterior wall velocity. In five patients PEPI was abnormal (>144 msec), but mean posterior wall velocity was within the normal range, whereas the converse was true in three patients.

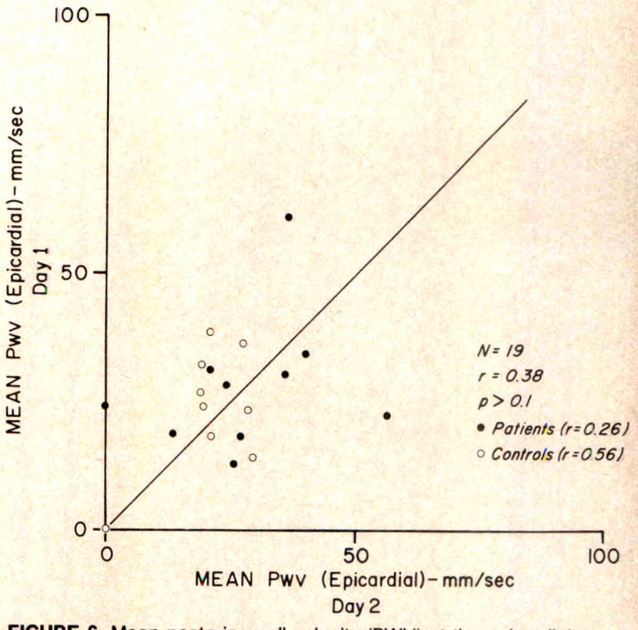

FIGURE 6. Mean posterior wall velocity (PWV) at the epicardial surface obtained on one day (Day 1) is plotted against mean epicardial posterior wall velocity measured on the next day (Day 2). Seven patients with myocardial infarction and three patients with angina pectoris **(closed circles)** and nine normal subjects **(open circles)** were studied. The **solid line** represents the line of identity.

Maximal epicardial posterior wall velocity (average 2.3 cm/sec, range 1.1 to 4.1) also failed to distinguish patients with normal left ventricular function (average 2.5 cm/sec, range 1.9 to 3.0) from those with reduced performance (average 2.2 cm/sec, range 1.1 to 4.1). This measure also failed to show significant correlation with mean endocardial posterior wall velocity, maximal endocardial posterior wall velocity, echocardiographic ejection fraction, echocardiographic mean V_{CF}, PEP/LVET, PEPI, cineangiographic ejection fraction, cineangiographic mean V_{CF} or heart rate.

Posterior wall velocity in acute myocardial infarction: Estimations of mean epicardial posterior wall velocity performed in 10 patients with acute myocardial infarction or angina pectoris studied in the coronary care unit also failed to distinguish patients from normal control subjects. Thus, mean epicardial posterior wall velocity averaged 2.27 cm/sec (range 0.5 to 4.4) in these patients, and 2.2 cm/sec (range 0.5 to 3.0) in nine normal control subjects. Furthermore, despite careful attention to consistent localization of the ultrasound beam, daily estimations of epicardial posterior wall velocity in individual subjects showed wide variation. Figure 6 depicts mean epicardial posterior wall velocity as measured on two successive days in the 10 patients hospitalized in the coronary care unit and in 9 normal control subjects. There is a disappointing correlation be-

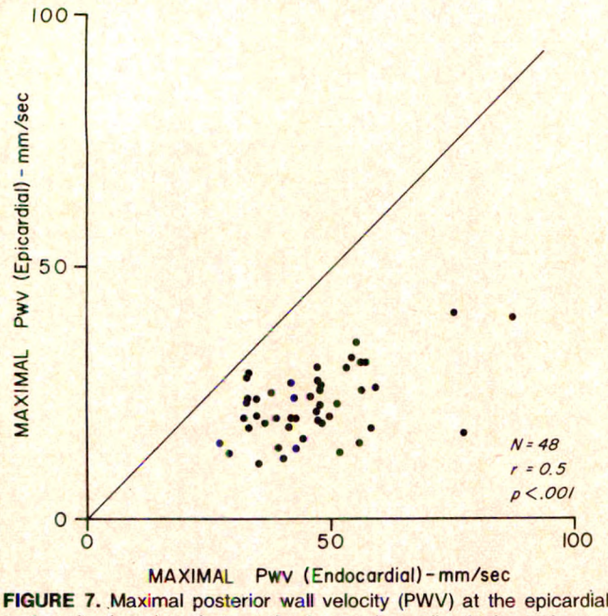

FIGURE 7. Maximal posterior wall velocity (PWV) at the epicardial surface is plotted against maximal posterior wall velocity at the endocardial surface in all 48 patients studied. The **solid line** represents the line of identity. In each instance, the endocardial velocity exceeds the epicardial velocity. Such a disparity is to be expected, since the posterior wall myocardium not only moves anteriorly, but also thickens during systole.

tween the paired measurements in each patient, indicating that the measurement of mean epicardial posterior wall velocity is poorly reproducible from day to day.

Similarly, endocardial posterior wall velocity is also a poorly reproducible measure. For example, in six patients, four of whom had normal left ventricular function, mean endocardial posterior wall velocity determined on 16 occasions varied by an average of 20.5 percent (range 6 to 52 percent) and maximal endocardial posterior wall velocity by an average of 15.8 percent (range 7.5 to 27 percent). Further, despite the use of only strictly satisfactorily recorded beats for calculation, there was a beat to beat variation in maximal endocardial posterior wall velocity averaging 42 percent (range 6.0 to 143 percent). These variations in endocardial posterior wall velocity occurred despite careful attention to visualization of the mitral valve supporting apparatus ("x"-line) as a landmark (Fig. 1).

Since epicardial posterior wall velocity is rapidly and easily obtainable by echocardiography, we compared this measure with endocardial posterior wall velocity, which is difficult and time-consuming to obtain, in all 48 patients. The results, shown in Figure 7, indicate a poor correlation between the two measures of posterior wall velocity.

Echographic and ventriculographic ejection fraction and V_{CF}: Highly significant correlations were obtained by comparing echocardiographic and ventriculographic estimations of ejection fraction. These values also correlated well with systolic time intervals, particularly the PEP/LVET ratio and the preejection period corrected for heart rate (PEPI). Thus echocardiographic ejection fraction (mean 0.61, range 0.21 to 0.83) correlated well with cineangiographic ejection fraction (mean 0.54, range 0.19 to 0.73; $r = 0.83$, $P < 0.001$); with PEP/LVET (mean 0.443, range 0.87 to 0.263; $r = -0.84$, $P < 0.001$) and with PEPI (mean 137.3 msec, range 81.0 to 186.0; $r = -0.71$, $P < 0.001$). Cineangiographic ejection fraction, in turn, was closely related both to PEP/LVET ($r = -0.77$, $P < 0.001$) and to PEPI ($r = -0.60$, $P < 0.005$).

Further, comparable estimates of mean V_{CF} were obtained from both the echocardiogram and the ventriculogram. Thus, echocardiographic mean V_{CF} (average 1.07 circumferences/sec, range 0.33 to 2.23) correlated with cineangiographic mean V_{CF} (average 1.1 circumferences/sec, range 0.33 to 2.28; $r = 0.70$, $P < 0.001$); with PEP/LVET ($r = -0.62$, $P < 0.001$) and with PEPI ($r = -0.70$, $P < 0.001$).

Discussion

Noninvasive techniques, such as ultrasound echocardiography and measurement of systolic time intervals, recently have been utilized to quantitate left ventricular function in man. Thus, echocardiographic determinations of both ejection fraction[1] and mean velocity of basal circumferential fiber shortening (mean V_{CF}[3]) previously have been reported to correlate well with standard cineangiographic estimates of these measures, and thereby to provide reliable estimates of left ventricular performance in the basal state. It has also been shown that the ratio of preejection period to left ventricular ejection time (PEP/LVET) correlates highly with cineangiographic determinations of ejection fraction[16] and that the preejection period corrected for heart rate (PEPI) reflects the contractile state of the ventricle during isovolumetric systole.[17] Systolic time intervals have also been reported to be of use in routine follow-up studies of patients who have had coronary bypass surgery, particularly in the documentation of early changes in left ventricular function before clinical deterioration occurs.[18]

However, ultrasound determinations of ejection fraction and mean V_{CF} require an operator highly experienced in the performance of echocardiography, considerable time and a cooperative, supine patient. These requirements may be difficult to meet in sick patients, especially those with acute myocardial infarction. Because the velocity of the posterior left ventricular epicardial surface is among the simplest of ultrasound measurements to obtain, it has been suggested that calculation of posterior wall velocity might provide a suitable alternative to more complex echocardiographic measurements of left ventricular function. Posterior wall velocity has been reported to reflect the velocity of circumferential fiber shortening[6] and to correspond to changes in left ventricular performance induced by physiologic and pharmacologic interventions,[6,7] and by acute myocardial infarction.[8]

Reliability and reproducibility of posterior wall velocity determinations: Our results indicated that measurement of posterior wall velocity did not correlate satisfactorily with either echocardiographic

or standard cineangiographic measurements of ejection fraction and mean V_{CF}. Equally poor results were obtained when posterior wall velocity was compared with measurement of systolic time intervals. Disappointing correlations were obtained whether posterior wall endocardium or epicardium was examined, or mean or maximal velocity calculated. The closest correlation observed was between mean endocardial posterior wall velocity and echocardiographic mean V_{CF} ($r = 0.70$), presumably because calculation of posterior wall excursion is part of the calculation of mean V_{CF} by this method. However, in 16 patients with wall motion abnormalities documented by cineangiography, mean endocardial posterior wall velocity was normal in 13 and echocardiographic mean V_{CF} was depressed in 15.

Our serial studies in 10 patients with acute myocardial infarction or angina pectoris who were hospitalized in the coronary care unit showed that both endocardial and epicardial posterior wall velocity vary widely from day to day, and from beat to beat in individual patients, despite careful efforts to achieve a consistent ultrasound beam plane by careful visualization of the mitral valve apparatus. Therefore, these measures appeared to be unreliable for assessment of basal left ventricular performance or changes in myocardial function produced by interventions.

In searching for a noninvasive measure of cardiac function that could be obtained rapidly and easily in the coronary care unit, we examined the velocity of movement of left ventricular posterior wall epicardium, since consistent definition of posterior wall endocardium is usually more difficult and time consuming. However, as indicated, this measure also did not distinguish normal from abnormal left ventricular performance, correlate significantly with other indexes examined, or demonstrate adequate reproducibility from beat to beat or day to day. Thus, we were unable to confirm the observation that abnormalities in the contour of the left ventricular posterior wall epicardial echo could be utilized to predict alterations in myocardial function.[6]

Reasons for unreliability of posterior wall velocity as an index of myocardial performance: In comparison with other measures of myocardial performance, the values for posterior wall velocity generally tended to overestimate left ventricular function. Furthermore, despite the inability of posterior wall velocity to provide accurate information on total left ventricular performance in patients with coronary heart disease, ultrasound estimates of other ejection phase indexes of myocardial function, particularly mean V_{CF}, remain highly comparable to cineangiographic measurements.[19] Why posterior wall velocity is unreliable and mean V_{CF} accurate may be explained as follows: (1) Despite accurate localization and consistent examination of one area of the posterior left ventricular wall, and despite use of the same cycles for determination of both mean V_{CF} and posterior wall velocity, it is probable that in patients with coronary artery disease such an area is unrepresentative of the left ventricular myocardium as a whole. This is so because the posterior wall is an uncommon site for the localization of ischemic damage in comparison with the anterior, lateral, inferior or apical segments of the left ventricle, and the motion of these segments is entirely ignored in the determination of posterior wall velocity. (2) It has been our observation that when excursion of one of the ventricular walls is reduced because of ischemia or fibrosis, some compensation frequently is provided by increased excursion of the opposing wall, so that any error introduced by measurement of movement of one wall tends to be canceled by that of the other.

McDonald et al.[20] have recently described the influence on the echocardiogram of the anterior motion of the whole heart during systole. This systolic anterior motion diminishes the recorded posterior excursion of the interventricular septum and, conversely, increases the recorded anterior movement of the posterior left ventricular wall. This effect of the anterior motion of the whole heart during systole tends to be nullified when both septal and posterior wall movement are measured in the echocardiographic estimation of left ventricular dimensions, but it may lead to exaggeration of calculated posterior wall velocity.

The results of our study are in agreement with the recent observations of Fogelman et al.,[21] who found no consistent abnormalities in the rate of systolic motion of the posterior left ventricular wall during exercise-induced angina pectoris. They also reported that early diastolic motion of the posterior wall was reduced only during stress-induced angina.[21] In our study we did not examine patients with valvular heart disease or nonischemic cardiomyopathy. Although the possibility remains that in such patients estimation of posterior wall velocity might provide useful information on total left ventricular performance, Belenkie et al.[22] recently demonstrated that mean posterior wall velocity correlated poorly with other ultrasound and cineangiographic measures of left ventricular performance in 20 patients with valvular heart disease and in 3 subjects with nonischemic cardiomyopathy.

We conclude that despite its ease and speed of performance, calculation of posterior wall endocardial or epicardial velocity, whether derived as a mean or maximum, is unreliable for basal or serial assessment of total left ventricular performance in patients with ischemic heart disease.

Mortality in Patients Undergoing Coronary Artery Bypass Surgery After Myocardial Infarction

JOHN T. DAWSON, MD
ROBERT J. HALL, MD, FACC
GRADY L. HALLMAN, MD, FACC
DENTON A. COOLEY, MD, FACC

Houston, Texas

Data on 1,700 patients who underwent coronary artery bypass surgery without additional cardiovascular procedures at the Texas Heart Institute were analyzed, relating the interval between myocardial infarction and operation to early mortality (within 30 days after operation). Patients who underwent coronary artery bypass surgery after a recent infarction (within 2 months before operation) had a higher rate of early mortality (14.5 percent) than patients who had an old infarction (6.9 percent) or no previous infarction (4.1 percent). The interval between recent infarction and operation was most significant. Mortality in patients who underwent operation within the first 7 days after acute infarction (38.1 percent) was more than six times greater than in patients who were operated on 31 to 60 days after infarction (5.8 percent). Mortality of those operated on 8 to 30 days after infarction was 16.4 percent. Elective coronary artery bypass surgery after recent infarction is best accomplished after the first 30 days, when there is no increased risk to the patient. Emergency coronary artery bypass after complicated acute myocardial infarction may be a lifesaving procedure, but it is associated with increased early mortality and should be reserved for those whose condition has not responded to aggressive medical therapy.

Evaluation of patients who have undergone coronary artery bypass procedures has elucidated factors associated with higher rates of early mortality. In previous reports,[1,2] we presented data that define these factors, which include advanced age, female sex, higher coronary artery scores (by the method of Friesinger et al.),[3] the presence of congestive heart failure, increased left ventricular diastolic pressure, significant left ventricular dysfunction, lesions of the left main coronary artery, concomitant endarterectomy with bypass, associated valvular lesions and recent acute myocardial infarction before operation. This report further analyzes the relation between recent myocardial infarction and early (within 30 days after operation) mortality after coronary artery bypass surgery.

Material and Methods

During a 39 month period ending December 1972, a total of 1,944 patients underwent aortocoronary saphenous vein bypass surgery at the Texas Heart Institute. Of these, 1,700 patients who had no additional cardiovascular procedures, except for concomitant endarterectomy, were classified into three groups: Patients in Group 1 had no previous infarction according to electrocardiogram and history; patients in Group 2 had old myocardial infarction more than 2 months before operation, as determined by electrocardiogram or history, or both; and patients in Group 3 had a recent myocardial infarction within 2 months before operation, as documented by electrocardiogram, history and serum enzyme determinations. Electrocardiographic changes in all three groups included development of new Q waves in all but two patients. Patients in Group 3 were closely analyzed for exact intervals between infarc-

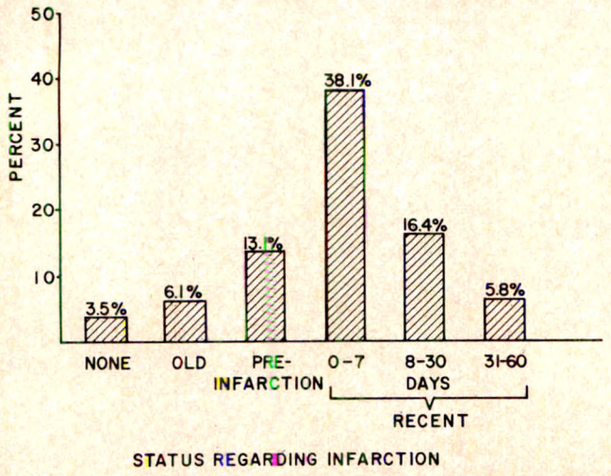

FIGURE 1. Early mortality rates in patients undergoing coronary artery bypass surgery, in relation to interval between infarction and operation.

tion and operation. The results relating to early mortality were tabulated in all groups. Most of the patients underwent total cardiopulmonary bypass with ischemic cardiac arrest. During the latter part of this study general body hypothermia and direct cooling of the heart with cold saline solution were used for patients undergoing multiple bypass procedures. Intraaortic balloon counterpulsation and emergency femoral vein to artery partial bypass were employed before thoracotomy in selected cases.

Results

The overall early mortality rate in the total group of 1,700 patients was 6.9 percent (118 deaths). The early mortality rate of patients who had no previous infarction (Group 1) was 4.1 percent (15 deaths among 361 patients). In Group 2, patients with old myocardial infarction, the early mortality rate was 6.9 percent (82 deaths among 1,194 patients). There were 145 patients who had a myocardial infarction within 2 months before operation (Group 3), and 21 of these patients died in the early postoperative period (early mortality rate 14.5 percent).

Further classification of the patients in Group 3 according to the time interval from infarction to operation revealed marked differences in the mortality of the subgroups. Patients who underwent coronary artery bypass surgery within 7 days after a recent myocardial infarction had a 38.1 percent mortality rate. There were no significant differences between the early mortality rate of those who were operated on within the first 24 hours after acute infarction (36.4 percent) and those who were operated on within 2 to 7 days after acute infarction (40 percent). The early mortality rate of patients who had coronary artery bypass surgery within 8 to 30 days after acute infarction was 16.4 percent; the rate was 5.8 percent in patients operated on within 31 to 60 days after acute infarction. Figure 1 demonstrates the more than sixfold greater early mortality in patients who underwent operation within 7 days after acute infarction than in those who underwent operation 31 to 60 days after infarction.

Coronary artery bypass within 24 hours after acute infarction: Table I lists the 11 patients who underwent operation within the first 24 hours after acute infarction. The period from infarction to thoracotomy was estimated to the closest half hour. Pa-

* Time interval between infarction and thoracotomy.
† Femoral partial bypass before thoracotomy.
‡ Intraaortic balloon counterpulsation.

tient 8 underwent thoracotomy within 65 minutes after acute cardiac arrest associated with acute myocardial infarction. Seven of the 11 patients in this group had a myocardial infarction during or shortly after cardiac catheterization. In most cases these patients before operation manifested cardiac arrest, severe heart failure, hypotension or frank cardiogenic shock complicating an acute infarction. Only two patients underwent coronary artery bypass after an uncomplicated infarction that occurred at the time of catheterization. Four patients died, all of whom had a complicated infarction. Three of the four who died (Patients 8, 9 and 10) had severe lesions of the left main coronary artery. All four patients died in the operating room with an essentially noncontractile left ventricle.

Coronary artery bypass within 2 to 7 days after acute infarction: Ten patients underwent coronary artery bypass surgery 2 to 7 days after acute infarction. Seven of these patients had a complicated infarction: Three had severe congestive heart failure and four had extension of the infarction. Three patients had an uncomplicated infarction. Four of the 10 patients in this group died in the early postoperative period. Three of these patients had a complicated myocardial infarction.

Coronary artery bypass between 8 and 30 days after acute infarction: Fifty-five patients underwent coronary artery bypass surgery 8 to 30 days after acute infarction. Almost half of these patients had complications of infarction including cardiac arrest, extension of infarction or persistent pain at rest. There were five early deaths among those with a complicated infarction and four early deaths among those who had uncomplicated infarction.

Coronary artery bypass between 31 and 60 days after acute infarction: Sixty-nine patients underwent coronary artery bypass surgery 31 to 60 days after acute infarction. Only one fourth of these patients had complications of infarction including extension of infarction, recurrent pain at rest or cardiac arrest. There were two deaths among these patients with a complicated infarction and two deaths among the patients with an uncomplicated infarction.

Effect of preinfarction angina on early mortality after coronary artery bypass: One additional factor that had a very significant effect on early mortality was the presence of preinfarction angina. We have reserved the term "preinfarction angina" for patients with prolonged pain at rest without transmural infarction, and have not included patients with crescendo angina or other unstable anginal patterns. Of 137 patients who met this criterion of preinfarction angina, 18 died in the early period after operation (13.1 percent). When these patients with preinfarction angina are subtracted from Groups 1 and 2, the lower mortality figures of 3.5 and 6.1 percent are found in the remaining patients of Groups 1 and 2, respectively. Figure 1 displays the early mortality of each of the clinical subgroups. It is apparent that the risk of surgery during the first 7 days after infarction far exceeds that of any of the clinical situations presented. It is also apparent that early mortality in patients who undergo operation later than the first 30 days after an acute myocardial infarction is no greater than in those who experience an infarction more than 2 months before operation.

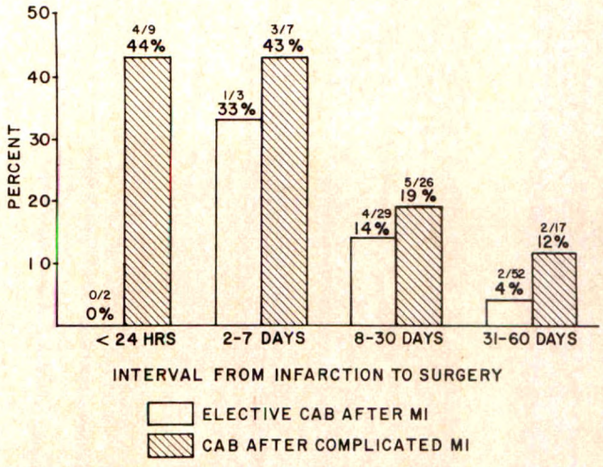

FIGURE 2. Early mortality rates in patients undergoing coronary artery bypass surgery (CAB) after recent myocardial infarction (MI), in relation to indications for surgery.

Discussion

Surgical procedures performed after a recent myocardial infarction are accompanied by a high mortality rate. In 1964, Arkins et al.[4] reported a 40 percent mortality rate among patients who underwent general surgical procedures within 3 months after acute myocardial infarction. The mortality rates of patients undergoing coronary artery bypass surgery after an established myocardial infarction have ranged from 0 to 80 percent in previous reports.[5–9] Our data suggest that revascularization can be performed after the first 30 days without an increase in early mortality. During the first 30 days, and especially during the first week after infarction, the mortality rate of patients undergoing coronary artery bypass is very high and suggests that the beneficial effects of revascularization do not overcome the risks of surgery in a patient with an area of myocardial necrosis.

Myocardial revascularization within the first few hours after coronary occlusion has been experimentally demonstrated to have beneficial effects by decreasing the area of myocardial necrosis and saving ventricular function.[10] After several hours have elapsed, there remains no theoretical benefit of early revascularization and, in the patient whose condition is stable, there is no reason to consider operation within the first 30 days after infarction.

Mortality related to indications for surgery: Figure 2 shows the mortality rates of patients operated on after complicated and uncomplicated myocardial infarction according to the interval between infarction and coronary artery bypass surgery. High mortality rates were noted in all patients after a complicated infarction. Patients operated on within the first 7 days experienced twice the mortality of those operated on 8 to 30 days after infarction and more

than three times the mortality of those operated on more than 30 days after complicated myocardial infarction. The more severe complications, including shock and severe heart failure, were present only in patients operated on less than 31 days after infarction. The numbers are too small in the first two subgroups of patients operated on after uncomplicated myocardial infarction to draw definite conclusions. The early mortality of all patients (after stable or unstable myocardial infarction) undergoing coronary artery bypass within the first 30 days after infarction is statistically greater than the mortality in the second month after an acute myocardial infarction ($P < 0.01$; chi-square = 8.03).

A significant factor that must be considered in assessing the high mortality rates is the large number of patients who underwent operation as a resuscitative attempt in the early postinfarction period.

Clinical implications: From our experience with patients undergoing coronary artery bypass after recent myocardial infarction, we make the following conclusions: (1) Coronary artery bypass performed after a recent myocardial infarction is associated with a high rate of early mortality. (2) Elective coronary artery bypass after a stable recent infarction is best accomplished after the first 30 days, when there is no increased risk to the patient. (3) Emergency coronary artery bypass after complicated acute myocardial infarction may be a life-saving procedure; however, it is associated with a high early mortality rate and should be reserved for those in whom aggressive medical therapy is unsuccessful.

Lidocaine-Induced Heart Block in Patients with Bundle Branch Block

PREM K. GUPTA, MD, FACC
EDGAR LICHSTEIN, MD, FACC
KUL D. CHADDA, MD

Elmhurst, New York

His bundle electrography and atrial pacing were used to evaluate the effect on cardiac conduction of an intravenous bolus injection (50 to 100 mg) of lidocaine in 21 patients with various intraventricular conduction abnormalities and ventricular premature beats. Sixteen patients (76 percent) had prolonged His-Purkinje conduction time (H–V interval greater than 55 msec). Six patients (all with a prolonged H–V interval) had earlier shown transient second degree or complete heart block. Administration of lidocaine produced complete heart block distal to the His bundle potential in two patients. Both patients had a prolonged H–V interval (100 and 140 msec, respectively) and had shown 2:1 A–V block distal to the H deflection on atrial pacing before the injection. A third patient, with an H–V interval of 70 msec, showed second degree block distal to the H deflection during atrial pacing after administration of lidocaine but not before. An additional patient, observed clinically to have alternating right and left bundle branch block, experienced cardiac standstill after the injection. Lidocaine should be used cautiously in patients with incomplete bilateral bundle branch block, and a temporary pacemaker should be considered in patients with a prolonged H–V interval or known trifascicular disease.

Lidocaine, one of the commonest antiarrhythmic drugs used today, is the drug of choice in the initial treatment of ventricular premature beats.[1–8] The efficacy of lidocaine in treating atrial arrhythmias has also been reported but is not well established. Therapeutic doses of lidocaine have minimal effects on cardiac hemodynamics and may produce minor side effects such as paresthesia, confusion and lightheadedness. Sinus bradycardia and heart block have been considered contraindications for the use of lidocaine. In this study we evaluated the effect of lidocaine on cardiac conduction in 21 patients with various forms of intraventricular conduction abnormalities and ventricular premature contractions.

Methods and Material

The study group consisted of 21 patients with various forms of intraventricular conduction abnormalities and ventricular premature beats. Fifteen were male and six female; their ages ranged from 48 to 89 years. None of the patients had acute myocardial infarction; patients with clinical evidence of congestive heart failure and liver disease were excluded. Sixteen patients had an electrocardiographic pattern of right bundle branch block and left anterior hemiblock (mean frontal plane QRS axis greater than −30°). Four had a pattern of right bundle branch block and left posterior hemiblock (mean frontal plane QRS axis greater than +100°) and one a pattern of complete left bundle branch block. Twenty patients had sinus rhythm and one had atrial fibrillation. When studied, all patients with sinus rhythm had 1:1 atrioventricular (A–V) conduction although six had earlier shown transient Mobitz type II or complete heart block.

The nature and purpose of the study were explained and consent of the patients was obtained. His bundle electrograms were recorded by the method of

UNIVERSITY COLLEGE OF MEDICINE LIBRARY

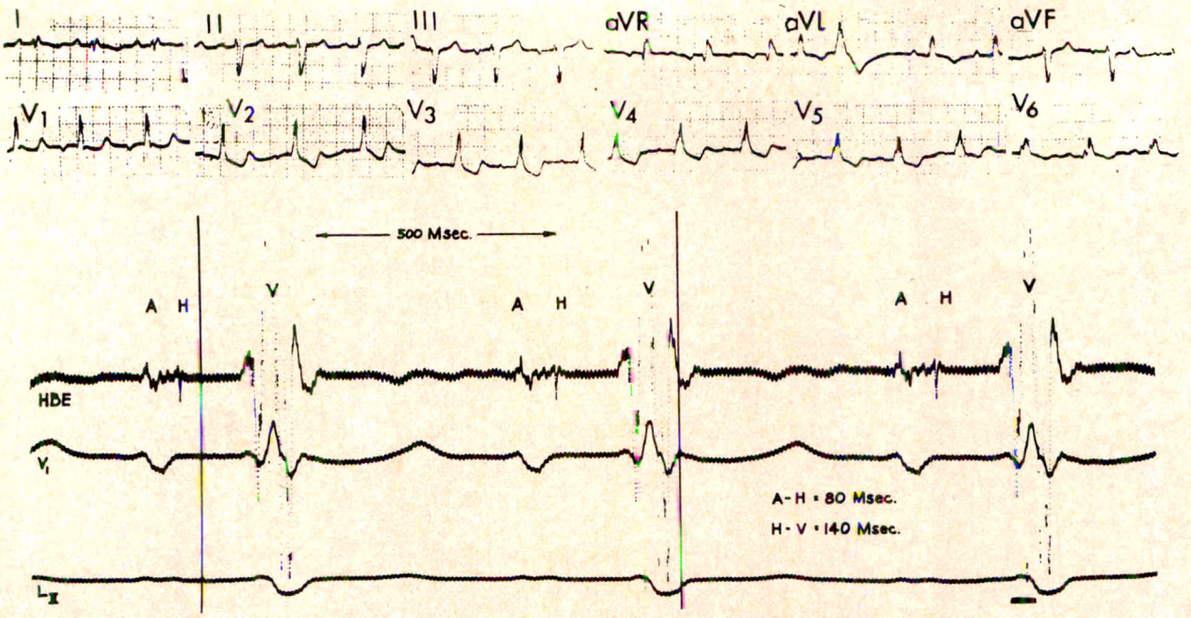

FIGURE 1. Case 2. Twelve lead electrocardiogram with base-line His bundle electrogram (HBE).

Scherlag et al.[9] A no. 6 bipolar electrode catheter with interelectrode distance of 1 cm was passed percutaneously by way of a femoral vein and, under fluoroscopic control, the tip was advanced until it lay across the tricuspid valve. His bundle electrograms were recorded on an EEP channel of an Electronics for Medicine multichannel recorder at paper speeds of 75 to 150 mm/sec with a frequency response of 40 to 500 Hz. One or more leads of the peripheral electrocardiogram were recorded simultaneously. In 15 patients atrial pacing was performed by a second catheter positioned against the lateral wall of the right atrium. The pacing rate was increased gradually to a maximum of 150/min or until second degree A–V block appeared. Lidocaine (50 mg in 10 patients and 100 mg in 11 patients) was administered intravenously after the base-line studies. A trial pacing was repeated 5 minutes after injection of lidocaine.

Results

The A–H interval was within normal limits (70 to 140 msec) in all 20 patients with sinus rhythm and did not change significantly after administration of lidocaine. The H–V interval was prolonged (greater than 55 msec) in 16 patients (76 percent). In four, the prolongation was marked (greater than 95 msec). Second degree A–V block appeared in 9 of 15 patients during atrial pacing. In six, the block was at the A–V node, and in three it was distal to the H deflection. After injection of lidocaine, two patients showed spontaneous high grade and complete A–V block lasting for several seconds. Block in each instance was localized distal to the H deflection, and instantaneous ventricular pacing was achieved in both cases. Both patients had a significantly prolonged H–V interval (100 and 140 msec, respectively) and had shown second degree block distal to the H deflection during atrial pacing before injection of lidocaine. A third patient, with an H–V interval of 70 msec, had 1:1 A–V conduction with atrial pacing before administration of lidocaine and second degree block distal to the H deflection when atrial pacing was repeated after administration. Another patient had a 5 to 10 msec increase in the H–V interval after injection of lidocaine.

Illustrative Cases

Case 1: This case has previously been reported by us[10] and will be discussed briefly. The patient is an 83 year old man who was seen in the emergency room because of palpitations and weakness. The electrocardiogram revealed sinus rhythm with right bundle branch block, left anterior hemiblock and many ventricular premature systoles. A 50 mg bolus injection of lidocaine produced high grade and then complete heart block lasting for 20 seconds with spontaneous return to 1:1 A–V conduction. Because of this episode of block and the continuing indication for lidocaine, a temporary transvenous pacemaker was inserted. A His bundle electrogram recorded at this time showed an A–H interval of 90 msec and an H–V interval of 100 msec. Atrial pacing at a rate of 130/min produced 2:1 block distal to the H deflection; 1:1 A–V conduction promptly returned when atrial pacing was discontinued. Injection of 50 mg of lidocaine resulted in a transient period of 2:1 A–V block followed by complete A–V block distal to the H deflection. Instantaneous ventricular pacing was achieved during the episode of complete heart block. A permanent pacemaker was advised, but refused by the family.

Case 2: A 63 year old man was admitted because of increasing angina pectoris. He gave a history of several episodes of dizziness but denied syncope. The electrocardiogram on admission showed complete right bundle branch block with left anterior hemiblock. Transient high grade block was noted on a cardiac monitor, and a temporary transvenous pacemaker was immediately inserted. The His bundle electrogram recorded during antegrade conduction showed an A–H interval of 80 msec and an H–V interval of 140 msec. Atrial pacing at a rate of 120/min produced 2:1 block distal to the H deflection with prompt return to 1:1 A–V conduction at the termination of atrial pacing. A 50 mg bolus injection of lidocaine resulted in an increase of the H–V interval to 180 msec with progression to transient high grade block distal to the H deflection. The block disappeared spontaneously in 10 seconds. A permanent transvenous demand pacemaker was implanted subsequently.

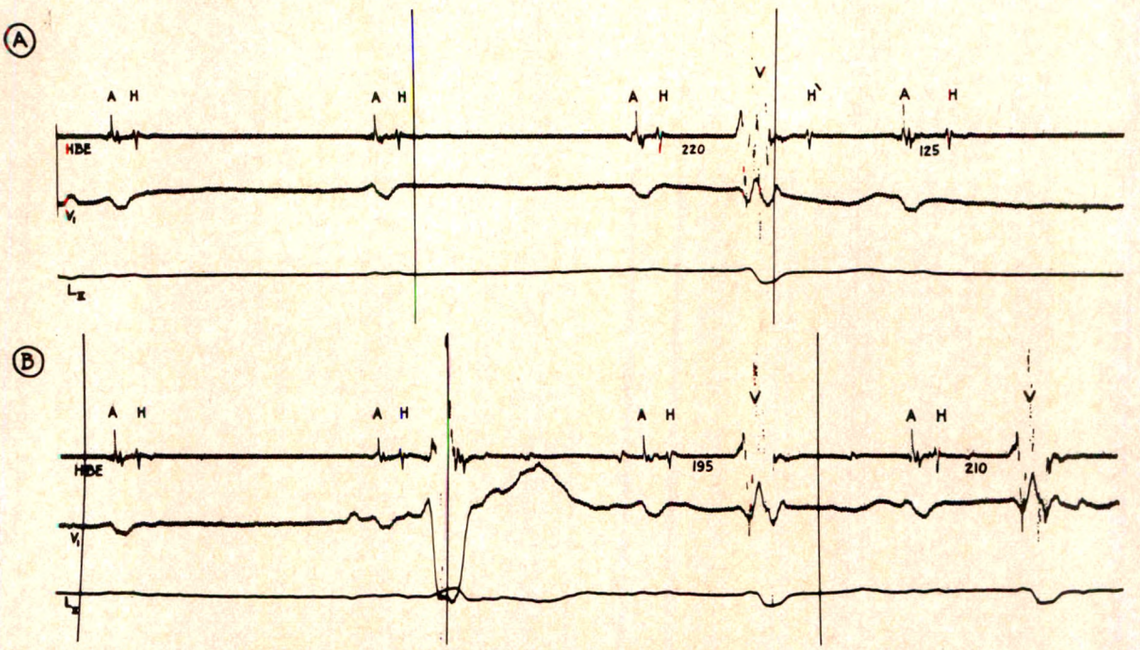

FIGURE 2. Case 2. His bundle recordings after administration of lidocaine (50 mg intravenously) show high grade A–V block distal to the H deflection. The H–V interval of the conducted beats is shown in the H–V segment. **A** and **B** are continuous strips.

Interpretation of electrocardiogram and His bundle electrogram: Figure 1 shows a 12 lead electrocardiogram obtained from this patient. The rhythm is sinus with a P–R interval of 0.24 second. The QRS complexes have a pattern of right bundle branch block and left anterior hemiblock. A ventricular premature beat is seen in lead aVL. In the baseline His bundle electrogram (Fig. 1, bottom) the A–H interval of 80 msec is within normal limits but the H–V interval is prolonged to 140 msec. Panels A and B in Figure 2 are continuous strips recorded after intravenous injection of 50 mg of lidocaine. Many nonconducted P waves are seen with block distal to the H deflection. The only QRS deflection in panel A and the last two QRS deflections in panel B are conducted beats with H–V intervals of various lengths. The first QRS deflection in panel B is a ventricular escape beat. A sharp spike marked H′ is seen after the ventricular depolarization in panel A. This is possibly a premature His bundle depolarization that is blocked antegrade. However, its retrograde conduction into the A–V node is evident from the prolongation of the next A–H interval to 125 instead of the normal 80 msec.[11] The possibility that this H′ spike represents a His bundle echo caused by prior ventricular depolarization cannot be ruled out since the previous beat has a long H–V interval.

Case 3: A 78 year old woman was admitted with a history of syncope. The electrocardiogram on admission revealed complete A–V block with wide idioventricular complexes at a rate of 32/min. A temporary endocardial pacemaker was immediately inserted. Antegrade 1:1 conduction reappeared soon after admission and persisted throughout the

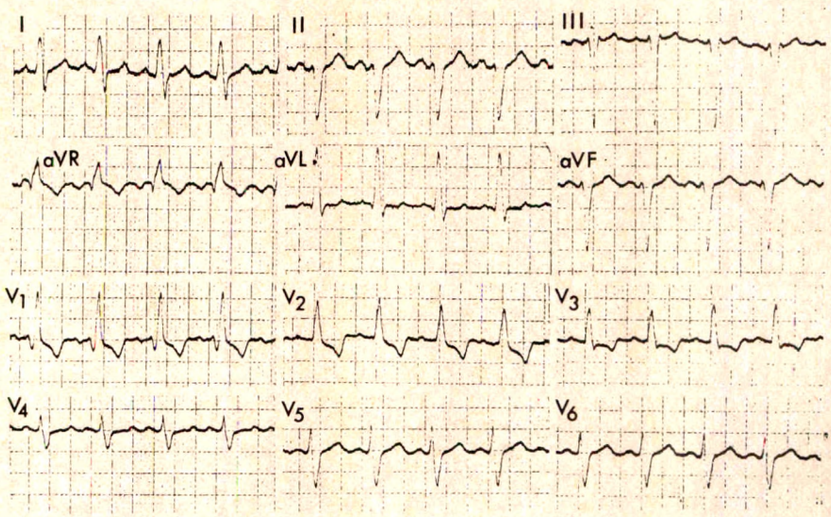

FIGURE 3. Case 3. Twelve lead electrocardiogram obtained before the study reveals right bundle branch block with left anterior hemiblock.

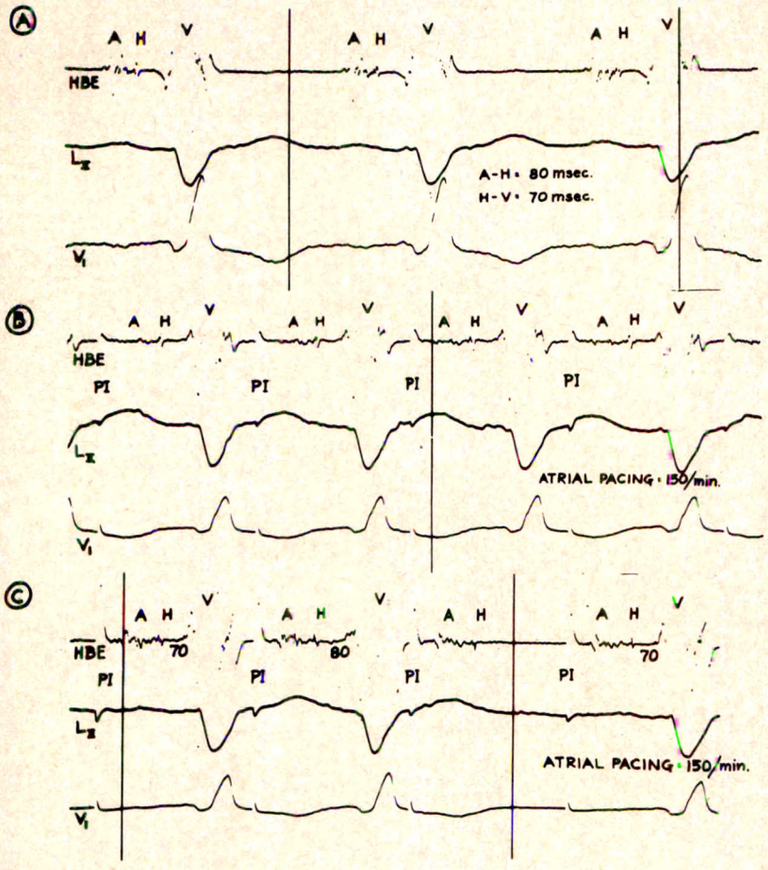

FIGURE 4. Case 3. **A,** base-line His bundle electrogram (HBE). **B,** 1:1 A–V conduction persists during atrial pacing at 150/min. **C,** atrial pacing at 150/min after administration of lidocaine produces Wenckebach type block distal to the H deflection. The H–V interval is shown in the H–V segment of the conducted beats. PI = pacing impulse.

hospital course. The electrocardiogram recorded during antegrade conduction showed right bundle branch block and left anterior hemiblock with ventricular premature beats. A His bundle electrogram recorded at that time showed an A–H interval of 80 and an H–V interval of 70 msec. Atrial pacing at 150/min produced a 1:1 A–V response. After intravenous injection of 100 mg of lidocaine, 1:1 A–V conduction persisted. However, when atrial pacing at 150/min was repeated, Wenckebach type second degree block appeared distal to the His bundle potential; the 1:1 A–V conduction returned when pacing was stopped. The patient underwent implantation of a permanent transvenous demand pacemaker 1 week after the study.

Interpretation of electrocardiogram and His bundle electrogram: The 12 lead electrocardiogram of this patient is shown in Figure 3. The rhythm is sinus with 1:1 A–V conduction and a P–R interval of 0.18 second. A pattern of complete right bundle branch block with left anterior hemiblock is present. Panel A in Figure 4 shows the His bundle electrogram during sinus rhythm. The H–V interval is 70 msec. In panel B, the effect of atrial pacing at a rate of 150/min is shown; the 1:1 A–V conduction persists and the H–V interval remains unchanged. Panel C illustrates the effect of atrial pacing at a rate of 150/min after intravenous administration of 100 mg of lidocaine. The H–V interval progressively increases from 70 to 80 msec and then one beat is blocked distal to the H deflection. This is an example of Wenckebach type block distal to the H deflection and has been reported previously.[12–14]

Case 4: An 84 year old woman, who was admitted with a chief complaint of pain in the right side of the chest, was not among our study group. Her electrocardiogram revealed atrial fibrillation with moderate ventricular response and complete left bundle branch block. Intermittent complexes with a right bundle branch block pattern were noted and thought to be premature ventricular beats. Twenty-four hours after admission, the frequency of these abnormal complexes had increased; the patient was given 100 mg of lidocaine intravenously because she was thought to have a ventricular arrhythmia. Twenty seconds after this injection, there was marked slowing of the ventricular rate followed by asystole with occasional ventricular escape beats. The patient was resuscitated and ventricular pacing was initiated, but she died several hours later.

Interpretation of electrocardiogram: Figure 5, a 12 lead electrocardiogram obtained from this patient, reveals atrial fibrillation and a moderate ventricular response. A pattern of left bundle branch block is evident, with the first beat in lead V_1 suggesting right bundle branch block. Strips A to F are continuous and show the effect of intravenous injection of 100 mg of lidocaine. Alternating left and right bundle branch block are seen in strips A to C. Slowing of the ventricular rate with complete asystole is evident in strips D to F.

Discussion

The effect of lidocaine on atrioventricular and intraventricular conduction has been evaluated in the experimental animal.[15] Lidocaine in therapeutic doses had no significant effect on A–V nodal and His-Purkinje conduction in dogs[15]; however, a prolonga-

tion of the A–V nodal conduction time was seen after administration of large doses. In canine ventricular muscle-Purkinje fiber preparations, lidocaine in a concentration comparable to in vivo therapeutic levels produced a slight increase in conduction velocity of the Purkinje tissue and caused marked acceleration of conduction through the ventricular muscle-Purkinje fiber junction.[16] In the same experiment, a further increase in the concentration of lidocaine slowed the conduction in the Purkinje tissue. Lidocaine in therapeutic doses has also been found to abolish decremental conduction and reduce the block at the ventricular muscle-Purkinje fiber junction.[17]

Using His bundle electrography and atrial pacing, Rosen et al.[18] studied the effect of lidocaine on cardiac conduction in 10 patients with heart disease. Only two of these patients had a QRS duration of more than 0.12 second. There was no significant change in the A–V nodal and His-Purkinje conduction time after administration of lidocaine. In a similar study, Bekheit et al.[19] found no significant change in the A–H or H–V interval after administration of lidocaine.

Heart block secondary to administration of lidocaine: Gianelly et al.[1] described two cases of heart block secondary to administration of lidocaine. In one case the block was probably due to acute inferior wall myocardial infarction since it persisted for several days after cessation of lidocaine infusion. In the second case second degree block progressed to complete heart block after the infusion. Since the type of block and the QRS configuration were not described, it is not possible to locate the site of block in this patient. More recently, Josephson et al.[20] described a patient with left bundle branch block and an H–V interval of 50 msec. After an infusion of 100 mg of lidocaine, the patient experienced several seconds of complete heart block. The block was localized at the A–V node by His bundle electrography. However, since the H–V interval had increased to 95 msec on return of antegrade conduction, the possibility of the proximal His bundle segment as the site of block cannot be ruled out. Liss et al.[21] in a recent brief communication described a patient with right bundle branch block and left axis deviation who had cardiac standstill after injection of lidocaine.

Our study was initiated to test the safety of lidocaine as an antiarrhythmic drug in patients with bundle branch block and premature ventricular beats. Most of the patients studied by Rosen and Bekheit and their co-workers[18,19] had a normal QRS configuration; by contrast, all of our patients had bundle branch block and 76 percent had trifascicular disease manifested by a prolonged H–V interval.[13,14,22,23] The extent of their conduction abnormality is further shown by the earlier transient second degree or complete heart block that occurred in six patients. Our Patients 1 and 2 had a markedly prolonged H–V interval (100 and 140 msec, respectively) and block occurred spontaneously after administration of lidocaine. In both, 2:1 A–V block indicative of advanced disease of the conduction system occurred distal to the H deflection during atrial pacing before administration of lidocaine. In Case 3 the H–V interval was only slightly prolonged (70 msec), and the stress of atrial pacing was necessary to induce block after injection of lidocaine. Patient 4 was observed clinically and was not in our study group. The beats with right bundle branch block were thought to be ventricular premature contractions (the reason the patient received lidocaine). In retrospect, this patient showed alternating left and right bundle branch block, thus fulfilling another criterion for trifascicular block.[22]

The results of our study suggest that lidocaine in therapeutic doses may not affect intraventricular conduction time in the majority of patients with bundle branch block. An occasional patient with more advanced trifascicular disease may have block distal to the His bundle potential after administration of lidocaine. It is possible that therapeutic doses of lido-

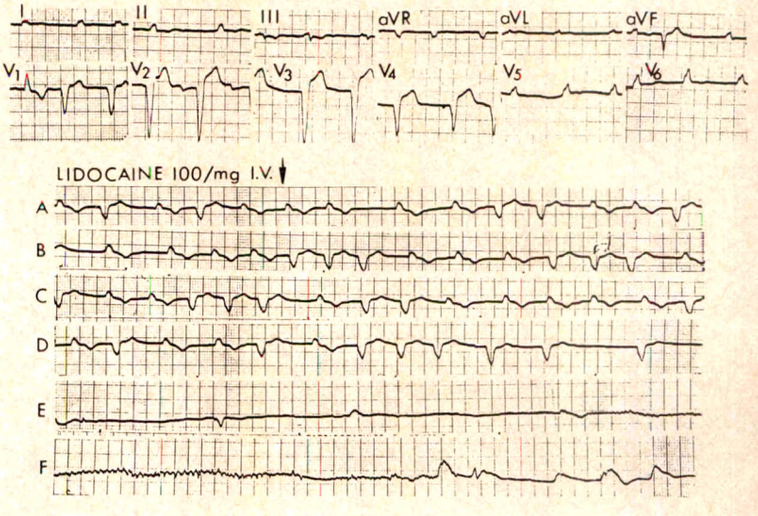

FIGURE 5. Case 4. Atrial fibrillation with ventricular response averaging 75/min is present in the 12 lead electrocardiogram **(top).** The QRS configuration is consistent with complete left bundle branch block. The first beat in lead V_1 shows a right bundle branch block configuration. A continuous lead V_1 rhythm strip is shown from **A** to **F.** Complexes with right and left bundle branch block are present. Marked slowing with cardiac standstill is present during the later part of strip **D** and in strips **E** and **F.**

caine are in fact toxic to these patients and that their already abnormal conduction system is further jeopardized with resultant heart block. Although gross heart failure was not evident in our patients, subclinical congestive heart failure could not be ruled out. Delayed metabolism secondary to heart failure may have resulted in toxic blood levels of lidocaine.[24] Determinations of blood levels of lidocaine will be necessary to study this hypothesis. Another possibility is that lidocaine depresses cardiac function and produces a transient reduction in cardiac output.[25] If this were true, a decrease in coronary perfusion might further slow conduction in the abnormal conduction system and result in heart block.

Clinical implications: We conclude that lidocaine should be administered cautiously to patients with incomplete bilateral bundle branch block. Patients with known H–V prolongation and intermittent high grade block are at greater risk and should be considered for temporary pacemaker insertion before treatment with lidocaine.

Improved Intraventricular Conduction of Premature Beats After Diphenylhydantoin

JOE K. BISSETT, MD
NEIL D. B. de SOYZA, MBBS
JAMES J. KANE, MD
MARVIN L. MURPHY, MD, FACC

Little Rock, Arkansas

To determine the effect of diphenylhydantoin on intraventricular conduction in man, we utilized His bundle recordings and coupled atrial pacing to record the relative refractory period of the His-Purkinje system and the functional refractory period of the atrioventricular (A–V) node in 14 patients before and after administration of diphenylhydantoin at a rate of 50 mg/min. Before infusion of diphenylhydantoin (5 mg/kg at a rate of 50 mg/min) His-Purkinje conduction delay occurred with right bundle branch block in nine patients and with left bundle branch block in five patients. After infusion of diphenylhydantoin the onset or degree of His-Purkinje delay was altered in all patients. In nine patients diphenylhydantoin reduced the relative refractory period of the His-Purkinje system to a value less than that of the functional refractory period of the A–V node so that His-Purkinje conduction delay could not be demonstrated after diphenylhydantoin. In five patients, diphenylhydantoin reduced the relative refractory period of the His-Purkinje system or altered the degree of aberrant conduction, or both. Diphenylhydantoin reduced the minimal H_1–H_2 interval achieved before the onset of His-Purkinje block from 421 ± 27 (standard deviation) to 384 ± 34 msec ($P < 0.01$). The functional refractory period of the A–V node was decreased from a control value of 389 ± 39 to 374 ± 26 msec after administration of diphenylhydantoin, but the effect was not statistically significant ($P > 0.1$). These results establish that diphenylhydantoin has a significant effect on intraventricular conduction in man.

In 1950 diphenylhydantoin was reported to reverse experimental ventricular tachycardia produced by coronary arterial ligation,[1] and in 1954 it was shown to be effective in abolishing ouabain-induced ventricular tachycardia in dogs.[2] Subsequent clinical experience confirmed the antiarrhythmic properties of diphenylhydantoin and its value in the treatment of some instances of ventricular tachycardia and ventricular arrhythmias induced by digitalis.[3–6]

With the introduction of His bundle recording, interest has focused on the electrophysiologic actions of diphenylhydantoin. Although some types of ventricular arrhythmias respond favorably to diphenylhydantoin, initial reports have suggested that the drug has no effect on intraventricular conduction in man as measured by a stable interval from the His bundle potential to the onset of ventricular depolarization (H–V interval) during atrial pacing with a fixed cycle length.[7–9] The purpose of this study was to determine the effect of diphenylhydantoin on intraventricular conduction in man utilizing the introduction of premature atrial beats and measurements of the refractory periods of the His-Purkinje conduction system.[10,11] The results demonstrate a significant effect of diphenylhydantoin on intraventricular conduction in man. An abstract of these findings has been published previously.[12]

* These measurements were made in the control beats during atrial pacing at 80 to 90 beats/min.

A–H = interval from atrium to His bundle potential; ASHD = arteriosclerotic heart disease; DPH = diphenylhydantoin; H–V = interval from His bundle potential to onset of ventricular depolarization; *P* = probability; SD = standard deviation.

Methods

Studies were performed in 14 patients who were undergoing elective cardiac catheterization for evaluation of chest pain. No patient had clinically unstable angina or evidence of recent myocardial infarction. After informed consent was obtained, right heart catheterization was performed with the patients in the postabsorptive nonsedated state. No patient was receiving medications known to affect atrioventricular (A–V) conduction. Under local anesthesia induced by Xylocaine®, a bipolar or tripolar catheter was inserted percutaneously in the femoral vein and positioned in the region of the tricuspid valve for recording of His bundle electrograms.[13,14] A bipolar or quadripolar catheter was inserted in an antecubital vein and positioned against the wall of the right atrium for atrial pacing. Atrial pacing was accomplished with a Tektronics 2600 series pacemaker, using pulses of 2 msec duration at twice the diastolic threshold. The stimulator was connected to a battery-powered stimulus isolation box to prevent current leakage.

In each patient the conduction system was studied using the extrastimulus method.[10,11] With the atria driven at a basic drive rate of 80 to 90 beats/min, premature atrial impulses were introduced at intervals of 5 to 10 msec. The interval between the atrium and His spike (A–H time) was used as an approximation of A–V nodal conduction time. The interval between the His spike and onset of ventricular depolarization (H–V interval) was used as an approximation of His-Purkinje conduction time.

The atria were paced at a basic rate of 80 to 90 beats/min. After every 10th drive beat a premature beat (A_2) was introduced. The drive stimulus after the premature beat was then inhibited for 2,000 msec to facilitate measurement.

Determination of the refractory periods of the A–V conduction system was performed according to the method of Wit and Damato and co-workers.[10,11] The functional refractory period of the A–V node was defined as the minimal interval between two successive His bundle responses, both propagated from the atrium. The relative refractory period of the His-Purkinje system was defined as the H_1–H_2 interval at which H_2 conducted with an H_2–V_2 interval longer than the control beat or H_2 resulted in aberrant ventricular activation. The minimal H_1–H_2 interval not associated with His-Purkinje block was also recorded.

Pacing was performed in all patients until the premature stimulus did not conduct to the atrium. The refractory periods were determined at identical driving rates before and immediately after the intravenous administration of 5 mg/kg of diphenylhydantoin given at a rate of 50 mg/min.[7] All studies were completed within 10 minutes of the termination of drug administration. Recordings were made on an eight channel Electronics for Medicine recorder at paper speeds of 100 mm/sec.

Results

His bundle recording and refractory period determinations were made without difficulty in all patients. No episodes of bradycardia, A–V block or marked hypotension were associated with infusion of diphenylhydantoin. Four patients noted a mild sensation of dizziness immediately after the infusion, but the sensation subsided after 10 to 15 minutes and was not followed by neurologic sequelae.

A–V conduction: The A–H and H–V times at the control pacing rates of 80 to 90 beats/min before and after infusion of diphenylhydantoin are shown in Table I. No significant reduction was observed in the mean A–H interval after diphenylhydantoin. No changes were observed in the H–V interval in any of the patients studied. The functional refractory period of the A–V node was reduced from a control value of 389 ± 39 to 374 ± 26 msec (Table I). This change was not statistically significant ($P > 0.1$).

P value	*P* <0.01		...		...		*P* >0.1	

DPH = diphenylhydantoin; FRP = functional refractory period of the A-V node, the minimal interval between two successive His bundle responses, both conducted from the atrium; LBBB and RBBB = left and right bundle branch block, respectively; *P* = probability; SD = standard deviation.

Intraventricular conduction: The results of His-Purkinje refractory period determinations before and after infusion of diphenylhydantoin are shown in Table II. Before the infusion nine patients manifested right bundle branch block aberration at a reproducible H_1–H_2 interval indicating the onset of the relative refractory period of the His-Purkinje system. The remaining five patients manifested left bundle branch block at a critical H_1–H_2 interval, and the disturbance was accompanied by an increase in H–V time in four. In all patients His-Purkinje conduction delay developed at all H_1–H_2 intervals below the relative refractory period of the His-Purkinje system.

After the administration of diphenylhydantoin, the relative refractory period of the His-Purkinje system was not measurable in 9 of the 14 patients (Table II), thus indicating that diphenylhydantoin had reduced the His-Purkinje relative refractory period to a value less than that of the minimal H_1–H_2 interval achieved (functional refractory period of the A–V node). In the remaining five patients, the relative refractory period of the His-Purkinje system was reduced (four patients) or the degree of aberrant conduction was altered (Case 3) by a reduction in H–V prolongation. The minimal H_1–H_2 interval without His-Purkinje conduction delay was reduced from a control value of 421 ± 27 to 384 ± 34 msec after administration of diphenylhydantoin. This change was statistically significant (P <0.01).

In all patients the administration of diphenylhydantoin altered the onset of aberrant conduction or the increase in H–V time, or both (Fig. 1). Diphenylhydantoin thus altered the conduction of premature beats in the His-Purkinje system in all 14 patients.

In one patient (Case 1) (Fig. 1) His-Purkinje block disappeared with decreasing A_1–A_2 intervals. The onset of His-Purkinje conduction delay occurred at an H_1–H_2 interval of 420 msec with an A_1–A_2 interval of 395 msec. At a shorter A_1–A_2 interval of 320 msec, the resulting H_1–H_2 interval of 430 msec exceeded the relative refractory period of the His-Purkinje system, and His-Purkinje delay was not produced. After infusion of diphenylhydantoin, the onset of His-Purkinje delay occurred at an H_1–H_2 interval of 350 msec. No H_1–H_2 intervals less than 350 msec were produced before atrial capture was lost.

Although the plasma levels of diphenylhydantoin were not measured in these patients, the dose used has been shown to result in initial therapeutic concentrations of 10 to 18 μg/ml when given at 5 minute intervals or as a 300 mg dose given over 1 to 3 minutes.[15] This method of administration has been shown to be effective in the treatment of clinical arrhythmias.[5] Previous reports suggest that the plasma concentration would be in the therapeutic range during the 10 minutes after drug administration.[15]

Discussion

Electrophysiologic effects: The electrophysiologic effects of diphenylhydantoin have been studied in both the isolated Purkinje fiber and the intact heart.[7–9,16,17] In the perfused canine Purkinje fiber

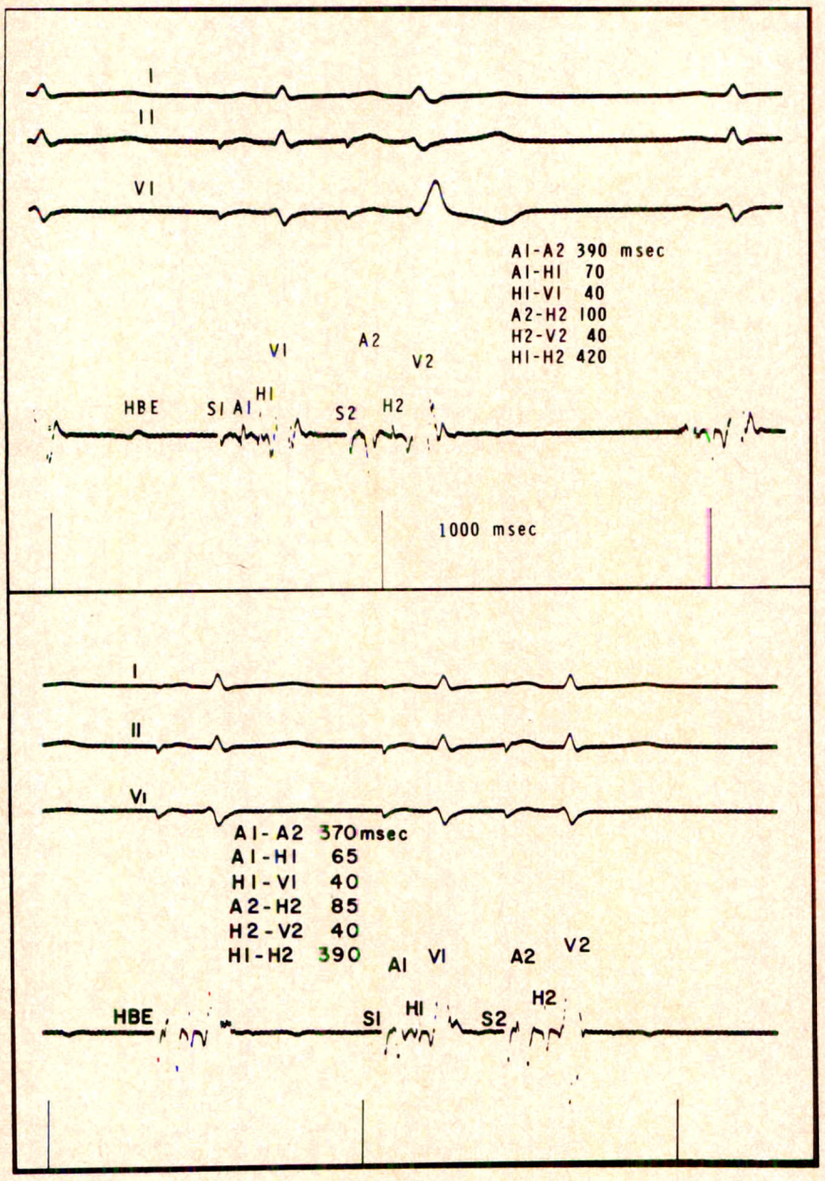

FIGURE 1. Case 1. His bundle electrograms. The basic pacing rate is 84 beats/min; the time lines are at 1,000 msec intervals. The recordings made before infusion of diphenylhydantoin **(top panel)** show the development of right bundle branch block and the shift of the QRS axis toward the left at an H_1–H_2 interval of 420 msec. All H_1–H_2 intervals less than 420 msec were associated with right bundle branch block. After administration of diphenylhydantoin **(bottom panel)** conduction is normal at an H_1–H_2 interval of 390 msec. Even when the H_1–H_2 interval was reduced, diphenylhydantoin inhibited the appearance of right bundle branch block by altering the relative refractory period of the His-Purkinje system.

diphenylhydantoin caused a decrease in the slope of phase 4 depolarization resulting in a decrease in automaticity.[17] In addition, diphenylhydantoin alters the time course of the transmembrane action potential by reducing all phases of repolarization. The time course of recovery of repolarization shortens more than that of the recovery of excitability; this effect may act to reduce decremental conduction and alter the appearance of aberrant conduction.

The effect of diphenylhydantoin in the intact heart has also been studied extensively. The P–R and A–H intervals have been reduced when compared during rapid atrial pacing in both human subjects[7–9] and experimental animals.[16] However, when diphenylhydantoin was tested in three animals with chronic cardiac denervation, depression of sinus rate and prolongation of A–V conduction was observed.[16] These findings suggest that diphenylhydantoin may act in part through an anticholinergic effect. Additional studies have shown that diphenylhydantoin inhibits the action of acetylcholine on the myoneural junction.[18] Bradycardia and increased A–V block have been observed[19,20] in patients who died after intravenous administration of diphenylhydantoin. In the experimental animal, the decrease in A–V conduction time produced by diphenylhydantoin was significantly greater in the digitalized animals.[8] Diphenylhydantoin has also been effective clinically in treating both supraventricular and ventricular arrhythmias produced by digitalis.[4–6]

Effects on intraventricular conduction defects: The effect of diphenylhydantoin on intraventricular conduction has been recently studied. Measurements of the total H–V time during atrial pacing have shown no change after intravenous administration of diphenylhydantoin in human subjects.[7–9] Similar

findings have been reported in the intact dog heart.[16] In contrast, Haiat et al.[21] recently reported a case of right bundle branch block and left posterior hemiblock associated with atrial tachycardia. The intravenous administration of 250 mg of diphenylhydantoin restored normal intraventricular conduction. The normalization of intraventricular conduction was not rate-related since the conduction disturbances were previously observed at a slower ventricular rate. The results obtained in the patients described here are consistent with the loss of intraventricular conduction defects after intravenous diphenylhydantoin. Diphenylhydantoin produced a significant decrease in the minimal H_1–H_2 interval achieved without His-Purkinje delay and altered the conduction of premature beats in the His-Purkinje system in all 14 patients.

Our results demonstrate only a qualitative effect of diphenylhydantoin on the His-Purkinje system. Additional studies are needed to correlate the effects of diphenylhydantoin in the normal and abnormal heart with changes in serum and tissue levels. Our data do show that the administration of diphenylhydantoin alters intraventricular conduction by decreasing the relative refractory period of the His-Purkinje system or shortening the H–V prolongation associated with aberrant conduction, or both. In contrast to previous findings,[7–9] they indicate that diphenylhydantoin has a significant effect on intraventricular conduction in man.

Between the publication of these findings in part in abstract form[12] and the submission of this manuscript, Damato et al.[22] reported significant changes in His-Purkinje conduction after administration of diphenylhydantoin.[22] As in our study, no significant changes were observed in the functional refractory period of the A–V node. Our report confirms their results and provides specific examples of the effect of diphenylhydantoin on left and right bundle branch aberration in man.

Effect of Glucose-Insulin-Potassium Infusion on the Human Conduction System

LAWRENCE GOULD, MD, FACC
C. V. REDDY, MD
ROBERT F. GOMPRECHT, MD, FACC

Bronx, New York
New York, New York

His bundle electrograms were performed in 21 patients with organic heart disease. Recordings were made at various rates utilizing right atrial pacing. A mixture containing 50 g of glucose, 10 mEq of potassium and 20 units of insulin was given intravenously over 10 minutes to 10 subjects. The P–A, A–H, H–Q and H–S intervals were determined before and immediately after the glucose-insulin-potassium infusion. A significant prolongation in the A–H interval occurred with negligible effects on the P–A, H–Q and H–S intervals. At the atrial pacing rate of 100/min, the average A–H interval increased from the control value of 140 msec to 151 msec after the infusion ($P < 0.05$); at the pacing rate of 140/min, the A–H interval increased from 145 to 165 msec ($P < 0.05$). The identical study was performed in three additional patients who received an infusion of 50 g of glucose and 20 units of insulin. No significant change was observed in the conduction system. In eight patients a solution of 2.6 mEq of potassium in 65 cc of 5 percent glucose and water was infused over an 8 minute period. A significant prolongation of the A–H interval was observed. At the atrial pacing rate of 100/min, the average A–H interval increased from the control value of 122 to 133 msec after the glucose and potassium infusion ($P < 0.05$), whereas at the pacing rate of 140/min, the A–H interval increased from 165 to 188 msec ($P < 0.05$). These findings demonstrate that the potassium in a glucose-potassium-insulin infusion may cause impaired conduction through the atrioventricular node.

In 1962 Sodi-Pallares et al.[1] reported that intravenous infusion of a potassium-glucose-insulin solution can normalize the electrocardiographic signs of myocardial infarction. These workers also stressed the usefulness of this solution in reducing the incidence of cardiac arrhythmias. The Medical Research Council working party questioned the validity of these observations.[2] Recently, two groups of workers[3,4] documented that glucose-insulin-potassium infusions are a useful adjunct to the management of severe congestive heart failure. When Maroko et al.[5] observed that such infusions can reduce the extent of myocardial necrosis in dogs after coronary arterial occlusion, renewed interest in this form of therapy quickly followed.

The effects of this solution on the human conduction system are unknown. We therefore administered glucose, potassium and insulin to 10 patients with cardiac disease, and a solution of glucose and potassium to an additional 8 patients. Electrocardiograms and bundle of His electrograms were recorded before and after the infusions, and the effects on atrioventricular and intraventricular conduction were determined.

TABLE I

Clinical Data in 21 Cases

Case no.	Age (yr) & Sex	Electrocardiographic Findings	Diagnosis
1	80F	Sinus bradycardia	Arteriosclerotic heart disease
2	62F	Left ventricular hypertrophy	Hypertension
3	78M	Right bundle branch block	Cor pulmonale
4	78M	Recent anterior wall myocardial infarction	Arteriosclerotic heart disease
5	79F	Nonspecific ST–T wave changes	Arteriosclerotic heart disease
6	57F	P mitrale	Rheumatic heart disease
7	70M	1st degree A–V block	Arteriosclerotic heart disease
8	78M	Nonspecific ST–T wave changes	Arteriosclerotic heart disease
9	42F	Recent anterior wall myocardial infarction	Arteriosclerotic heart disease
10	66M	Sinus bradycardia	Primary myocardial disease
11	55M	Recent anterior wall myocardial infarction	Arteriosclerotic heart disease
12	58M	Left ventricular hypertrophy	Arteriosclerotic heart disease
13	25F	Right bundle branch block	Rheumatic heart disease
14	67F	Sinus bradycardia	Bradycardia-tachycardia syndrome
15	73M	Recent inferior wall myocardial infarction	Arteriosclerotic heart disease
16	68M	Left bundle branch block	Arteriosclerotic heart disease
17	78F	Nonspecific ST–T wave changes	Arteriosclerotic heart disease
18	19F	Left ventricular hypertrophy	Idiopathic hypertrophic subaortic stenosis
19	72M	Left anterior hemiblock	Bradycardia-tachycardia syndrome
20	42M	Normal	Syncope (origin unknown)
21	24F	Nonspecific ST–T wave changes	Sarcoidosis

Material and Methods

The study group consisted of 21 patients with organic heart disease. The clinical features of the group are summarized in Tables I and II. All patients were informed of the nature of the study and gave signed consent. They were studied in the supine position in a postabsorptive, nonsedated state.

With use of local anesthesia, a bipolar pacing catheter was introduced percutaneously into the right femoral vein and fluoroscopically positioned at the tricuspid valve. The position was adjusted to obtain optimal recordings of the bundle of His electrogram. The proximal terminals of the catheter were attached to an electrocardiographic amplifier, and the bipolar His electrogram was recorded at a frequency setting of 40 to 500 cycles/sec on a DR-12 Electronics for Medicine recorder at paper speeds of 100 mm/sec. A no. 6F bipolar catheter was passed by way of the right antecubital vein and positioned along the lateral wall of the right atrium. The proximal terminals of the electrodes were connected to a battery-powered Medtronic pacemaker (model 5837). The milliamperage was adjusted to twice threshold to assure reliable atrial capture. A simultaneous surface electrocardiographic lead was also recorded. All electrical equipment was carefully grounded. Measurements, in milliseconds, were made of the following intervals:

1. *The P–A interval:* the interval from onset of the P wave during normal sinus conduction recorded on the standard electrocardiographic lead to the first rapid deflection of the A wave on the bipolar electrogram. The P–A time represents intraatrial conduction time. The normal value is 27 ± 18 msec.[6] During atrial pacing the P–A time is measured from the pacing impulse to A.

*Conduction values at the slowest heart rate in each patient were obtained without pacing.
HR = heart rate (beats/min).

2. *A–H interval:* the interval from the first rapid deflection of the A wave to the first rapid deflection of the bundle of His electrogram. The A–H time represents conduction time through the atrioventricular (A–V) node. The normal value is 92 ± 38 msec.[6]

3. *H–Q interval:* the interval from the first rapid bundle of His deflection to the onset of the QRS deflection in the electrocardiogram. The H–Q interval approximates conduction time in the specialized tissues of the His-Purkinje system. The normal value is 43 ± 12 msec.[6]

4. *H–S interval:* the interval from the first rapid bundle of His deflection to the end of the QRS deflection on the electrocardiogram. The H–S interval approximates total intraventricular conduction time.

The P–A, A–H, H–Q and H–S intervals were recorded before atrial pacing and at atrial pacing rates of 80 to 150 beats/min. In 10 patients a solution containing 50 g of glucose, 10 mEq of potassium and 20 units of insulin was then infused intravenously over 10 minutes and the various intervals were recorded, without atrial pacing, immediately after the infusion. Atrial pacing was then performed with simultaneous recording of the His bundle electrogram. In addition, the recovery time of the sinus nodal pacemaker, after sudden cessation of the highest pacing rate obtained, was observed before and after the infusion. The identical studies were performed in three additional patients who received a solution containing 50 g of glucose and 20 units of insulin but no potassium. In a third study, performed in the identical manner, 8 additional patients received an infusion of 2.6 mEq of potassium in 65 cc of 5 percent glucose and water. This solution was infused over 8 minutes.

Results

Glucose-potassium-insulin solution: Table III shows the measurements of the P–A, A–H, H–Q and H–S intervals in the 10 patients before and after

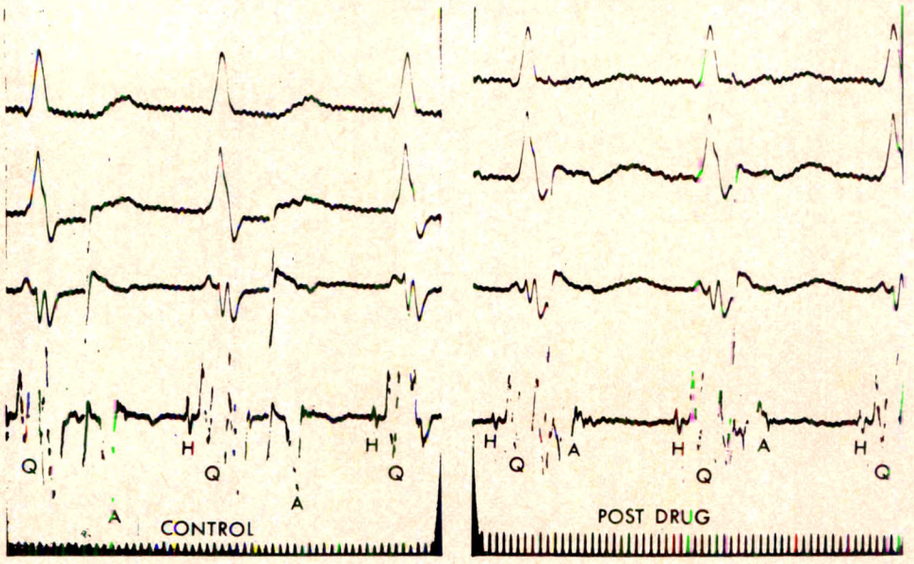

FIGURE 1. Case 7. His bundle electrogram obtained before and immediately after the glucose-potassium-insulin infusion. The right atrial pacing rate is 120 beats/min. The A–H interval in the control period is 250 msec and after the infusion it increases to 330 msec. Time lines are 0.02 second apart.

infusion of the glucose-potassium-insulin solution. The infusion had no significant effect on the P–A, H–Q or H–S intervals. However, at the atrial pacing rate of 100 beats/min, the average A–H interval increased from a control value of 140 msec to 151 msec after the infusion ($P < 0.05$). At the atrial pacing rate of 140 beats/min, the A–H interval increased from 145 to 165 msec ($P < 0.05$). Figure 1 shows a representative recording. Second degree heart block occurred at lower pacing rates in three subjects after administration of glucose-potassium-insulin than before the infusion. The postsuppression sinoatrial recovery time was increased in six of eight patients after infusion. The average recovery time control value of 915 msec increased to 958 msec after the infusion. This change was not significant.

Insulin-glucose solution: No significant change was observed in any of the intervals in the three patients who received the insulin-glucose solution (Table IV).

Glucose-potassium solution: The infusion of potassium in 5 percent glucose and water had no significant effect on the P–A, H–Q or H–S intervals in the eight patients to whom it was administered (Table V). At the atrial pacing rate of 100 beats/min, the average A–H interval increased from 122 to 133 msec ($P < 0.05$). At the atrial pacing rate of 120 beats/min, the A–H interval increased from 136 to 148 msec ($P < 0.02$); at the pacing rate of 140 beats/min, the A–H interval increased from 165 to 188 msec ($P < 0.05$). Figure 2 shows a typical recording. Second degree heart block occurred at lower pacing rates in five patients after the glucose-potassium infusion than before the infusion. The postsuppression sinoatrial recovery time was increased in five of eight patients after the infusion.

Discussion

The glucose-potassium-insulin infusion produced in patients with cardiac disease a significant increase

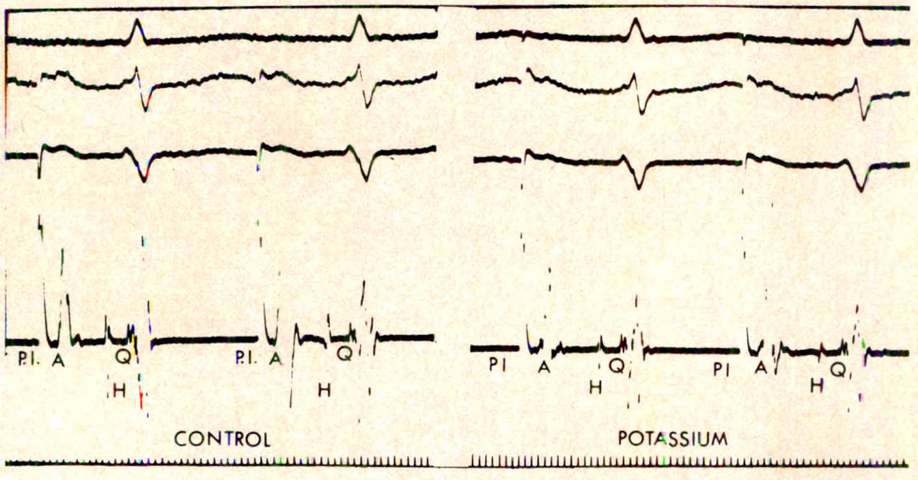

FIGURE 2. Case 19. His bundle electrogram obtained before and immediately after the glucose-potassium infusion. The right atrial pacing rate is 90 beats/min. The A–H interval in the control period is 140 msec and after the infusion it increases to 170 msec. Time lines are 0.02 second apart. P.I. = pacing impulse.

in the A–H interval but had only minimal effects on the P–A, H–Q and H–S intervals. This represents a delay in conduction through the A–V node. Second degree heart block occurred in three subjects at lower pacing rates after the glucose-potassium-insulin infusion than before the infusion. The postsuppression sinoatrial recovery time was increased in most cases after the infusion.

The infusion of a solution containing only glucose and insulin had no significant effect on the conduction system, thus suggesting that potassium played a major role in the impaired conduction in the A–V node. When the infusion of glucose and potassium also produced a significant increase in the A–H interval, this finding confirmed that potassium was indeed the agent responsible for the impaired conduction in the A–V node.

Sodi-Pallares et al.[1] were the first to popularize use of the polarizing solution in patients with cardiac disease. They observed that the combined metabolic activity of insulin and glucose can accelerate the movement of potassium into the myocardial cell. The potassium may even be preferentially picked up by injured myocardium, which is more deficient in this cation than normal tissue. Such an ionic shift has been thought to stabilize the electrical state of the myocardial cell and thus reduce myocardial irritability and arrhythmias by restoring normal polarity. However, Surawicz[7] in his extensive review of the subject observed that the two important assumptions underlying the theoretical basis of treatment with polarizing solutions remain unproved. There is no evidence that the ischemic area contains fibers that have lost only a portion of their potassium and there is no evidence that in such fibers the administration of a glucose-insulin-potassium solution restores the concentration of potassium to normal.

Most clinical studies have shown that the frequency of arrhythmias in patients with myocardial infarction is not reduced with the administration of potassium, glucose and insulin[2,8,9]; however, some workers have reported a decreased frequency of arrhythmias.[1,10] Mittra[11] reported that an infusion of glucose, potassium and insulin can decrease atrioventricular block complicating myocardial infarction; however, the solution was given only to patients with

an inferior wall myocardial infarction, and normal conduction did not return for many hours. It is now recognized that spontaneous restoration of sinus rhythm is the rule in patients with inferior wall myocardial infarction complicated by various degrees of A–V block.

Effects of potassium on A–V conduction: Potassium can have profound effects on A–V conduction. Intravenous administration of potassium in the dog has a biphasic effect on A–V conduction. Initially, mild hyperkalemia accelerates A–V conduction by anticholinergic effects and a direct effect upon the action potential of the conduction fibers. Subsequently, continued elevation of potassium levels depresses A–V conduction by a potentiation of vagal effects and a reduction of the resting potential and the rate of rise of phase 0 of the action potential.[12] Electrophysiologic studies of the A–V junction indicate that the depression of conduction by potassium occurs largely at the atrionodal, nodal–His, or His–Purkinje regions and that the true nodal or N region is quite resistant to the depressing effect of potassium.[13,14]

Plasma potassium concentration is only one of several factors that determine the effect of potassium on A–V conduction. Individual variations in response to the same change of plasma potassium concentration may be caused by organic diseases of the conducting system or by physiologic factors, such as the complex interplay between potassium and acetylcholine.[15] Indeed, Patient 7 in our study had first degree A–V block due to a prolongation of the A–H interval. With the administration of the glucose-potassium-insulin solution a 100 msec prolongation in the A–H interval occurred at the atrial pacing rate of 130 beats/min. This suggests that a glucose-potassium-insulin infusion can prolong conduction time to an alarming degree in patients with depressed A–V conduction.

Another important factor is the rate of change of plasma potassium concentration. A rapid change in the plasma potassium concentration may have a different effect than a slow change on the electrophysiologic properties of cardiac fibers.[16] A rapid change from a low to normal potassium concentration may depress pacemaker activity.[17] One can produce or abolish at will the A–V block in patients and in dogs by slight but rapid changes of the rate of potassium administration.[18] When potassium is administered rapidly, complete A–V block may occur, even in the absence of a measurable rise in plasma potassium concentration.[19]

The antiarrhythmic effect of potassium is attributed to a slowing of the diastolic depolarization of the pacemaker fibers. It is also probable that by affecting conduction, potassium eliminates ectopic rhythms caused by reentry.[20]

Burchell[21] has recently postulated that more lives may have been lost than saved by potassium therapy in the past year in American hospitals. There are no statistics to support or negate this hypothesis. However, our study throws new light on the potential hazards of a potassium infusion. Small amounts of infused potassium can impair cardiac conduction. Undoubtedly larger amounts of potassium, particularly when infused, can cause even more profound alterations in cardiac conduction. Thus, in certain clinical settings the administration of potassium may prove fatal.

Effect of Glucagon on Cardiac Conduction in Man

RAMESH C. DHINGRA, MD
ASHFAQUE KHAN, MD
DELON WU, MD
PABLO DENES, MD
J. MAURICE POUGET, MD
KENNETH M. ROSEN, MD, FACC

Chicago, Illinois

His bundle electrograms were obtained in 26 patients before and after intravenous administration of glucagon (50 μg/kg). The group consisted of 4 patients with normal conduction and 22 patients with conduction disease. The P–A interval, measured in all patients, was 35 ± 1.4 msec (mean ± standard error of the mean) before and 30 ± 1.5 msec after infusion of glucagon ($P < 0.001$). The mean A–H interval during sinus rhythm in all patients and during pacing at 100/min in 21 patients was, respectively, 97 ± 6.0 msec and 114 ± 6.4 msec before, and 96 ± 6.0 msec and 114 ± 6.6 msec after infusion of glucagon (not significant). The mean H–V interval in 25 patients was 48 ± 2.6 msec before and 49 ± 2.0 msec after infusion of glucagon (not significant). The mean sinus rate and sinus recovery times were, respectively, 73 ± 3.0 beats/min and 1,025 ± 42.0 msec before and 81 ± 3.0 beats/min and 919 ± 27.0 msec after infusion of glucagon ($P < 0.001$ and < 0.01). Functional and effective refractory periods were measured (in milliseconds) with use of the atrial extrastimulus technique. The mean atrial functional and effective refractory periods (21 patients) were, respectively, 273 ± 11.6 and 252 ± 12.0 before and 256 ± 10.0 and 238 ± 9.6 after infusion of glucagon ($P < 0.001$ and < 0.01). Mean atrioventricular (A–V) nodal functional refractory period (22 patients) and effective refractory period (15 patients) were 465 ± 22.0 and 404 ± 33.0 before and 457 ± 23.0 and 395 ± 32.0 after the infusion (not significant). The mean effective refractory period of the His-Purkinje system (2 patients) was 440 ± 45.0 before and 425 ± 55.0 after infusion of glucagon (not significant).

In summary, glucagon increased sinus nodal automaticity, as manifested by an increase in sinus rate and decrease of sinus nodal recovery time, and improved intraatrial conduction as manifested by a reduction of the P–A interval and atrial functional and effective refractory periods. Glucagon had no effect on A–V nodal or intraventricular conduction.

Glucagon, which has both positive inotropic and chronotropic actions, has been recommended for management of intractable congestive heart failure and cardiogenic shock.[1–9] Canine studies have demonstrated that this agent also facilitates atrioventricular (A–V) nodal conduction.[10–12] This latter action has been cited as potentially advantageous, particularly in patients with conduction disease. However, human studies concerning the effects of glucagon on cardiac conduction have been limited.[13]

In the present study we used His bundle recording and cardiac pacing to examine systematically the effects of glucagon on cardiac conduction in man. Conduction intervals as well as refractory periods were measured. Our results confirm the positive chronotropic effect of glucagon on the sinus node, as manifested by increase in sinus rate and shortening of sinoatrial (S–A) nodal recovery time. In addition,

TABLE I

Summary of Electrophysiologic Findings After Administration of Glucagon

	Patients (no.)	State	Mean ± SEM	P Value
Sinus rate (beats/min)	26	C	73 ± 3.0	<0.001
		G	81 ± 3.0	
SRT (msec)	26	C	1025 ± 42.0	<0.01
		G	919 ± 27.0	
P–A interval (msec)	26	C	35 ± 1.4	<0.001
		G	30 ± 1.5	
A–H interval (NSR) (msec)	26	C	97 ± 6.0	NS
		G	96 ± 6.0	
A–H interval (at HR 100/min) (msec)	21	C	114 ± 6.4	NS
		G	114 ± 6.6	
H–V interval (msec)	25	C	48 ± 2.6	NS
		G	49 ± 2.0	
HR during Wenckebach periods (beats/min)	21	C	144 ± 6.0	<0.05
		G	149 ± 6.0	
Atrial FRP (msec)	21	C	273 ± 11.6	<0.001
		G	256 ± 10.0	
Atrial ERP (msec)	21	C	252 ± 12.0	<0.01
		G	238 ± 9.6	
A–V nodal FRP (msec)	22	C	465 ± 22.0	NS
		G	457 ± 23.0	
A–V nodal ERP (msec)	15	C	404 ± 33.0	NS
		G	395 ± 32.0	
VSCS ERP (msec)	2	C	440 ± 45.0	NS
		G	425 ± 55.0	

A–V = atrioventricular; C = control; ERP = effective refractory period; FRP = functional refractory period; G = glucagon; HR = heart rate; NS = not significant; NSR = normal sinus rhythm; SEM = standard error of the mean; SRT = sinus nodal recovery time; VSCS = ventricular specialized conduction system.

glucagon facilitated intraatrial conduction as manifested by a shortening of both the P–A interval and atrial refractory periods. Glucagon had no significant effect on A–V nodal or intraventricular conduction.

Methods

The study group consisted of 26 patients with heart disease undergoing diagnostic cardiac catheterization or electrophysiologic studies. Four had normal conduction, 21 had first degree A–V block or bundle branch block, or both, and 1 had complete heart block. Informed consent was obtained.

His bundle electrograms were recorded using a tripolar catheter passed by way of the femoral vein.[14,15] A quadripolar catheter was passed to the high right atrium for atrial pacing (2 poles) and for recording high right atrial electrograms (2 poles). Recordings were obtained on a multichannel oscilloscopic photographic recorder (DR-16, Electronics for Medicine) at paper speeds of 100 and 200 mm/sec. Simultaneous electrocardiographic leads I, II, III and V_1 were recorded.

Atrial pacing was performed at increasing rates in increments of 10 beats/min until Wenckebach periods were observed. Sinus nodal recovery time was defined as the interval between the last paced P wave to the first spontaneous P wave after sudden cessation of pacing at a rate of 130/min.[15] Effective and functional refractory periods of the atrium, A–V node and His-Purkinje system were measured with the extrastimulus technique as described by Wit et al.[16] A cycle length approximately 10 to 20 percent faster than the sinus rate was utilized so that refractory periods could be measured at identical cycle lengths before and after administration of glucagon.

The following intervals were measured in milliseconds[15,17]*:*

1. P–A (normal 9 to 45 msec): The interval from the onset of the P wave to the first rapid deflection of the low right atrial electrogram recorded from the His bundle catheter, reflecting conduction time from the high to the low right atrium. If the onset of the P wave could not be well delineated, the onset of the high right atrial electrogram was utilized. This was measured in all patients.

2. A–H (normal 54 to 130 msec): The interval from the onset of the low right atrial electrogram to the first high frequency component of the His bundle electrogram, reflecting A–V nodal conduction time. This interval was measured during sinus rhythm and at equivalent paced rates before and after administration of glucagon.

3. H–V (normal 31 to 55 msec): From the first high frequency component of the His bundle electrogram to the earliest QRS deflection on the surface electrocardiogram. This interval reflects conduction time in the His-Purkinje system. It could not be measured in the patient with complete heart block, since it was distal to the H potential.

For each of these intervals, 10 beats were averaged before and after infusion of glucagon, and the mean values were used for comparison.

The following definitions were used in regard to refractory periods: A_1, H_1 and V_1 were the atrial, His bundle and ventricular electrograms of driven beats (S_1). A_2, H_2 and V_2 were the atrial, His bundle and ventricular electrograms in response to the extrastimulus (S_2). The atrial effective refractory period was the longest S_1–S_2 interval at which S_2 did not result in atrial capture. The atrial functional refractory period was the shortest attainable propagated A_1–A_2 interval. The A–V nodal effective refractory period was the longest A_1–A_2 interval at which conduction failed to the His bundle. The A–V nodal functional refractory period was the shortest conducted H_1–H_2 interval. The effective refractory period of the ventricular specialized conducting system was the longest H_1–H_2 interval at which H_2 failed to conduct to the ventricles.

Glucagon was administered intravenously in a dose of 50 μg/kg to each patient after control recordings. Electrophysiologic studies were repeated 5 to 10 minutes after the infusion. In two patients with rate-dependent bundle branch block, the paced rates at which the block appeared before and after administration of the drug were also determined. Statistical analysis of all data was performed using the Student *t* test for paired data.

Results (Table I)

Intraatrial conduction: The P–A interval was measured in all patients (Fig. 1). The mean P–A interval ± standard error of the mean was 35 ± 1.4 msec before and 30 ± 1.5 msec after administration of glucagon (P <0.001). Atrial functional and effective refractory periods could be measured in 21 patients (Fig. 2). The mean functional refractory period

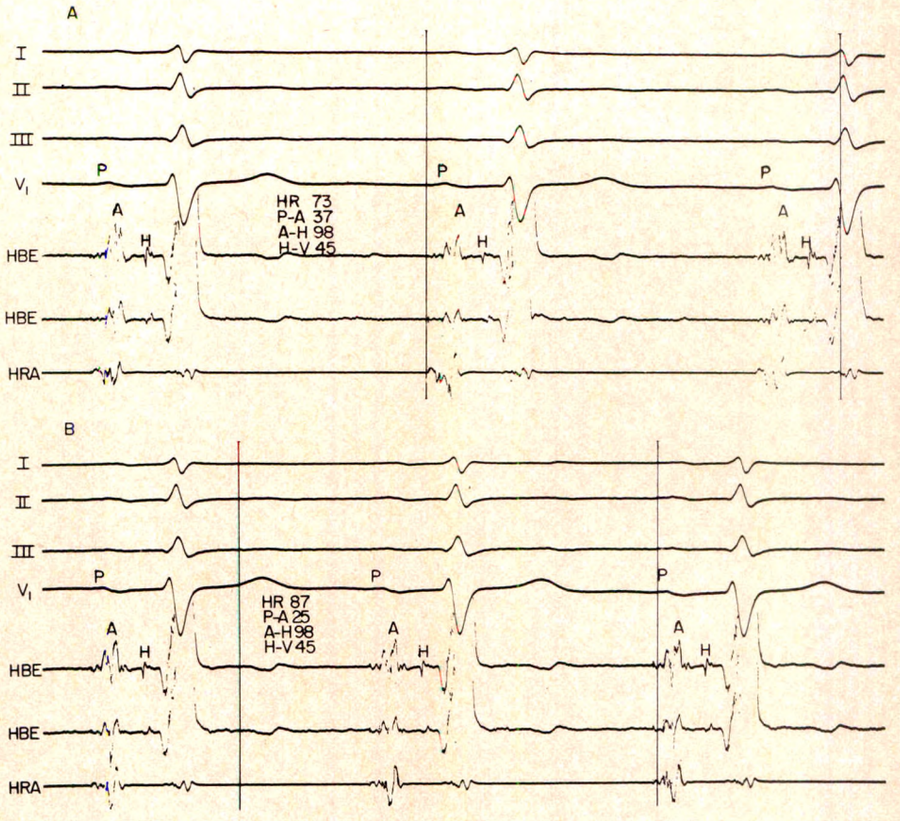

FIGURE 1. Case 3. Conduction intervals before (**A**) and after (**B**) administration of glucagon. Shown are electrocardiographic leads I, II, III and V_1, His bundle electrogram (HBE), and a bipolar intracardiac high right atrial electrogram (HRA). P waves are labeled P, atrial electrogram A and His bundle potentials H. The heart rate (HR) and electrophysiologic intervals are listed. The conduction intervals listed are the means of 10 consecutive beats.

of the atrium was 273 ± 11.6 msec before and 256 ± 10 msec after administration of the drug (P <0.001). The mean effective refractory period of the atrium was 252 ± 12 msec before and 238 ± 9.6 msec after infusion of glucagon (P <0.01). No measurable change in P wave duration was noted after administration of glucagon.

A–V nodal conduction: A–H intervals could be measured in all patients (Fig. 1). The mean A–H interval during sinus rhythm was 97 ± 6 msec before and 96 ± 6 msec after administration of glucagon (not significant). With atrial pacing A–H intervals at equivalent paced rates (90 to 140/min) were not significantly different before and after infusion of glucagon. For example, the mean A–H interval at a paced rate of 100/min in 21 patients was 114 ± 6.4 msec before and 114 ± 6.6 msec after the infusion (not significant). The paced rate at which Wenckebach periods proximal to the His bundle occurred was noted in 21 patients. This mean rate was 144 ± 6 beats/min before and 149 ± 6 beats/min after administration of glucagon (P <0.05). The mean A–V nodal functional refractory period was 465 ± 22 msec before and 457 ± 23 msec after the infusion (not significant). The effective refractory period of the A–V node was 404 ± 33 msec before and 395 ± 32 msec after administration of glucagon (not significant).

Intraventricular conduction: H–V intervals could be measured in 25 patients (Fig. 1). The mean H–V interval was 48.0 ± 2.6 msec before and 49.0 ± 2.0 msec after administration of glucagon (not significant). In one of two patients with rate-dependent left bundle branch block, the critical paced rate for producing left bundle branch block was increased from 110 to 120/min, and in the other patient the critical rates were identical (90/min) both before and after the infusion (not significant). No improvement of conduction was observed in one patient with complete heart block distal to the H potential.

The effective refractory period of the ventricular specialized conduction system could be measured in only two patients, before and after administration of glucagon, because the A–V node limited conduction. The mean values were, respectively, 440 ± 45 msec before and 425 ± 55 msec after the infusion (not significant).

Automaticity and recovery periods of the sinus node: The effect of glucagon on automaticity of the sinus node was evaluated in all patients. Sinus rate increased in all patients. The mean sinus rate was 73 ± 3 beats/min before and 81 ± 3 beats/min after administration of glucagon (P <0.001). Sinus nodal recovery times decreased after glucagon (Fig. 3). Mean recovery times before and after infusion of glucagon were 1,025 ± 42 msec and 919 ± 27 msec, respectively (P <0.01).

Arrhythmias: Premature ventricular contractions were noted in three patients before administration of glucagon. In two, these disappeared completely and in one they became more frequent after administra-

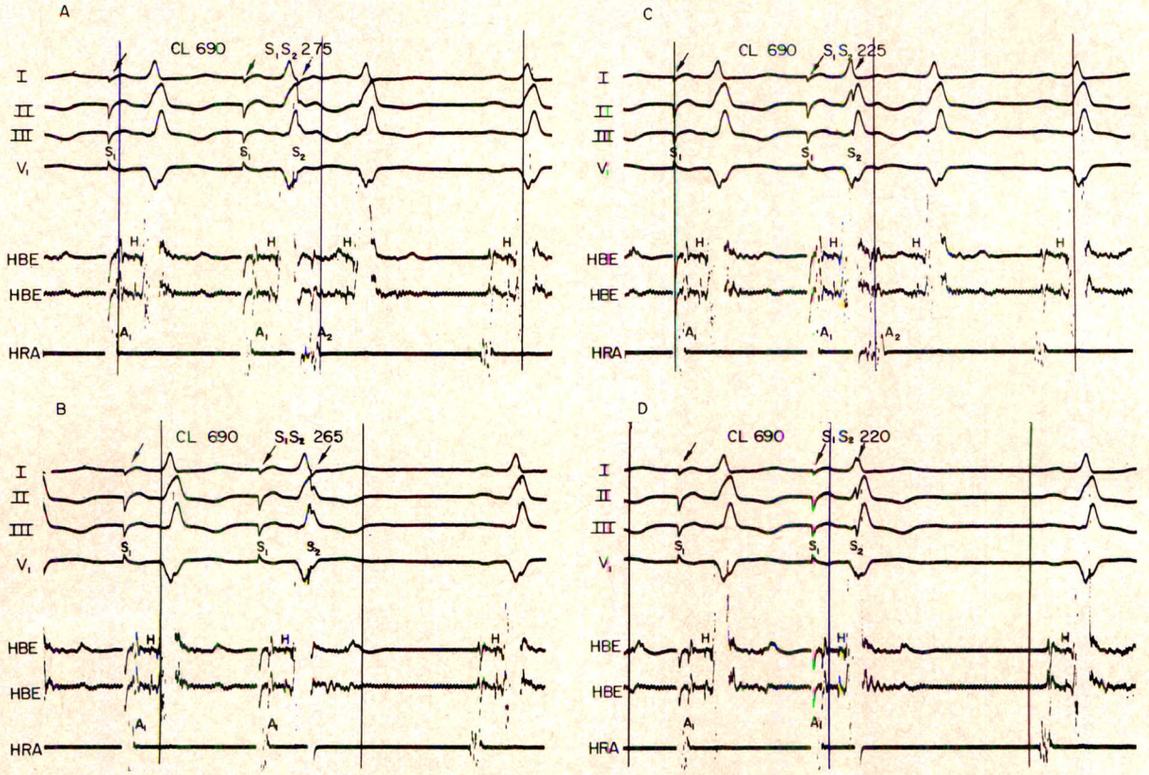

FIGURE 2. Case 11. Measurement of atrial refractory periods before and after administration of glucagon. Paper speed is 100 mm/sec and time lines are at 1 second intervals. The cycle length (CL) of the basic drive (S_1) is 690 msec and the atrial coupling interval (S_1–S_2) is listed at the top of each panel. A_1 is the atrial electrogram induced by S_1, and A_2 is the atrial electrogram of the extrastimulus. **A** and **B** are control recordings, **C** and **D** were obtained after administration of glucagon. **A,** at a coupling interval of 275 msec, S_2 is conducted to the atrium (and ventricle). The A_1–A_2 interval is 295 msec and is the shortest attainable A_1–A_2 interval, defining the functional refractory period of the atrium before administration of glucagon. **B,** S_2 fails to capture the atrium at a coupling interval of 265 msec. This defines the effective refractory period of the atrium before administration of glucagon. **C,** at a coupling interval of 225 msec, S_2 is conducted to the atrium (and ventricle). The A_1–A_2 interval is 260 msec and is the shortest attainable A_1–A_2 interval, defining the functional refractory period of the atrium after administration of glucagon. **D,** S_2 fails to capture the atrium at a coupling interval of 220 msec. This defines the effective refractory period of the atrium after administration of glucagon.

tion of glucagon. In one patient multiple premature atrial contractions, observed in the control period, occurred less frequently after administration of glucagon. No new arrhythmias were observed after administration of the drug.

Discussion

Farah and Tuttle[18] reported that glucagon produced a positive inotropic and chronotropic effect on the heart of several species including canines. Experimental studies in dogs by Whitsitt and Lucchesi[10] revealed that glucagon was capable of rapidly reversing the depression of A–V conduction induced by propranolol. In their study, A–V nodal conduction was evaluated by examining A–V intervals (the time required by an impulse to travel from an atrial stimulating electrode to a ventricular recording electrode) before and after administration of glucagon.

Steiner et al.[11] using the His bundle recording technique, also studied the electrophysiologic effects of glucagon in dogs. They reported facilitation of A–V conduction as manifested by a 26 to 30 percent decrease in the P–H interval after administration of glucagon, but no effect on the H–V interval. They also noted that glucagon reversed the depressant effect of propranolol on A–V conduction. Lipski et al.[12] demonstrated similar facilitation of canine A–V nodal conduction after glucagon, as suggested by a 21 percent decrease in the P–H interval after administration of the drug.

Data on the electrophysiologic effects of glucagon on A–V conduction in man are limited. Nishimura et al.[13] studied the effects of glucagon in 11 patients and found no change in the P–R interval with glucagon. They also noted an insignificant decrease in the P–H interval by 15 msec in the two patients who had His bundle electrogram recordings. The H–V interval was unchanged in these two patients.

Electrophysiologic Effects of Glucagon

The results of our study partially confirm previous observations. The P–A interval, a measure of conduction from the high to the low right atrium, decreased in 22 of 26 patients after administration of glucagon. In addition, glucagon induced a significant decrease in atrial functional and effective refractory periods. These observations suggest that glucagon facilitates intraatrial conduction. The cellular basis for this fa-

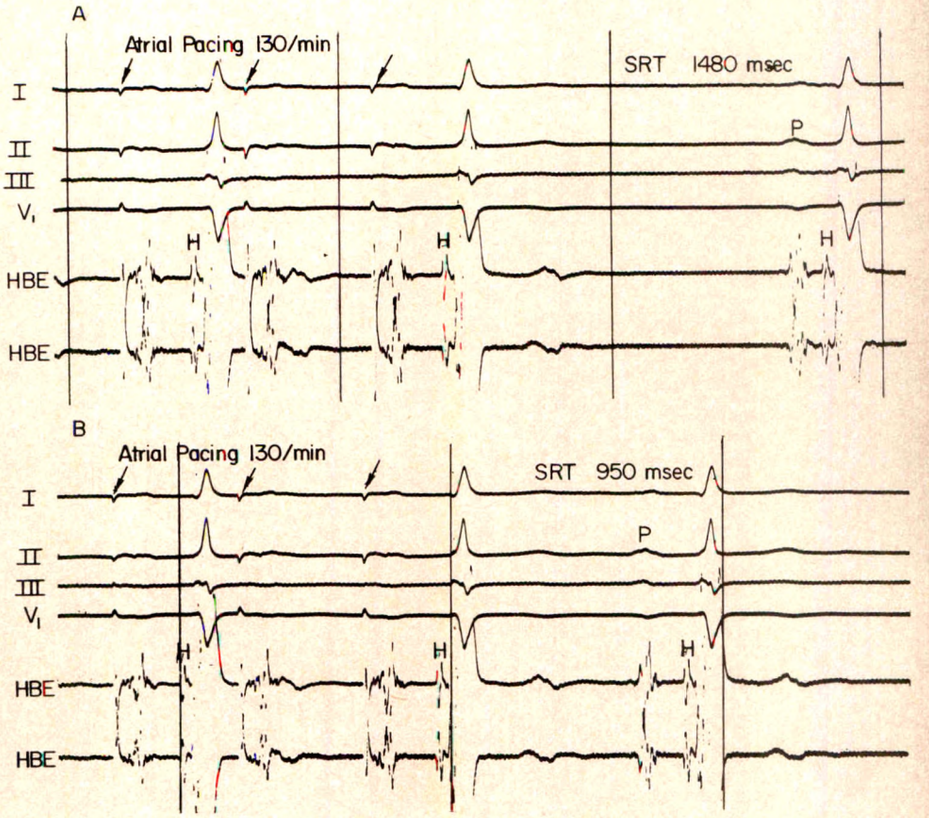

FIGURE 3. Case 2. Recordings demonstrating sinus nodal recovery times (SRT) before (**A**) and after (**B**) administration of glucagon. Atrial pacing spikes are labeled with **arrows,** the pacing rate is 130/min. At this rate 2:1 A–V block proximal to the His potential is present.

cilitation of intraatrial conduction is not apparent and deserves further study. Our findings suggest that glucagon has a minimal effect on A–V nodal conduction in man. The shortening of the P–H interval (which encompasses the P–A and A–H intervals) or the P–R interval with glucagon previously noted[10–13] in animals and man may partially reflect facilitation of intraatrial conduction. The marked decrease of the P–H interval in dogs may also reflect a species-specific facilitation of A–V nodal conduction. Our results regarding lack of effect on intraventricular conduction are consistent with previously reported observations.[9–13]

The effects of glucagon on the sinus node have been well studied in both animals and man. It has been demonstrated that glucagon has a positive chronotropic effect on the sinus as well as the A–V node.[1,3,4,9–13,19–21] The data from our study on enhanced automaticity of the sinus node are in agreement with previous observations. Sinus rates increased in all patients after administration of glucagon. In addition, glucagon decreased sinus nodal recovery time in 25 of 26 patients. The effect of glucagon on A–V junctional automaticity could not be examined in our study.

There are conflicting reports about the effects of glucagon on ventricular automaticity. Steiner et al.[11] and Lucchesi et al.[22] reported that glucagon had no effect on ventricular automaticity in dogs. In contrast, several other workers[12,23,24] have shown an increase in ventricular automaticity in animals induced by glucagon. Wilkerson et al.[24] demonstrated in dogs that glucagon increased ventricular automaticity and that this increase was masked by the positive chronotropic action of the drug on the sinus or A–V node, or both. Nishimura et al.[13] demonstrated in man that glucagon did not significantly change the ventricular automaticity in patients with A–V block. In our patient with complete heart block, the ventricular rate was not increased after administration of glucagon.

It has been suggested that glucagon possesses antiarrhythmic properties since it has been noted to abolish digitalis-induced ventricular arrhythmias.[25–27] In contrast, Lipski et al.[12] observed multiple premature ventricular contractions after administration of glucagon, suggesting that this drug increased ventricular irritability. In two of our three patients with premature ventricular contractions, the ectopic beats were abolished by glucagon whereas they became more frequent in the third patient. In our patients, no new arrhythmias were noted after administration of glucagon, thus suggesting that glucagon is not arrhythmogenic in man. We cannot draw any conclusions about the antiarrhythmic properties of glucagon from this study.

Clinical Implications

Glucagon, in a dose of 50 μg/kg intravenously, produced slight but significant facilitation of intraatrial conduction without demonstrably affecting either

A–V nodal or intraventricular conduction. In addition, this agent produced a modest increase in automaticity of the sinus node, as manifested by an increase in sinus rate and a decrease of sinus nodal recovery time. Glucagon did not appear to be arrhythmogenic.

Although these effects are of pharmacologic interest, they should not play a major role in the decision to use or not to use glucagon as a positive inotropic agent in the management of cardiogenic shock or congestive heart failure. In a clinical situation, glucagon would probably not depress conduction, and thus could be used safely in patients with conduction disease. Its lack of arrhythmogenic properties gives it an advantage over catecholamines in the management of low output states. Our results suggest that glucagon will not be useful in the management of block in the A–V node or His-Purkinje system. The potential value of glucagon in patients with depressed sinus nodal function needs further study.

Beneficial Electrophysiologic Effects of Nitroglycerin During Acute Myocardial Infarction

KENNETH M. KENT, MD, PhD
ELDON R. SMITH, MD*
DAVID R. REDWOOD, MD
STEPHEN E. EPSTEIN, MD

Bethesda, Maryland

Nitroglycerin reduces ischemic injury after experimental coronary occlusion. To determine whether it also has the potential of protecting the heart against the development of serious ventricular arrhythmias, the effects of nitroglycerin on electrical stability of acutely ischemic myocardium were determined in open chest dogs. Electrical stability of the ventricle was assessed by measuring ventricular fibrillation threshold before and after acute myocardial ischemia was produced by occlusion of the left anterior descending coronary artery. Ventricular fibrillation threshold was measured in a random manner under conditions of nonischemia, ischemia, ischemia plus nitroglycerin, and simultaneous infusion of phenylephrine to maintain mean systemic arterial pressure at control levels. Heart rate was kept constant at 120 beats/min by destruction of the atrioventricular node and use of ventricular pacing. In the absence of ischemia ventricular fibrillation threshold was 77 ± 5 milliamperes (ma), a value unaffected by either nitroglycerin or phenylephrine. After 6 minutes of acute myocardial ischemia, ventricular fibrillation threshold was reduced to 30 ± 6 ma ($P < 0.01$). When nitroglycerin was infused at a rate of 200 μg/min (with a reduction in arterial pressure of 24 percent), ventricular fibrillation threshold after 6 minutes of acute ischemia increased from 30 ± 6 to 55 ± 3 ma ($P < 0.005$). Restoration of arterial pressure by phenylephrine during infusion of nitroglycerin further raised the ventricular fibrillation threshold to 75 ± 6 ma, a value identical to that present in nonischemia. Thus, nitroglycerin enhances electrical stability of the heart during experimental acute myocardial ischemia, an effect probably related to reduction of ischemic injury. Since the ventricular fibrillation threshold increases even further after arterial pressure is restored to control levels, this beneficial electrophysiologic effect is probably caused by some action of nitroglycerin other than reduction in myocardial oxygen consumption mediated by decreased afterload.

Despite the long-standing use of nitroglycerin in the treatment of angina pectoris, it is generally accepted that the drug should not be used to treat ischemic pain caused by acute myocardial infarction. This concept is based on the belief that the nitroglycerin-induced decrease in arterial pressure and reflex increase in heart rate might exacerbate the ischemic insult. The demonstration that hypotension (induced either by hemorrhage[1] or reflexly by stimulation of the carotid baroreceptors[2]) and an increase in heart rate[3] augment the degree of ischemic injury occurring during experimental acute coronary occlusion appears to support this view.

Recently, the concept that nitroglycerin is contraindicated in acute myocardial infarction has been challenged by the finding that during experimental coronary occlusion, nitroglycerin actually diminishes the intensity of ischemia[1] and the area of infarcted myocardium.[4] If these beneficial effects are of physiologic significance, and if the pro-

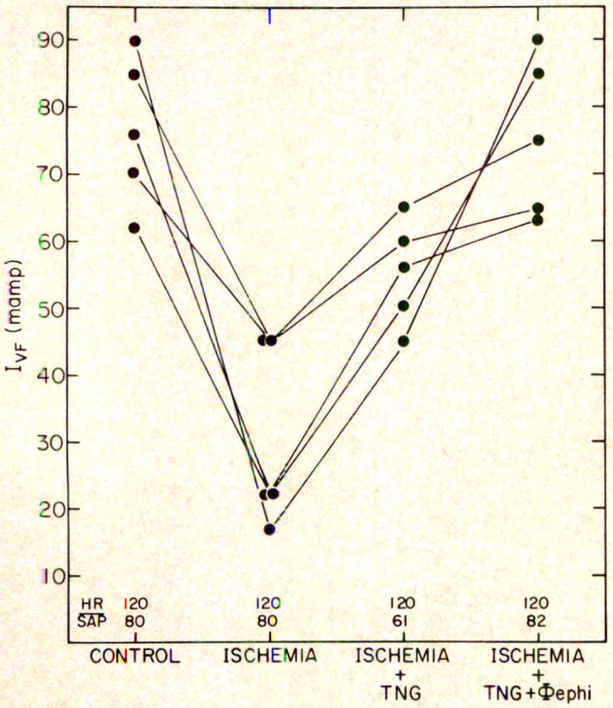

FIGURE 1. Ventricular fibrillation threshold (I_{VF}) in 5 dogs under conditions of nonischemia, ischemia, ischemia with nitroglycerin (TNG) infusion, and ischemia with nitroglycerin and phenylephrine (Φephi). Heart rate (HR) was kept constant by ventricular pacing. $\overline{SAP}$ = mean systemic arterial pressure.

pensity for arrhythmias to develop during coronary occlusion is related to the degree of associated myocardial ischemia, nitroglycerin might also counteract the diminution of electrical stability in ischemic myocardium.[5] In this study we tested this hypothesis by determining the effect of nitroglycerin on the vulnerability of the ventricle to fibrillation during experimental acute myocardial ischemia.

Methods

Mongrel dogs weighing from 15 to 18 kg were anesthetized with sodium pentobarbital, 30 mg/kg intravenously, and studied in the supine position. The heart was exposed through a transverse thoracotomy and an adjustable ligature was placed around the left anterior descending coronary artery approximately 2 cm from its origin. Heart rate and systemic arterial pressure were recorded continuously. Heart rate was kept constant at 120 beats/min with ventricular pacing after induction of complete heart block by the injection of 1 ml of 10 percent formalin into the region of the atrioventricular (A–V) node.

Ventricular fibrillation threshold was assessed by delivering a train of pulses, each 2 msec in duration and separated by 8 msec, through a bipolar platinum electrode sutured to the left ventricle outside of the region of subsequent ischemia. The train of pulses was delivered during the ventricular vulnerable period, starting 80 msec after ventricular activation and continuing for 50 msec after the end of the T wave in lead II of the electrocardiogram. The current was increased by four milliampere (ma) steps (measured with a Hewlett-Packard current probe and displayed on a storage oscilloscope) until ventricular fibrillation occurred. Ventricular fibrillation threshold was defined as the current (in milliamperes) required to produce fibrillation. This procedure was similar to that previously described.[5] Ventricular defibrillation was accomplished within 30 seconds after the initiation of fibrillation by a direct current shock (capacitor-discharged) applied to the heart through two 6 cm electrodes.

Ventricular fibrillation threshold was determined under four conditions: (1) in the absence of ischemia, (2) during ischemia (5 minutes after occlusion of the left anterior descending coronary artery), (3) during ischemia when nitroglycerin was being administered, and (4) during ischemia with simultaneous administration of nitroglycerin and phenylephrine. When nitroglycerin was administered it was given before coronary occlusion as a single injection of 300 μg followed by a constant infusion of 200 μg/min. When phenylephrine was administered it was given after the effects of the nitroglycerin infusion had stabilized and was infused at a rate sufficient to maintain systemic arterial pressure at control levels. The interventions were randomized, and each was separated by a 1 hour period. (We recently demonstrated[5] that ventricular fibrillation threshold during acute myocardial ischemia under control conditions of arterial pressure and heart rate was unchanged over a time course similar to that used here.) The effects on ventricular fibrillation threshold in the absence of ischemia of nitroglycerin alone, phenylephrine alone and the combination of nitroglycerin and phenylephrine were determined in two dogs.

Statistical analysis was performed by Student's *t* test for paired data. Results are expressed as mean ± 1 standard error of the mean.

Results

Systemic Arterial Pressure

Occlusion of the left anterior descending coronary artery at a heart rate of 120 beats/min did not induce any changes in systemic arterial pressure. Administration of nitroglycerin (300 μg intravenously followed by an infusion of 200 μg/min) caused mean systemic arterial pressure to decrease from 80 ± 6 to 61 ± 3 mm Hg ($P < 0.05$). Infusion of phenylephrine during administration of nitroglycerin restored arterial pressure to control values.

Ventricular Fibrillation Threshold

Nonischemia: Ventricular fibrillation threshold averaged 77 ± 5 ma in the five experimental animals. In two additional control animals nitroglycerin and phenylephrine were administered separately and in combination in the doses previously described. In the first of these two animals under control conditions the fibrillation threshold was 62 ma, during infusion of nitroglycerin alone 60 ma (systemic arterial pressure decreased 20 percent), during infusion of phenylephrine alone 68 ma (arterial pressure increased 10 percent) and with the combined administration of nitroglycerin and phenylephrine 66 ma (arterial pressure unchanged). In the second animal the fibrillation threshold under control conditions was 76 ma, during infusion of nitroglycerin alone 70 ma (arterial pressure decreased 22 percent), during infusion of phenylephrine alone 80 ma (arterial pressure increased 16 percent) and with the combined adminis-

tration of nitroglycerin and phenylephrine 74 ma (arterial pressure unchanged).

Effects of ischemia: Ventricular fibrillation threshold decreased 61 percent from control (nonischemic) values 5 minutes after occlusion of the left anterior descending coronary artery. The fibrillation threshold was lowered from an average of 77 ± 5 to 30 ± 6 ma ($P < 0.01$, Fig. 1).

Effects of nitroglycerin during acute myocardial ischemia: When nitroglycerin was infused during coronary occlusion ventricular fibrillation threshold increased 83 percent from the level reached during ischemia in the absence of nitroglycerin (Fig. 1). The improvement occurred despite a 24 percent reduction in mean arterial pressure. Thus, fibrillation threshold averaged 30 ± 6 ma during myocardial ischemia under control conditions and 55 ± 3 ma during ischemia when nitroglycerin was infused ($P < 0.005$).

Effects of nitroglycerin and phenylephrine during acute myocardial ischemia: When the nitroglycerin-induced reduction in arterial pressure was prevented by the simultaneous administration of phenylephrine, ventricular fibrillation threshold during acute myocardial ischemia increased even further to 75 ± 6 ma (Fig. 1). This value was not significantly different from the control (nonischemia) fibrillation threshold (mean difference 2 ± 8 ma).

Discussion

The results of our investigation demonstrate that nitroglycerin increases the electrical stability of acutely ischemic myocardium, as manifested by a decreased vulnerability of the heart to the development of ventricular fibrillation in response to an electrical stimulus. Moreover, this beneficial electrophysiologic effect is potentiated when the nitrate-induced hypotension is prevented by the simultaneous administration of phenylephrine, an alpha receptor agonist. The potential efficacy of combination therapy appears considerable, since the decrease in electrical stability that occurred during ischemia was completely reversed by simultaneous administration of nitroglycerin and phenylephrine.

The absolute values for the ventricular fibrillation threshold in these experiments were considerably higher than those previously reported from our laboratory[5] and by others[6,7] in anesthetized open chest dogs. The only difference between this preparation and those of previous studies, in which fibrillation thresholds were lower, was that in the studies described here the A–V node was destroyed by formalin in order to induce heart block. The latter was required to achieve slower heart rates than those usually obtained in pentobarbital-anesthetized dogs. The mechanism responsible for the increased threshold for fibrillation caused by the induction of heart block is unknown. However, there are several possible explanations. The formalin injection in the A–V nodal region could have interrupted sympathetic nerve fibers to the ventricular conducting system. Stimulation of these fibers is known to decrease the ventricular fibrillation threshold.[8] Destruction of the A–V nodal region also could have destroyed some of the particularly vulnerable areas of the conducting system. The elucidation of the exact mechanism responsible for the increased ventricular fibrillation threshold in animals with heart block requires further study.

Mechanism of effect of nitroglycerin on ventricular fibrillation threshold: How nitroglycerin reverses the ischemia-induced decrease in electrical stability cannot be determined precisely from the results of our investigation. Nitroglycerin increased fibrillation threshold only in the presence of ischemia. Thus, it is unlikely that its actions were due to a nonspecific membrane-stabilizing effect although such direct effects could be demonstrable only in ischemic tissue. Alternatively, the beneficial electrophysiologic effect could have resulted from a favorable change in the balance between myocardial oxygen supply and demand within the ischemic zone. This mechanism would be operative if nitroglycerin reduced oxygen demands of the ischemic tissue by altering heart rate, wall tension and myocardial contractile state. However, the beneficial effects of nitroglycerin were observed even when heart rate and arterial pressure were kept constant, and under these conditions reduction of myocardial contractility also would have been unlikely. Thus, if nitroglycerin caused a significant decrease in myocardial oxygen consumption under the conditions of our study, it could have done so only by causing greater venodilatation than could be reversed by phenylephrine. This change would decrease ventricular volume, diminish myocardial wall tension and thereby decrease myocardial oxygen consumption.

Finally, nitroglycerin could have favorably altered the balance between myocardial oxygen supply and demand by increasing blood flow to the ischemic area. Nitroglycerin has been shown in the dog to be capable of dilating large coronary arteries, increasing retrograde coronary flow during coronary occlusion, and increasing coronary pressure distal to the site of an occluded coronary artery.[9] Winbury et al.[10] have shown an increase in endocardial PO_2 and a favorable redistribution of blood toward ischemic myocardium after administration of nitroglycerin. Recent studies from our laboratory[11] have demonstrated that nitroglycerin has the capacity to decrease resistance to collateral flow in patients undergoing coronary bypass surgery.

The increase in ventricular fibrillation threshold after administration of nitroglycerin is not necessarily equivalent to a decreased propensity for the *spontaneous* development of serious ventricular arrhythmias and ventricular fibrillation. However, data presented elsewhere in this issue [12] suggest that this is the case.

Clinical implications: Recently, additional data have been reported that suggest a role for nitroglycerin in the therapy of acute myocardial infarction. For example, the degree of ischemic injury occurring during experimental acute coronary occlusion is di-

minished by nitroglycerin, and this effect is further enhanced when the reduction in arterial pressure is prevented by the infusion of an alpha adrenergic agonist.[1] Later studies have shown that the extent of myocardial infarction (quantitated by measuring the depression of myocardial creatine phosphokinase activity) produced by 5 hours of occlusion of the left anterior descending coronary artery is considerably less in dogs treated by an infusion of nitroglycerin and methoxamine than in a control group.[4] In addition, Gold et al.[13] administered nitroglycerin sublingually to a group of patients with acute myocardial infarction. In some of the patients with persistent refractory left ventricular failure, nitroglycerin resulted in a reduction in pulmonary capillary wedge pressure and an increase in cardiac output. Similar results were obtained by Franciosa et al,[14] who infused the vasodilator, sodium nitroprusside, in patients with acute infarction. The results of our investigation, which demonstrate that nitroglycerin also enhances electrical stability, add another dimension to the potential beneficial role of nitroglycerin in acute myocardial infarction. Thus, although it is not certain whether our data are applicable to the clinical situation, they suggest that nitroglycerin may be uniquely valuable in the treatment of acute myocardial infarction by reducing the degree of ischemic injury and the incidence of serious ventricular arrhythmias.

Nitroglycerin-Induced Reduction in the Incidence of Spontaneous Ventricular Fibrillation During Coronary Occlusion in Dogs

JEFFREY S. BORER, MD
KENNETH M. KENT, MD, PhD
ROBERT E. GOLDSTEIN, MD
STEPHEN E. EPSTEIN, MD.

Bethesda, Maryland

Previous investigations have demonstrated that nitroglycerin reduces ischemic injury and enhances ventricular electrical stability during coronary occlusion in dogs. These beneficial effects were potentiated by preventing drug-induced hypotension with alpha adrenergic agonists. To determine whether nitroglycerin can prevent spontaneous post-occlusion ventricular fibrillation, 27 open chest dogs were assigned in random fashion to two groups—control (saline infusion) and nitroglycerin-treated (0.45 mg intravenous bolus infusion followed by 0.3 mg/min continuous infusion). After 10 minutes of infusion the left anterior descending and septal coronary arteries were occluded at their origins. Hypotensive effects of nitroglycerin were prevented by intermittent intravenous doses of methoxamine; mean arterial pressure and heart rate in control and treated animals were thus indistinguishable. Infusions continued until ventricular fibrillation occurred or 30 minutes elapsed. Twelve of 13 control dogs died with ventricular fibrillation; only 7 of 14 nitroglycerin-treated dogs died ($P < 0.05$). Thus, nitroglycerin may be capable of exerting important and unique beneficial effects in patients with acute myocardial infarction since, with its hypotensive effects obviated by alpha adrenergic agonists, it markedly diminishes ischemic injury, enhances ventricular electrical stability, and significantly reduces the incidence of spontaneous ventricular fibrillation in an experimental model of acute myocardial infarction.

The use of nitroglycerin traditionally has been avoided in the presence of acute myocardial infarction because of the fear that nitroglycerin-induced hypotension and tachycardia might exacerbate the ischemic insult. Recently, however, nitroglycerin was found to reduce the degree of ischemic injury and to increase the threshold at which ventricular fibrillation could be induced electrically during experimental acute coronary occlusion[1–4]; both of these salutary effects were enhanced if nitroglycerin-induced hypotension was prevented by administration of an alpha adrenergic agonist. In this investigation we have determined whether nitroglycerin is capable of inhibiting the *spontaneous* occurrence of ventricular fibrillation during acute coronary occlusion in dogs when drug-induced hypotension is prevented with methoxamine.

Methods

Twenty-seven male dogs weighing 16 to 25 kg were randomized into control and nitroglycerin-treated groups. Each dog was anesthetized with intravenously administered sodium pentobarbital (35 mg/kg). A catheter was introduced into the femoral artery for pressure recording and into a limb vein

for drug administration. Standard subcutaneous electrodes were inserted for recording the electrocardiogram. The heart was exposed through a left thoracotomy during positive pressure ventilation. The left anterior descending and septal coronary arteries were dissected free at their origins. Arterial hemoglobin oxygen saturation and pH were then determined and the respirator adjusted so that oxygen saturation was at least 91 percent, and pH was between 7.42 and 7.52. All dogs had sinus rhythm. Each dog in the treated group received an initial intravenous bolus infusion of 0.45 mg of nitroglycerin followed by a continuous intravenous infusion of 0.3 mg/min. The infusion solution was prepared by dissolving nitroglycerin tablets (Lilly) in normal saline solution in quantities permitting an infusion rate of 0.5 ml/min. Methoxamine, an alpha adrenergic agonist, was administered intermittently to maintain mean arterial pressure at the pre-nitroglycerin level. Each control dog received an infusion of normal saline solution, also at a rate of 0.5 ml/min. After 10 minutes of infusion, the left anterior descending and septal coronary arteries were simultaneously clamped at their origins; the clamp was suspended by sutures from an overlying crossbar so that traction on the coronary arteries was relatively constant despite respiratory movements. The clamp was carefully placed so as to avoid occluding either the left main or left circumflex coronary arteries. To ensure that such inadvertent occlusion had not occurred, after each experiment the heart was removed with the clamp in place and the coronary arteries were probed, opened and inspected. Mean arterial pressure and the electrocardiogram were recorded continuously.

After occlusion, each experiment continued until the dog died with ventricular fibrillation, or until 30 minutes had elapsed without ventricular fibrillation. This duration of observation was chosen since preliminary experiments with this model demonstrated that if fibrillation did not develop within 30 minutes after occlusion, it did not develop during a subsequent hour of observation either in control or nitroglycerin-treated dogs.

The rate of administration of methoxamine as well as nitroglycerin was identical in treated dogs that experienced ventricular fibrillation and in treated survivors.

Statistical analysis of the difference in incidence of ventricular fibrillation in control and treated groups was performed with the use of the Fisher Exact Test. Comparison of blood pressure and heart rate was performed with the Student *t* test.

Results

Before infusion, no significant differences in mean arterial pressure or heart rate existed between control and treated dogs. Mean arterial pressure in control dogs was 120 ± 5 mm Hg and in treated dogs 128 ± 6 mm Hg. Heart rate in control dogs was 166 ± 7 beats/min and in treated dogs was 170 ± 6 beats/min. Moreover, during the course of occlusion, no significant differences developed between the control and treated dogs that were alive at any given assessment point. Arterial pressure remained relatively constant in each dog for the duration of the experiment, except for transient fluctuations associated with arrhythmias which, when ventricular fibrillation did not supervene, were only of a few seconds' duration. Among the treated dogs, no significant differences in heart rate or blood pressure were discernible during the course of the experiments when comparing the dogs that died with those that survived.

Ventricular fibrillation occurred in 12 of 13 control dogs but in only 7 of 14 treated dogs ($P < 0.05$, Fig. 1). No dog had ventricular fibrillation after surviving more than 18.5 minutes of occlusion, and most (15 of 19) died between 11 and 18.5 minutes after occlusion. No dog had atrioventricular dissociation during the course of the experiment.

Discussion

The results of this investigation demonstrate that nitroglycerin (its hypotensive effects obviated by simultaneous administration of methoxamine) markedly diminishes the incidence of ventricular fibrillation occurring spontaneously in an experimental model of acute myocardial infarction. These results are in accord with and extend our previous studies[3,4] demonstrating that nitroglycerin, alone or with phenylephrine, significantly increases the threshold at which ventricular fibrillation can be induced electrically during coronary occlusion in dogs.

Mechanisms of beneficial action of nitroglycerin: The mechanisms by which nitroglycerin and methoxamine reduce the prevalence of ventricular fibrillation are unknown. Nitroglycerin alone, and in combination with methoxamine, decreases the degree of myocardial ischemia occurring during experimental coronary occlusion.[1,2] It appears likely that such an effect is responsible for enhanced survival. This conclusion is reinforced by our previous findings that nitroglycerin increases ventricular fibrillation threshold in the presence of ischemia but does not do so when ischemia is absent. It is unclear, however, whether nitroglycerin reduces ischemia by decreasing oxygen demand of the heart, increasing blood flow to ischemic areas, or both.

The actions of nitroglycerin alone on the prevalence of spontaneous ventricular fibrillation during

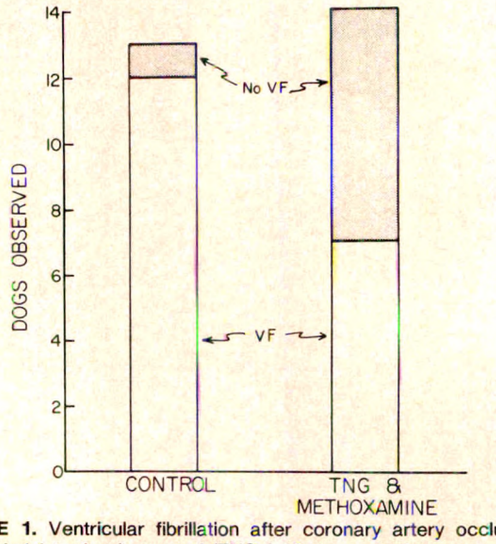

FIGURE 1. Ventricular fibrillation after coronary artery occlusion. Drug administration in treated (TNG & Methoxamine) group and saline infusion in control group were begun 10 minutes before coronary occlusion.

coronary occlusion is yet to be determined. That this agent contributes markedly to the decrease in ventricular fibrillation observed when both nitroglycerin and methoxamine are administered, however, is suggested by the finding that nitroglycerin itself increased ventricular fibrillation threshold during acute myocardial ischemia.[3,4] When the hypotensive effects of nitroglycerin were abolished by simultaneous administration of another alpha adrenergic agonist (phenylephrine), a further increase in ventricular fibrillation threshold was observed. Moreover, we have found no significant reduction in the incidence of spontaneous postocclusion fibrillation after the administration of phenylephrine alone, in amounts sufficient to raise mean arterial pressure to levels associated with significant reduction in ischemic injury (unpublished observations). Thus, the results of the previous studies, in conjunction with those of this investigation, indicate that nitroglycerin can inhibit the development of ventricular fibrillation occurring during experimental acute coronary occlusion and that this effect is potentiated by preventing the reduction in arterial pressure that this drug might cause.

The dog model of ischemia-induced ventricular fibrillation used in the present investigation differs considerably from models used in other studies. In such models, although wide fluctuations exist, the incidence of early ventricular fibrillation has generally been far lower than in the present model, whereas hemodynamic abnormalities have often been prominent. Thus, although occlusion of the left main coronary artery leads almost uniformly to ventricular fibrillation, this intervention usually causes hypotension and cardiogenic shock.[5–7] When the circumflex coronary artery is occluded in the open chest dog, the cumulative incidence of ventricular fibrillation is about 33 percent.[5,8,9] In the closed chest dog, the incidence has been approximately 60 percent, but the range from study to study is extensive (0 to 75 percent) and severe hypotension is a frequent complicating feature.[7,8,10–12] Approximately 30 percent of more than 750 closed and open chest dogs studied have had fibrillation within 30 minutes after proximal occlusion of the left anterior descending coronary artery[5,8,9,13–18]; in combined small series about 10 percent of dogs had early fibrillation after occlusion of the septal artery.[5,19,20] The incidence of ventricular fibrillation after occlusion of the right coronary artery is 10 percent.[5,7,9,21] In this study, the septal coronary artery was systematically occluded together with the left anterior descending coronary artery. Both vessels were occluded proximal to any branches. This intervention led to incidence of ventricular fibrillation of 92 percent in the control group. In more recent studies from our laboratory in which the same model has been used, the cumulative incidence of fibrillation in untreated animals has been 87 percent (71 of 82). Changes in blood pressure and heart rate after occlusion have been relatively slight in virtually all studies, and are comparable to those reported here. Moreover, our data indicate that the model can be influenced by therapeutic interventions, despite the ischemic insult and high rate of ventricular fibrillation. Hence, this model of acute infarction appears to have particular advantages for evaluating interventions that are capable of reducing the incidence of spontaneous ventricular fibrillation during the early phase of acute myocardial infarction.

Clinical implications: The applicability of our findings to acute myocardial infarction in man is unknown. The protective effects of nitroglycerin on the occurrence of ventricular fibrillation were demonstrated in dogs with acute coronary occlusion but with otherwise normal coronary arteries and normal myocardium. It is possible that nitroglycerin does not exert similar effects when long-term multivessel disease is present. Moreover, other workers[22] have demonstrated that the mechanism of ventricular fibrillation is different early after coronary occlusion than it is several hours later. Thus, although our results suggest potential benefit from nitroglycerin (with methoxamine) during the early phase of acute myocardial infarction in man (when most arrhythmic deaths occur[23,24]), the drug may not have similar effects later in the course of infarction.

There is now an impressive body of experimental evidence demonstrating that during acute coronary occlusion nitroglycerin decreases ischemic injury, enhances electrical stability of the ventricle and, as our study has shown, reduces the incidence of spontaneously occurring ventricular fibrillation. Clinical studies[25] indicate that during the course of acute myocardial infarction associated with left ventricular failure in man, administration of nitroglycerin can result in hemodynamic improvement. Thus, these experimental and clinical studies suggest that the general reluctance to administer nitroglycerin during acute myocardial infarction should be reconsidered since the drug may be of unique therapeutic value in this condition.

Modification of Experimental Myocardial Infarct Size by Cardiac Drugs

PRITPAL S. PURI, MD, FACC

Detroit, Michigan

After occlusion of a coronary artery in dogs, regionally ischemic myocardium was delineated by means of a strain gauge-tipped, two pronged catheter probe that measures myocardial fiber shortening. The curves of contraction were sensitive to the effects of ischemia. A central zone of complete ischemia was identified as the region in which fiber shortening was lost and replaced by passive fiber lengthening. As the probe was inched away from the center toward the periphery, an intermediate zone of incomplete ischemia was defined as the region in which contractility was partially diminished but not lost. It was assumed that a shift in oxygen balance induced by an intervention will be reflected as a change in contractility of the intermediate zone. Accordingly, the intermediate zone was used as the test zone to evaluate effects of drugs on the extent of regionally ischemic myocardium. Isoproterenol initially augmented contractility of the intermediate zone but, with continued infusion, a secondary reduction in contractility became evident at 30 to 45 minutes. Norepinephrine augmented contractility of the intermediate zone and this effect persisted through the 1 hour observation period. Ouabain similarly increased the velocity of shortening of the intermediate zone. An increase in left ventricular afterload induced by methoxamine resulted in loss of contractility and its replacement by fiber lengthening in the intermediate zone. These findings indicate that isoproterenol and methoxamine can increase the extent of noncontracting ischemic myocardium and, hence, infarct size. Norepinephrine and ouabain do not exert this effect.

Drugs that augment myocardial contractility or increase arterial pressure, or both, continue to be used to treat pump failure of the heart complicating acute myocardial infarction.[1–5] But the increases in both myocardial contractile state[6] and myocardial wall tension[7] induce an increase in myocardial oxygen consumption. If coronary circulation is impaired, it is postulated that such an increase in oxygen demand may so exceed the rate of oxygen delivery as to accentuate the severity of ischemia and result in an extension of the infarct.[8,9] Maroko et al.[9] recently reported that the severity and extent of ischemic injury after experimental coronary occlusion are increased by cardiac stimulating drugs that increase myocardial oxygen consumption. These observations, based on a study of the magnitude and distribution of S–T segment elevation in the epicardial electrogram, contrast with earlier data from Sayen et al.[10] demonstrating that levarterenol has a favorable effect on the ischemic area.

Earlier preliminary studies from this laboratory[8,11,12] indicated that changes in contractility of the zone of partial ischemia provide a method of evaluating the effect of drugs on the size of a myocardial infarct. The size of the infarct is delineated by means of a previously described strain gauge-tipped catheter probe that measures myocar-

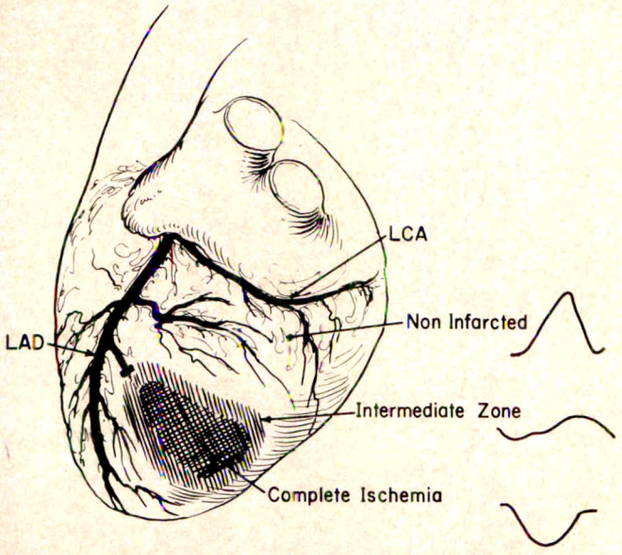

FIGURE 1. Definition of the intermediate zone of partial ischemia after coronary occlusion. In the noninfarcted myocardium, the curve of fiber shortening is inscribed in an upward direction during systole. In the central zone of complete ischemia where contractility is lost, the curve of fiber shortening is replaced by the inverted curve of passive fiber lengthening. As the probe is inched away from the center toward the periphery, an intermediate zone is delineated as the region in which velocity of shortening is diminished by at least 50 percent of the control value. LAD = left anterior descending coronary artery; LCA = left circumflex artery.

dial fiber shortening.[4,13] The probe is used to map segmental changes in myocardial contraction over the surface of the left ventricle.[4,14] Curves of cardiac contraction obtained with the strain gauge probe are extremely sensitive to the effects of ischemia.[4,11] Coronary occlusion results in a rapid loss of myocardial fiber shortening and its replacement by passive fiber lengthening in the center of the ischemic myocardium.[4,8,12] By inching the probe away from the center toward the periphery, one can define an intermediate zone of partial ischemia, interposed between infarcted and noninfarcted myocardial zones, in which contractility is diminished but not lost.[8,11,12] The intermediate zone is used as the test zone to evaluate the effects of drugs on the severity and extent of ischemia because it is assumed that a drug-induced shift in oxygen balance in this zone will be reflected as a primary change in contractility of this region.[8,11,12] Four cardiac drugs with contractile and hemodynamic effects that result in an increase in myocardial oxygen consumption were studied.

Methods

Experiments were performed in 47 mongrel dogs weighing 15 to 22 kg and anesthetized with sodium pentobarbital (25 mg/kg body weight) given intravenously. The trachea was intubated and artificial ventilation, using room air, was instituted by means of a Harvard respirator pump. Thoracotomy was performed in the left fifth intercostal space and the pericardium was opened anterior to the left phrenic nerve. The left anterior descending coronary artery or one of its major branches was mobilized by dissection and a rubber-sheathed curved arterial clamp described previously[4] was used to produce intermittent occlusion. Left ventricular pressure was monitored through a stiff-walled catheter directly connected to a Statham P23Db transducer system and an Electronics for Medicine recorder. Zero level for pressure measurements was set at the mid-chest position. The first derivative of left ventricular pressure pulse (dP/dt) was obtained by means of a resistance-capacitance differentiating circuit. Left ventricular end-diastolic pressure was recorded using higher sensitivity at the end expiratory phase of the respiratory cycle.

Regional contractility: A strain gauge catheter probe that measures myocardial fiber shortening, previously described in detail,[4,13] was used to measure segmental changes in contractility. Briefly, the device consists of two strain gauge-bearing prongs mounted on a stylette. There is a linear relation between the spacing of the prongs and strain in the gauges. The distance between the prongs is 2.5 mm, thus permitting study of curves of contraction over small segments of myocardium. The prongs were extended to the outside of the catheter and were directly inserted into the subepicardial surface of the left ventricular wall. Only the terminal points of the prongs were engaged into the myocardium.[4,13,14] As the prongs follow the course of fiber shortening during systole, curves of contraction are inscribed in an upward direction on a beat to beat basis. The velocity of shortening was measured by drawing a tangent at isolength points relating the height of the curve to time.[13] All recordings were made during expiration.

Regional ischemia: Medium-sized areas of ischemia were produced by occluding one of the major branches of the left anterior descending coronary artery. With use of the strain gauge probe, control curves of contraction were obtained from the region supplied by the artery to be occluded. The probe was positioned in the center of this area and recordings were made continuously as the artery was occluded. In this manner, the exact time course of changes in the curves of contraction was studied. In 15 animals, after a period of occlusion ranging from 5 to 45 minutes, the occlusion was released and recovery of contractility in the ischemic zone studied.

The region immediately surrounding the occluded artery (Fig. 1), in which contractility was lost and replaced by the inverted curve (inscribed downward) of passive fiber lengthening was referred to as the central zone of complete ischemia. As the probe was inched away from the center toward the periphery, an intermediate zone was delineated in which contractility (velocity of shortening) was diminished by at least 50 percent of the control values but not completely lost. This represented the zone of partial ischemia or intermediate zone interposed between infarcted and noninfarcted regions.

Changes in contractility of this zone induced by various drugs were used to assess the effect of these agents on the severity and extent of regionally ischemic myocardium and, hence, infarct size. It is assumed that a drug-induced shift in myocardial oxygen balance will affect the severity of ischemia and, hence, contractility of the intermediate zone. For example, a cardiac stimulating drug is expected to augment contractility through its positive inotropic action. However, should the increase in myocardial oxygen consumption resulting from the increased contractility exceed the oxygen supply, then the resulting negative oxygen balance produced by the increased severity of ischemia may result in a decline of contractility in the intermediate zone. Interventions with an oxygen-sparing action will have an opposite effect.

Protocol: The procedure followed in all experiments was identical. The intermediate zone was delineated 15 minutes

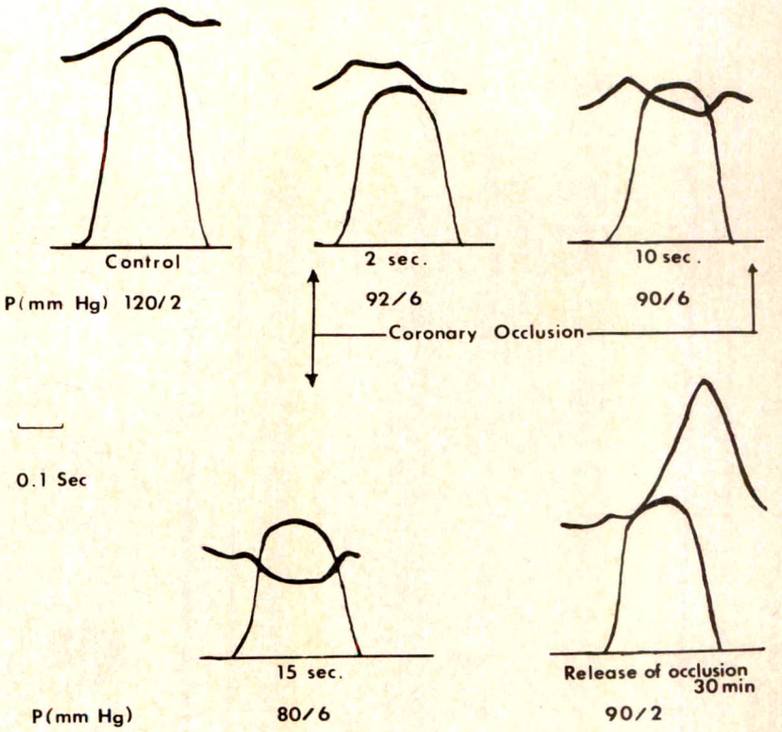

FIGURE 2. Effect of coronary occlusion and release of occlusion on the curves of contraction in 15 dogs. In the control state the curve of myocardial contraction is inscribed in an upward direction. Two seconds after occlusion, the late systolic portion of the curve begins to show inversion. At 10 seconds most of the curve except for the initial component is inverted. At 15 seconds the entire curve is inverted, indicating loss of fiber shortening and its replacement by passive fiber lengthening. After release of coronary occlusion at 30 minutes, the original upward inscription of the curve associated with an initial overshoot is restored, indicating recovery of contractility. P = left ventricular pressure.

after coronary occlusion when hemodynamic variables were stable. Drugs were administered at a constant rate by means of a power-driven infusion pump. Curves of contraction in the intermediate zone were continuously monitored. Recordings were made at 5 minute intervals for 30 to 60 minutes. Measurements were made on the average of 8 to 10 beats for each period of observation with reproducible results; those obtained at the time of optimal response were utilized for statistical analysis using Student's paired *t* test. Each of the four drugs studied was tested in eight dogs; no dog received more than one drug. The following drugs were administered intravenously: isoproterenol (0.25 to 0.50 μg/kg per min), norepinephrine (4.0 μg/min), ouabain (0.5 mg) and methoxamine (1.0 mg/min).

Results

In the control state the systolic curve of myocardial contraction (fiber shortening) is inscribed upward. During diastole, corresponding to myocardial relaxation and fiber lengthening, the curve is inscribed downward (Fig. 1 to 6).

Coronary occlusion resulted in an immediate decline in the amplitude of the curve of contraction in the central zone (Fig. 2). At 2 to 5 seconds, the late systolic portion of the curve was inverted and at 15 to 30 seconds the entire curve was inscribed downward, indicating loss of systolic fiber shortening and its replacement by dyskinetic passive fiber lengthening. If coronary occlusion was released and flow restored at any time up to 45 minutes, the original upward inscription of the curve returned, indicating recovery of contractility (Fig. 2). This sequence of events, in which the curve of contraction becomes inverted with coronary occlusion and returns to the original upward inscription with release of occlusion, could be repeated several times in the same animal. Reproducibility of these changes was established in 15 animals, thereby demonstrating that the curve of contraction is extremely sensitive to the effects of ischemia resulting from coronary occlusion. Changes in the curve of contraction could therefore be used to indicate the presence of myocardial ischemia.

After occlusion of a major branch of the anterior descending coronary artery (Fig. 1), a central zone of ischemia was identified as the region in which fiber shortening was lost and replaced by the inverted curve of fiber lengthening. The intermediate zone of partial ischemia interposed between infarcted and noninfarcted myocardial regions was delineated as the region in which velocity of shortening was diminished by at least 50 percent of the control values. The stability of the curves of contraction in the intermediate zone was established 15 to 60 minutes after coronary occlusion.

Isoproterenol (0.25 to 0.5 μg/kg per min) was administered to eight animals. The means ± standard errors of changes in various indexes were as follows: Heart rate increased from an average of 113 ± 3 to 148 ± 4 beats/min ($P < 0.001$). Left ventricular systolic pressure increased from 108 ± 5 to 120 ± 5 mm Hg, whereas left ventricular end-diastolic pressure decreased. Before administration of isoproterenol, the velocity of shortening in the intermediate zone was 0.64 ± 0.05 mm/sec compared to the control value of 2.02 ± 0.16 mm/sec. This represented an average decline of 68 percent ($P < 0.001$) (Fig. 3). After administration, the velocity of shortening in the intermediate zone initially increased to 2.37 ± 0.09 mm/sec, representing an average increase of 270 per-

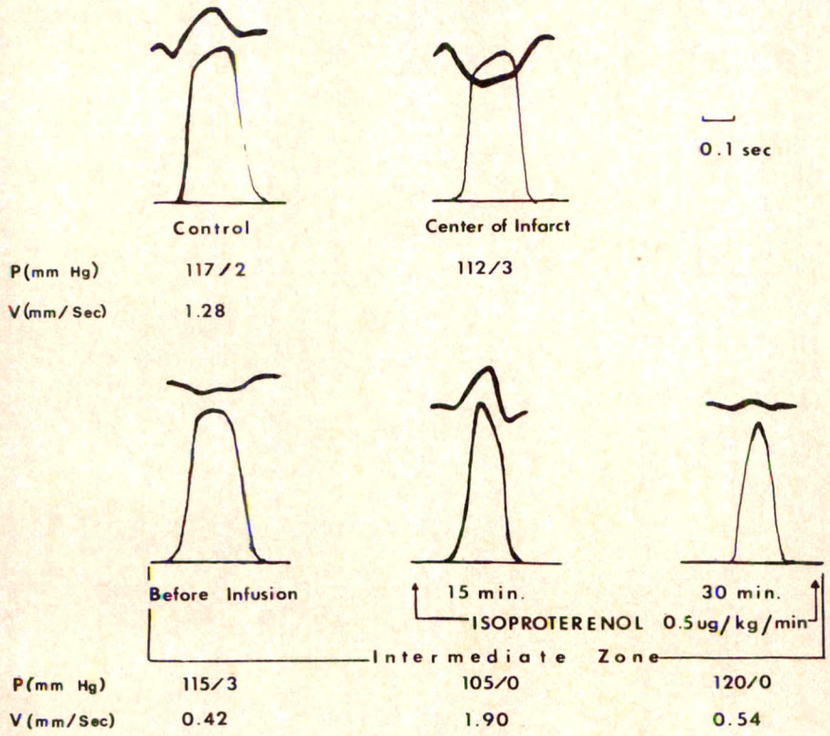

FIGURE 3. Effect of isoproterenol in eight dogs. An inverted curve of fiber lengthening is inscribed in the central zone (center of infarct). In the intermediate zone the curve of contraction shows a 67 percent decline in velocity of shortening (V) compared to the control value. Fifteen minutes after infusion of isoproterenol, velocity of shortening increased by 352 percent. At 30 minutes, a secondary reduction in velocity of shortening of 71 percent occurred, indicating a possible increase in the severity of ischemia in the intermediate zone.

cent (P <0.001). Such an increase in contractility persisted during the first 15 to 20 minutes of infusion. Thereafter, a secondary decline in velocity of shortening occurred in the test zone (Fig. 3). Thirty minutes after the onset of infusion, velocity of shortening decreased to 0.56 ± 0.02 mm/sec, a decline of 72 percent (P <0.001).

Norepinephrine was infused in a dose of 4.0 μg/min to eight animals (Fig. 4). Heart rate declined from 116 ± 2 to 104 ± 5 beats/min (P <0.01). Left ventricular systolic pressure increased from 110 ± 2 to 135 ± 3 mm Hg (P <0.005), whereas left ventricular end-diastolic pressure decreased. Before infusion of norepinephrine, velocity of shortening in the noninfarcted myocardium was 1.75 ± 0.12 mm/sec; in the intermediate zone it was 0.60 ± 0.02 mm/sec representing a decline of 66 percent (P <0.001) from the control level. After infusion, velocity of shortening in the intermediate zone increased to 1.47 ± 0.13 mm/sec, an increase of 145 percent (P <0.001). This increase in velocity of shortening persisted throughout the 60 minute observation period. Unlike isoproterenol, norepinephrine did not cause a secondary decline in contractility of the intermediate zone.

Ouabain (0.5 mg) was administered intravenously to eight animals. Sixty minutes after administration, heart rate decreased from 124 ± 2 to 119 ± 2 beats/min. Left ventricular systolic pressure did not change significantly, whereas left ventricular end-diastolic pressure decreased slightly. In the control state, velocity of shortening was 1.6 ± 0.04 mm/sec in the noninfarcted region and 0.60 ± 0.03 mm/sec in the intermediate zone, a reduction of 62 percent (P <0.01). Ouabain increased velocity of shortening in the intermediate zone to 1.21 ± 0.06 mm/sec, an increase of 84 percent (P <0.001) (Fig. 5).

Methoxamine (1 mg/min) was administered to eight animals. Within 5 minutes left ventricular systolic pressure increased from 118 ± 4 to 165 ± 2 mm Hg (P <0.001), whereas left ventricular end-diastolic pressure increased from 4 ± 2 to 12 ± 2 mm Hg (P <0.001). Heart rate decreased from 112 ± 3 to 96 ± 3 beats/min. In the control state, velocity of shortening in the intermediate zone measured 0.50 ± 0.02 mm/sec compared to 1.25 ± 0.02 mm/sec in the noninfarcted myocardial regions; this represents a reduction of 60 percent (P <0.001). Five minutes after administration of methoxamine there was loss of fiber shortening, which was replaced by fiber lengthening in the intermediate zone, as indicated by inversion of the systolic portion of the curve (Fig. 6). Such inversion of the curve indicates outward extension of the central zone of ischemia. In the noninfarcted region, velocity of shortening decreased to 0.65 ± 0.10 mm/sec (P <0.01).

Discussion

Apart from arrhythmias, infarct size appears to be the most important factor in determining the prognosis of patients with acute myocardial infarction.[15–17] During the early evolution of myocardial infarction, the size of the infarct is not fixed and may be altered.[8,9,18] Recent studies[8,12,19–21] have indicated that the severity and extent of ischemic injury may be modified by various physiologic and pharmacologic interventions.

The ability to modify infarct size is essentially dependent on the presence of ischemic but nonnecrosed

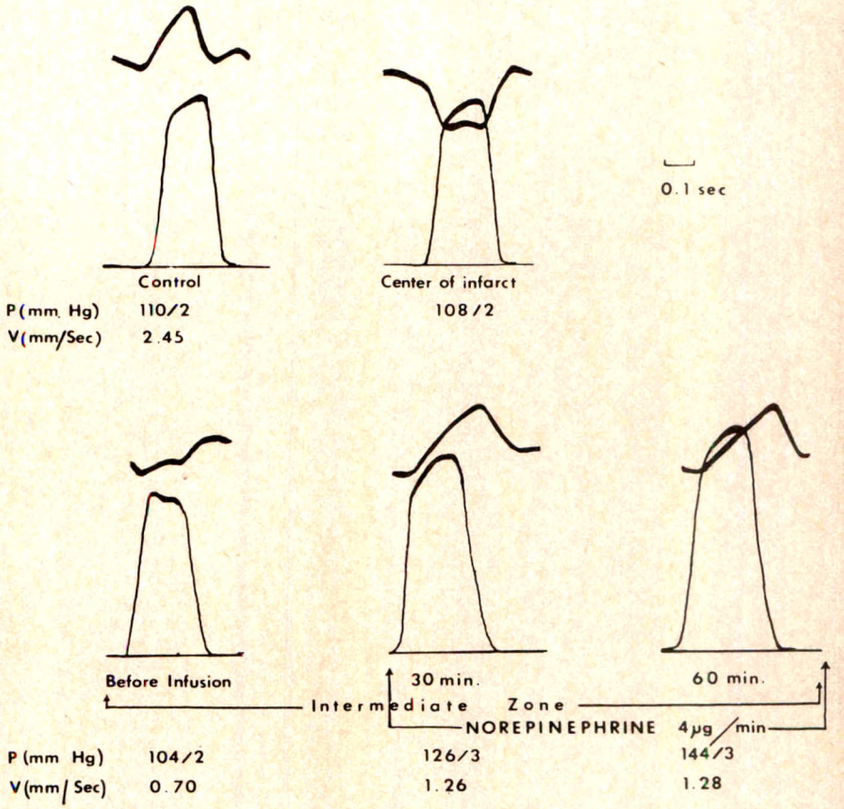

FIGURE 4. Effect of norepinephrine in eight dogs. The intermediate zone showed a 71 percent reduction in velocity of shortening compared to the control level. After infusion of norepinephrine, velocity of shortening increased by 80 percent at 30 minutes and 82 percent at 60 minutes. There was no secondary decline in contractility.

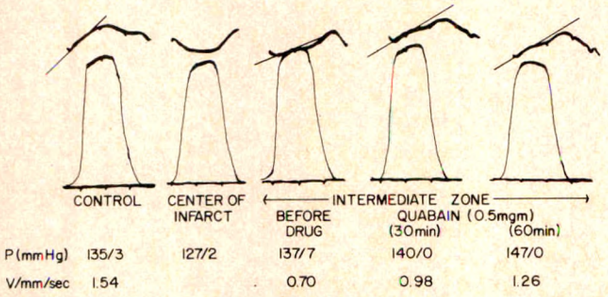

FIGURE 5. Effect of ouabain in eight dogs. In the intermediate zone velocity of shortening was 56 percent of the control value. Ouabain resulted in an increase in velocity of shortening of 25 percent at 30 minutes and 80 percent at 60 minutes. There was no secondary decline in contractility.

viable myocardial cells within the area of reversible ischemic injury.[18,22] These cells constitute the twilight or intermediate zone bordering the infarcted myocardium. The ultimate fate of an ischemic myocardial cell is determined by several factors. With a mild degree of anoxia anaerobic glycolysis may occur and the myocardium may recover uneventfully.[22,23] When ischemia is more severe, changes may occur in the mitochondria and reticulum. However, recovery is possible as long as nuclei and cell membranes are intact.[22,24] The severity of ischemic injury is also determined by the state of the cells before injury, the level of endogenous glycogen stores, substrate availability[25] and cellular environmental factors such as pH and ionic concentration.[22,23]

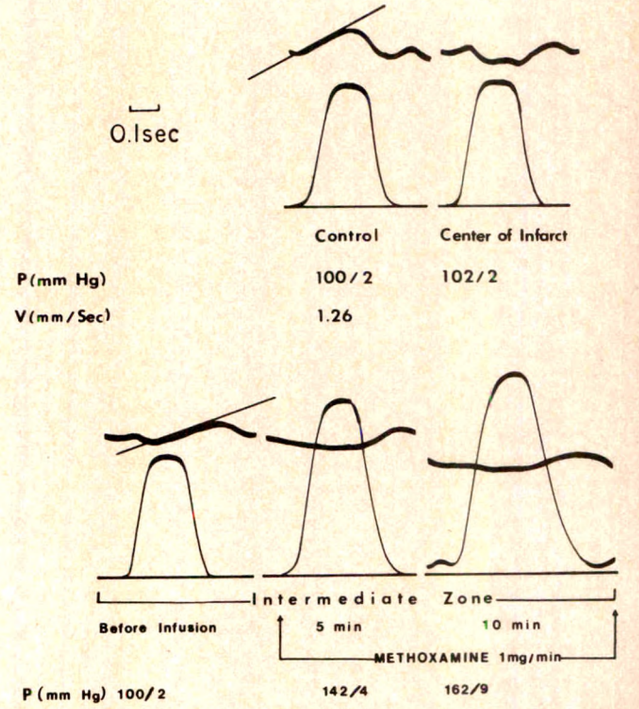

FIGURE 6. Effect of methoxamine in eight dogs. The intermediate zone showed a 55 percent decline in velocity of shortening compared to the control value. After infusion of methoxamine, the curve became inverted, indicating loss of fiber shortening and its replacement by passive fiber lengthening. Loss of contractility in the intermediate zone suggests extension of the central zone.

In this study, infarct size was delineated by means of a strain gauge-tipped catheter probe that measures myocardial fiber shortening.[4,13] The probe records curves of myocardial contraction over localized segments of ventricular wall[4,14]; these curves of contractility are extremely sensitive to the effect of ischemia.[4,8,14,26] After coronary occlusion, contractility immediately declines and the failure of contraction is complete within 15 to 30 seconds (Fig. 2). Inability to contract is associated with passive distension (fiber lengthening) as ischemic myocardium yields to intraventricular pressure.[27] This is reflected in the inversion or downward inscription of the curve in systole. If coronary occlusion is released and flow restored at any time within 45 minutes, myocardial contraction returns and the curve is restored to its original upward inscription (Fig. 2). This sequence of events is reproducible. The catheter probe can therefore be used to distinguish between the noncontracting central zone of complete ischemia and nonischemic myocardium on the basis of the direction in which the curve is inscribed in systole. The intermediate zone of partial ischemia that lies between infarcted and noninfarcted myocardium was defined as the region in which contractility was diminished but not completely lost (Fig. 1). Changes in contractility of the intermediate zone could therefore be used to evaluate the effect of cardiotonic drugs on the severity of ischemia. Thus, if a cardiac drug increases myocardial oxygen consumption in excess of oxygen delivery, then the resulting negative oxygen balance will lead to an increase in the degree of ischemia that, in the intermediate zone, will be reflected as an additional decline in contractility.

The positive inotropic action of the cardiac stimulating drugs examined in our study—isoproterenol, norepinephrine and ouabain—initially augmented contractility of myocardial fibers in the intermediate zone, as indicated by increased velocity of shortening (Fig. 3 to 5). This effect was similar to that observed in the noninfarcted region. An increase in contractility of partially ischemic cells implies a concomitant increase in oxygen supply since enhanced contractility increases oxygen consumption.[6] But during the 30 to 60 minute observation periods it became evident that these drugs had dissimilar effects.

Isoproterenol

Continuous infusion of isoproterenol resulted in a secondary decline in contractility of the intermediate zone which became noticeable at 30 to 45 minutes (Fig. 3). The positive inotropic action of the drug was not diminished at this time, as was evident from changes in the nonischemic region. It is therefore reasonable to assume that the decline in contractility of the intermediate zone, despite the continued positive inotropic action of the drug, reflects an increase in the severity of ischemia of cells in this region.[28] This increase may be due to either or both a progressive augmentation of oxygen consumption or decrease in oxygen supply due to decline in collateral flow or diminished coronary perfusion.[29] The increase in heart rate that accompanied isoproterenol action also has an effect of increasing myocardial oxygen consumption.[30] Other possible mechanisms are a direct effect whereby isoproterenol in large doses produces myocardial necrosis.[31] This effect is unlikely with the doses used in our study. Increased lactate production by the drug may be a factor in depressing myocardial contractility.[32] Maroko et al.[9] reported that the additional myocardial sites showing S–T segment elevation after isoproterenol infusion also showed depression of myocardial creatine phosphokinase, and they attributed this finding to an increment in cell death. Such actions of isoproterenol on the myocardium of the intermediate zone will have the effect of extending the size of the infarct.

Norepinephrine

Norepinephrine did not result in a secondary decline in contractility of the intermediate zone (Fig. 4). The hemodynamic effects of this drug differed from those of isoproterenol since there was an increase in arterial pressure thereby insuring adequate coronary perfusion.[33,34] Further, the decrease in heart rate permits an adequate diastolic filling period with its beneficial effect on cardiac output and coronary perfusion.[35] Because of these actions of the drug, the increase in oxygen supply apparently kept pace with the increased myocardial oxygen consumption. These findings are consistent with the observations of Sayen et al.[10] who reported that levarterenol results in an apparent shrinkage of the regionally ischemic myocardium. The difference in the effects of isoproterenol and norepinephrine on the severity of myocardial ischemia is also supported by the studies of Furuse et al.,[28] who measured myocardial PO_2 and PCO_2 by means of a mass spectrometer. They concluded that in the presence of coronary stenosis, isoproterenol failed to increase coronary flow enough to offset increased oxygen consumption and resulted in a marked reduction in myocardial PO_2 and increase in PCO_2. By contrast, norepinephrine led to an increase in coronary flow, augmentation of PO_2 and a decrease in PCO_2.

Ouabain

Ouabain augmented contractility of the intermediate zone, and this effect persisted during the 60 minute observation period (Fig. 5). Unlike isoproterenol, ouabain did not produce a secondary decline in contractility. It is assumed therefore that digitalis does not induce a negative oxygen balance and consequently in situations comparable to our experiments may not have the effect of extending infarct size. The net effect of digitalis on myocardial oxygen consumption is determined by at least two opposing factors.[36] In a failing heart it has an oxygen-sparing effect through its action in reducing myocardial wall tension. Further, by improving performance of the fail-

ing ventricle it may increase coronary flow and, hence, oxygen delivery. An increase in myocardial contractility ($\dot{V}_{max}$) has the opposite effect of increasing oxygen consumption; in a nonfailing heart this becomes the dominant effect of digitalis.

Methoxamine

Methoxamine led to inversion of the curve of contractility in the intermediate zone; that is, it resulted in loss of fiber shortening and its replacement by passive fiber lengthening (Fig. 6). Methoxamine stimulates alpha adrenergic receptors, resulting in vasoconstriction. The increase in arterial pressure may increase coronary perfusion.[33] At the same time the increase in left ventricular afterload and, hence, myocardial wall tension increases myocardial oxygen consumption. The increase in oxygen demand was apparently greater than that which could be offset by the possible improved coronary perfusion. This led to worsening of the severity of ischemia in the intermediate zone. A marked increase in afterload may therefore extend the size of myocardial infarction. These findings are in contrast to the conclusions of Maroko et al.,[9] who reported that methoxamine results in a decrease in the extent of ischemic injury.

Clinical Implications

Although one must be cautious in extrapolating the results of canine experiments to man, our observations have important clinical implications. Among cardiac stimulating drugs used in the treatment of pump failure in acute myocardial infarction, isoproterenol seems most likely to induce negative oxygen balance of a magnitude that may further reduce the already impaired contractility of partially ischemic myocardial fibers. This will have the effect of extending the nonfunctioning zone of ischemia. Norepinephrine and digitalis, when administered in doses comparable to those used in our study, are not likely to exert such deleterious effects. An excessive increase in left ventricular afterload such as that induced by methoxamine may result in extension of infarct. An increase in the noncontracting ischemic myocardium is likely to accentuate cardiac dysfunction and thereby set up a vicious cycle of decreasing coronary flow and enlarging infarct size.

Pathophysiology of Tachycardia- and Bradycardia-Dependent Block in the Canine Proximal His-Purkinje System After Acute Myocardial Ischemia

NABIL EL-SHERIF, MD

Miami Beach and Miami, Florida

An experimental model for the study of conduction disturbances in the proximal His-Purkinje system after acute myocardial ischemia was produced in 24 dogs by ligation of the anterior septal artery. Eighteen of the 19 dogs that survived the initial vulnerable arrhythmic period showed different degrees of conduction disturbance in the bundle of His, right and left bundles or any combination thereof usually within 1 to 2 1/2 hours after ligation. In 14 experiments normal conduction was restored within 8 hours. In all cases with bundle branch block, the block was initially demonstrated on increasing or slowing the heart rate, with a range of intermediate rates at which conduction was normal. Within 45 minutes the block became constant at all heart rates, but within 2 to 6 hours was again replaced by normal conduction at intermediate rates and, finally, consistent normal conduction. In 12 experiments showing intra-His bundle block (always demonstrated by splitting of the His potential into two deflections, Hb_1 and Hb_2) increasing the rate resulted in second or third degree block with the blocked impulse localized between the two deflections. In 5 of 12 experiments, slowing the rate gave rise to first degree intra-His bundle block (lengthening of the Hb_1–Hb_2 interval).

Our in vitro observations suggested that the initial phase of tachycardia- and bradycardia-dependent block in the proximal His-Purkinje system can be explained by characteristic changes in the electrophysiologic properties of two groups of Purkinje fibers which may be due to differential localization of metabolites released in the ischemic zone. Tachycardia-dependent block was based on a time-dependent response of Purkinje fibers partially depolarized by an increase in extracellular concentration of potassium ion. Bradycardia-dependent block was explained by a slight to moderate decrease of resting potential, a normal slope of phase-4 depolarization and reduced membrane responsiveness associated with shift of the threshold potential toward zero. Contrary to previous data, our findings indicate no relation between enhanced automaticity of pacemaker cells and bradycardia-dependent conduction disturbances.

The majority of cases of intermittent bundle branch block are rate-dependent, and the conduction disturbance is usually associated with either acceleration of the heart rate (tachycardia-dependent block) or slowing of the rate (bradycardia-dependent block).[1] Tachycardia-dependent bundle branch block at short cycle lengths is readily explained by impulse spread through incompletely repolarized fibers because of the time necessary for the physiochemical processes of re-

covery.[2] Tachycardia-dependent block at heart rates usually associated with normal intraventricular conduction is considered pathologic and is conventionally ascribed to abnormal prolongation of the functional refractory period of the conduction system; however, the underlying electrophysiologic mechanisms have not been precisely delineated. Bradycardia-dependent bundle branch block is the subject of a good deal of speculation. Although several mechanisms have been proposed, bradycardia-dependent block has recently been attributed to enhanced phase-4 depolarization in the bundle branch system.[1,3,4] This explanation represents an extrapolation of the observations of Singer et al.[5] on the behavior of isolated Purkinje fibers made abnormal by various pathophysiologic interventions. Both tachycardia- and bradycardia-dependent block may occur in the same bundle branch system.[1,3,6] We have shown by deductive analysis of clinical records that repetitive block of the impulse in one part of the bundle branch system (the posterior division of the left bundle) can be explained by the concomitant operation of a tachycardia- and a bradycardia-dependent block.[7] Recently, critical observations of the onset and course of transient bundle branch block with acute myocardial infarction in man revealed several examples of rate-dependent bundle branch block showing both tachycardia- and bradycardia-dependent block and normal intraventricular conduction at intermediate heart rates.[8,9]

These observations stimulated the production of an appropriate experimental model for the study of the onset and course of transient bundle branch blocks after ligation of the anterior septal artery in dogs. Bundle branch block during both rapid and slow heart rates with normal conduction at intermediate rates was observed at the onset and before the termination of the transient conduction abnormality. In addition, the behavior of the bundle of His was usually similar to that of the bundle branches showing both tachycardia- and bradycardia-dependent blocks. Our in vitro observations revealing characteristic changes in the Purkinje fibers involved in the acute ischemic process are highly relevant to the in vivo observations. This report describes the in vivo study with reference to the in vitro observations. A complete report of the latter will appear in a separate communication.

Material and Methods

Twenty-four mongrel dogs weighing 10 to 20 kg were anesthetized with intravenously administered sodium pentobarbital (30 mg/kg). The animals were intubated and placed on a mechanical respirator. Blood pressure in the right femoral artery was monitored through a polyethylene catheter connected to a Statham transducer. A thoracotomy was made through the fourth left intercostal space. The bifurcation of the left coronary artery was exposed by retracting the tip of the left atrial appendage and incising the epicardium overlying the proximal portions of the anterior descending and left circumflex arteries. The anterior septal

artery was exposed by blunt dissection of the bifurcation and branches of the left coronary artery and a ligature was loosely passed around the vessel. Recordings of electrocardiographic leads II and aVR toegether with catheter electrode recordings from the bundle of His and right and left bundle branches were obtained.[10–12] Accuracy of the His and bundle branch potentials was validated by pacing from the corresponding sites together with analysis of the temporal relations of these potentials to the V deflection (25 to 35 msec for the His bundle deflection, 15 to 20 msec for the proximal right and left bundle potentials and 5 to 15 msec for recording of the electrical activity of the distal bundle branches). Atrial pacing was performed with use of a bipolar plunge wire electrode inserted at the left atrial appendage, a Grass S88 stimulator and stimulus isolation unit. Vagally induced slowing or cardiac arrest was accomplished by delivery of a 0.05 msec square wave pulse of 1 to 10 volts intensity at a frequency of 20 Hz to the left or right cervical vagosympathetic trunk. All records were made on a multichannel oscilloscopic photographic recorder (Electronics for Medicine DR-8) at a paper speed of 25 to 200 mm/sec with the filter frequencies of 0.1 to 200 cycles/sec for electrocardiographic leads and 40 to 200 cycles/sec for electrographic recordings.

Control records during sinus rhythm, vagally induced cardiac slowing and atrial pacing up to rates that produced atrioventricular (A–V) Wenckebach conduction were obtained in each experiment before ligation of the anterior septal artery. The recorded electrical activity was then monitored for intervals of up to 12 hours after ligation. The effects of both cardiac acceleration and slowing were frequently tested throughout the experiment. In five dogs, after completion of the initial study, the thoracotomy incision was closed and the dogs were followed up for intervals of up to 7 days. Several dogs were sacrificed and their hearts used for in vitro studies performed by conventional microelectrode technique.[13] In all experiments postmortem dissection was performed to verify that the anterior septal artery had been ligated.

Results

Thirty seconds to 1 minute after ligation of the anterior septal artery, ST–T wave changes were observed in the surface electrocardiographic leads. A few minutes later, there was enhanced ventricular activity in the form of single or multiple closely coupled ectopic beats that usually reached a maximum after 15 to 20 minutes and subsided within 30 minutes. The initial burst of ectopic activity was followed by a quiescent period of 6 to 12 hours succeeded by a second surge of multifocal ventricular rhythm lasting several days. In spite of careful attention to the initial vulnerable arrhythmic period, five dogs died of ventricular fibrillation in the first 30 minutes after ligation. In two other dogs ventricular fibrillation developed 5 to 6 hours later. These dogs had complete A–V dissociation due to bilateral bundle branch block and an idioventricular escape rhythm. All the remaining dogs were sacrificed at intervals ranging from 6 hours to 7 days after ligation. Only one dog had no evidence of conduction disturbance at the proximal His-Purkinje system during 8 hours of observation. All other 18 dogs that survived the early vulnerable arrhythmic period showed various degrees of conduction disturbances at the level of the His bundle, right and left branches or any combination thereof (Table I).

Disturbances of conduction at the proximal His-Purkinje system usually appeared 100 minutes after ligation and were maximal 2 to 4 hours after ligation. In 14 experiments normal conduction was regained within 8 hours. In all cases showing bundle branch block, the block was initially demonstrated during rapid heart rates (tachycardia-dependent) or slow rates (bradycardia-dependent) with a phase of normal intraventricular conduction or incomplete bundle branch block at intermediate heart rates. The phase of normal conduction or incomplete block gradually disappeared, and block became constant at all rates. In some experiments stable block occurred within a few minutes; in others the intermittent conduction disturbance could be demonstrated for 15 to 45 minutes. Usually bradycardia-dependent bundle branch block could not be demonstrated until either a tachycardia-dependent block or an incomplete block at intermediate heart rates had appeared. In all but one case in which the bundle branch block was transient, normal intraventricular conduction at an intermediate heart rate with bundle branch block on increasing or decreasing the rate was again observed. The range of heart rates at which normal conduction occurred gradually increased until conduction was

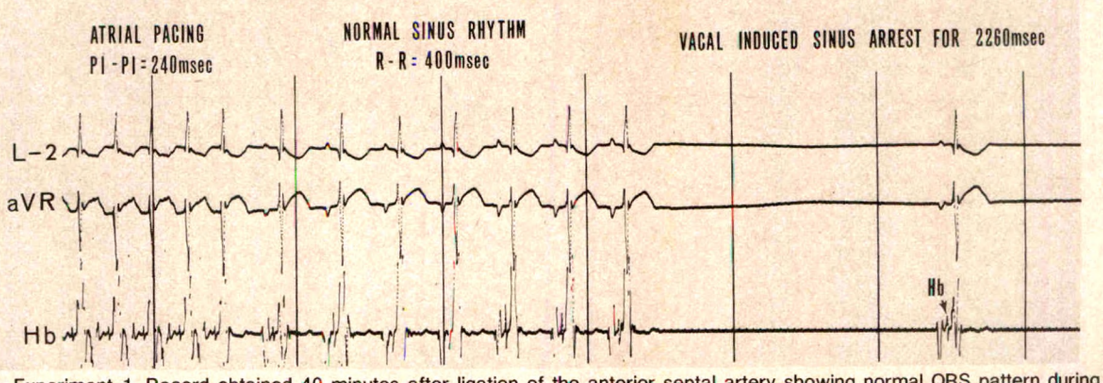

FIGURE 1. Experiment 1. Record obtained 40 minutes after ligation of the anterior septal artery showing normal QRS pattern during normal sinus rhythm, atrial pacing and a vagally induced sinus arrest for 2,260 msec. Hb represents the His bundle electrogram. Time lines in this and subsequent figures are at 1 second intervals.

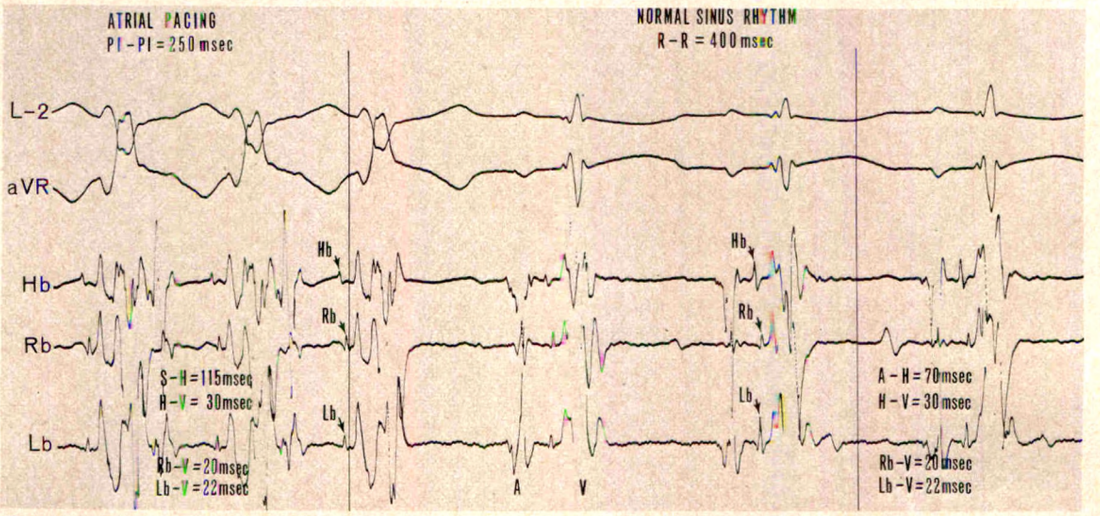

FIGURE 2. Experiment 1. Record obtained 90 minutes after ligation of the anterior septal artery showing a tachycardia-dependent right bundle branch block during atrial pacing. In this and subsequent records, Hb, Rb and Lb are the electrograms recorded from the bundle of His and right and left bundles, respectively, and A and V represent the atrial and ventricular deflections.

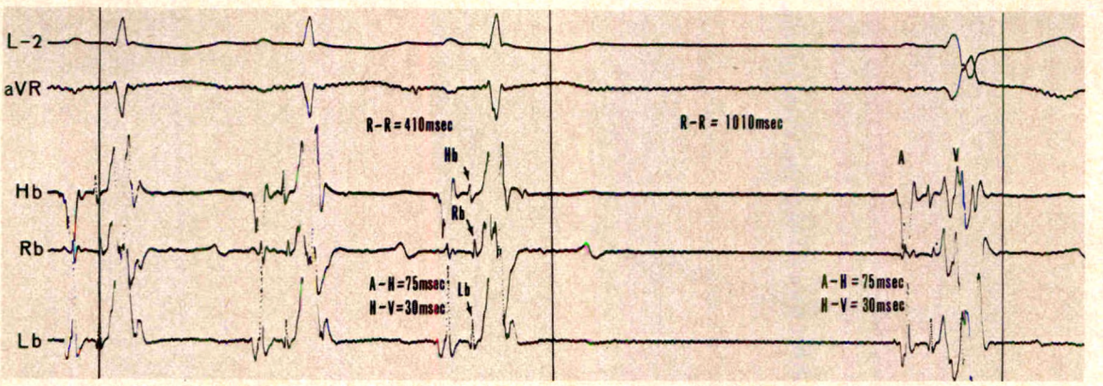

FIGURE 3. Experiment 1. Record obtained 2 minutes after Figure 2 illustrating a bradycardia-dependent right bundle branch block.

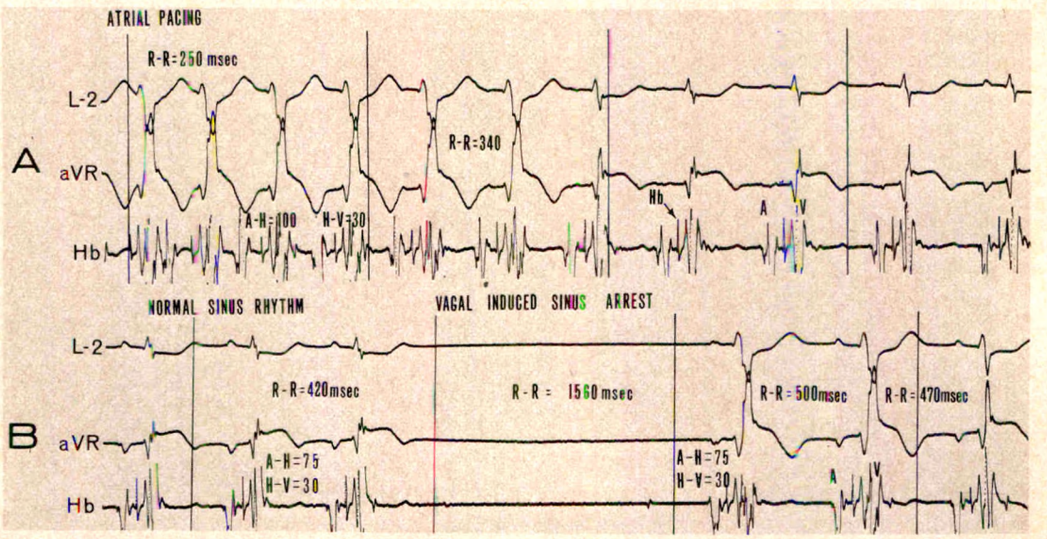

FIGURE 4. Experiment 1. Records A and B are continuous and were obtained 102 minutes after ligation of the anterior septal artery. They illustrate incomplete right bundle branch block at intermediate heart rate with tachycardia- and bradycardia-dependent complete block on increasing or slowing the rate to critical cycle lengths of 340 and 470 msec, respectively.

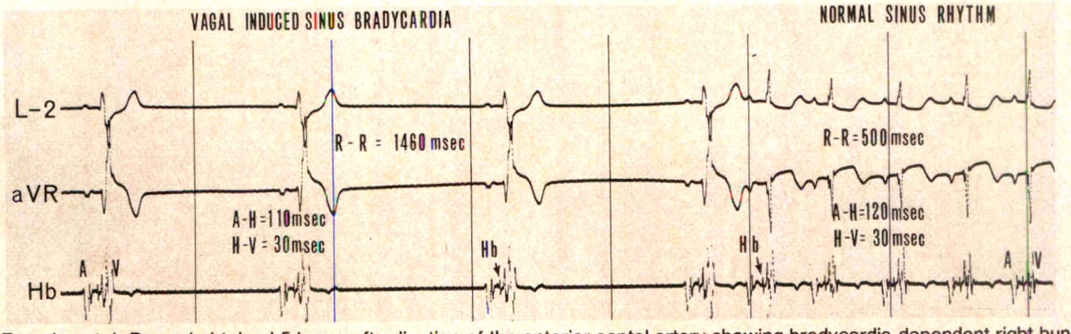

FIGURE 5. Experiment 1. Record obtained 5 hours after ligation of the anterior septal artery showing bradycardia-dependent right bundle branch block during vagally induced sinus bradycardia. Release of the vagal effect resulted in prompt return of sinus rhythm and normal intraventricular conduction.

consistently normal. In all cases showing intra-His bundle block, the bundle of His potential was fractionated into two (sometimes more) deflections termed Hb_1 and Hb_2. These cases responded to tachycardia by the development of first, second or third degree A–V block that was always localized between the Hb_1 and Hb_2 deflections. Response to bradycardia was demonstrated in only five experiments and always in the form of first degree block (an increase of the Hb_1–Hb_2 interval).

Selected examples illustrating the pertinent electrophysiologic changes in the proximal His-Purkinje system after ligation of the anterior septal artery are given below.

Experiment 1

Figure 1 was obtained 40 minutes after ligation of the anterior septal artery. The QRS configuration in leads II and aVR is the same as in the control records with the exception of the ST–T changes that usually develop within the first few minutes after ligation. The QRS configurations and H–V intervals are the same during normal sinus rhythm at a rate of 150/min, atrial pacing at a rate of 250/min and after a vagally-induced bradycardic interval of 2,260 msec (rate 26/min). These findings demonstrate that there are no tachycardia- or bradycardia-dependent conduction disturbances in the proximal His-Purkinje system at these rates.

Figure 2, obtained 90 minutes after ligation, illustrates a tachycardia-dependent complete right bundle branch block with atrial pacing at a rate of 240/min (the first three beats). Normal intraventricular conduction is still present during normal sinus rhythm at a rate of 150/min (last three beats). During the rapid rate, the A–H interval lengthens, which is a normal physiologic response of conduction in the A–V node. The H–V, Rb–V and Lb–V intervals remain unchanged during both normal intraventricular conduction and right bundle branch block. These findings suggest that during right bundle branch block, the maximal delay or block of impulse conduction in the right bundle branch sys-

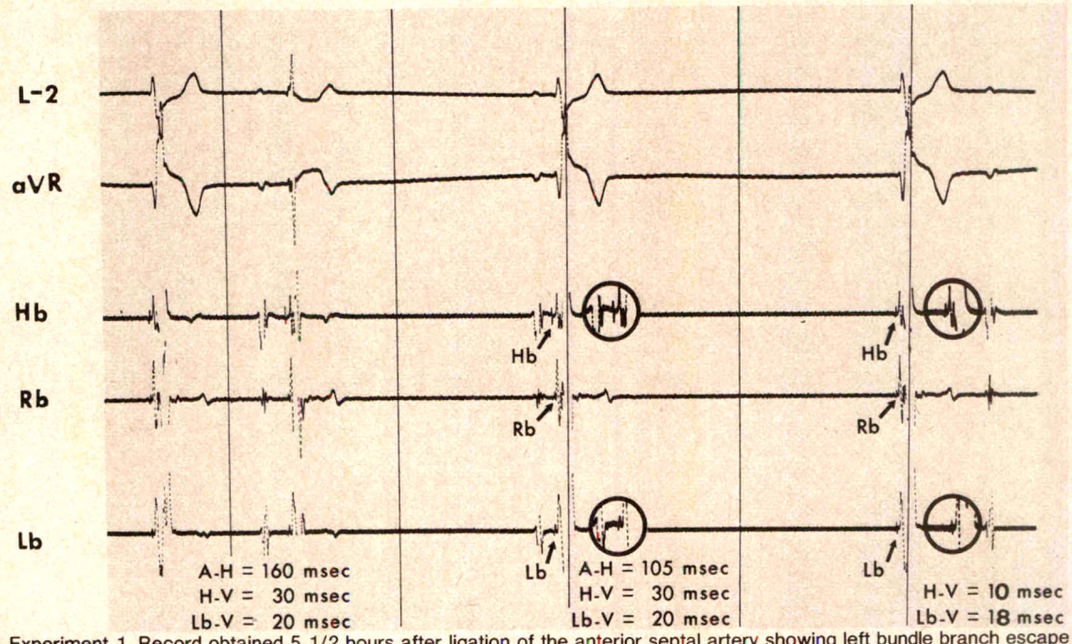

FIGURE 6. Experiment 1. Record obtained 5 1/2 hours after ligation of the anterior septal artery showing left bundle branch escape beats (first and fourth beats) and supraventricular capture beats (second and third beats). Bradycardia-dependent right bundle branch block is present with exactly the same QRS configuration both in the late supraventricular capture beat and the left bundle branch escape beats. Retrograde activation of the His bundle occurs during the escape beats and the H–V interval is short.

tem occurs below the recording site of the proximal right bundle potential.

Figure 3, obtained 2 minutes after Figure 2, illustrates a bradycardia-dependent right bundle branch block. During this block, the conduction delay in the right bundle branch system is again located distal to the recording site of the proximal right bundle branch potential.

Figure 4, obtained 10 minutes later, shows incomplete right bundle branch block during normal sinus rhythm and complete block developing on increasing or slowing the heart rate. The critical R–R cycles for tachycardia- and bradycardia-dependent complete block are 340 and 470 msec, respectively. Three minutes after this figure was recorded, complete right bundle branch block was constantly observed at all heart rates. This stable block remained for another 2 1/2 hours (4.15 hours after ligation) when normal intraventricular conduction was again observed at an intermediate heart rate with right bundle branch block elicited on increasing or slowing the rate.

Figure 5, obtained 5 hours after ligation, shows complete right bundle branch block during vagally induced sinus bradycardia at a rate of 41 beats/min. Sudden release of the vagal effect (right half of this figure) results in a prompt return of sinus rhythm at a rate of 120/min and normal intraventricular conduction. Increase of the heart rate to 240/min (not shown in the figure) induced a tachycardia-dependent right bundle branch block.

Figure 6 was obtained 5 1/2 hours after ligation. Vagally induced cardiac slowing reveals a regular escape rhythm arising from the left ventricle at an average rate of 30/min. The left ventricular escape beats (first and fourth beats) are preceded by a left bundle branch potential, thus suggesting that the beats originate in the proximal left bundle branch system. There is retrograde activation of the bundle of His and the H–V interval is short. The second and third beats in this figure are conducted sinus beats (capture beats). The second beat inscribed after an R–R interval of 690 msec conducts normally in the right bundle branch system; the third beat, occurring after a longer R–R interval of 1,580 msec, shows a right bundle branch block pattern. These findings indicate the presence of a bradycardia-dependent right bundle branch block. The configuration of the slow escape beats arising from the proximal left bundle branch system is exactly the same as that of conducted sinus beats with bradycardia-dependent right bundle branch block.

Figure 7 was obtained 6 1/2 hours after ligation. With vagally induced cardiac slowing, a regular right ventricular escape rhythm begins to occur at a relatively faster rate than that of the left ventricular rhythm (48/min) (last three beats). The escape beats are not preceded by a right bundle branch potential, thus suggesting that the beats originate distally in the right ventricular Purkinje system. Sinus tachycardia, present during the first three beats in this figure, is followed by vagally induced sinus slowing. The fourth and fifth beats represent conducted sinus impulses at cardiac cycle lengths longer than the escape cycle length. Bradycardia-dependent right bundle branch block is not present in these beats. Seven hours after ligation tachycardia-dependent bundle branch block was no longer observed.

Experiment 10

*Figure 8*A shows basal recordings, including the right bundle branch potential, before ligation of the anterior septal artery. In Figure 8B, obtained 60 minutes after ligation, the His bundle potential has clearly split into two deflections (Hb_1 and Hb_2) with only slight prolongation of the Hb_1–V interval. Panels C and D show pacing from the proximal and distal His deflections giving rise to stimulus to V intervals of 35 and 25 msec, respectively, which are equal to the Hb_1–V and Hb_2–V intervals in B.

Figure 9 was obtained 125 minutes after ligation. The conventional electrocardiographic leads show a constant degree of incomplete right bundle branch block at an intermediate heart rate (last two beats). Increasing the heart rate to 214/min (first two beats) leads to complete right bundle branch block during which the right bundle branch potential is not seen. This may be due to marked delay in the inscription of the potential which moves toward and becomes buried in the large V deflection or to a complete block of conduction proximal to the recording site. The former explanation is probably true as shown by the gradual movement of the right bundle branch potential outside the V deflection to its original position before this deflection on termination of atrial pacing. There is an associated but

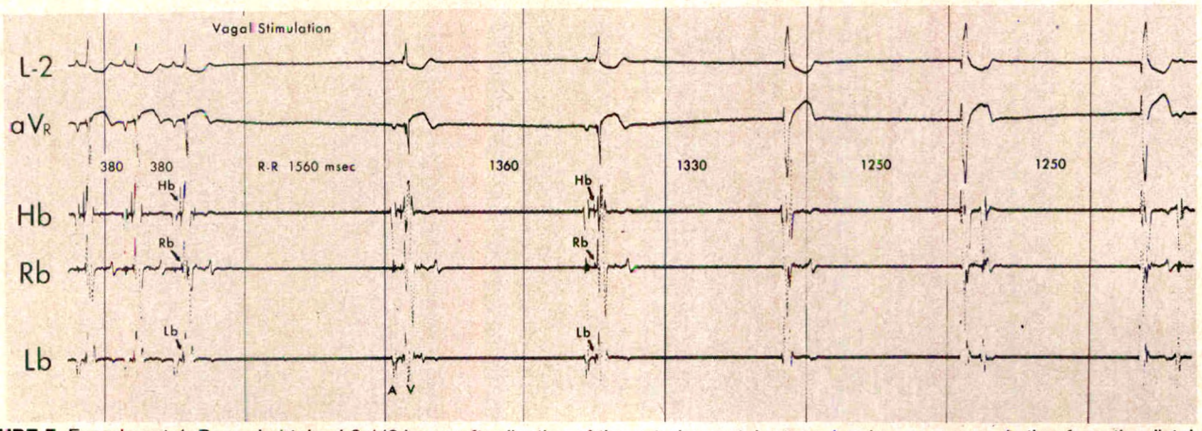

FIGURE 7. Experiment 1. Record obtained 6 1/2 hours after ligation of the anterior septal artery showing an escape rhythm from the distal right ventricular Purkinje system. Bradycardia-dependent right bundle branch block is absent in the fourth and fifth beats after cardiac cycle lengths longer than that of the escape cycle.

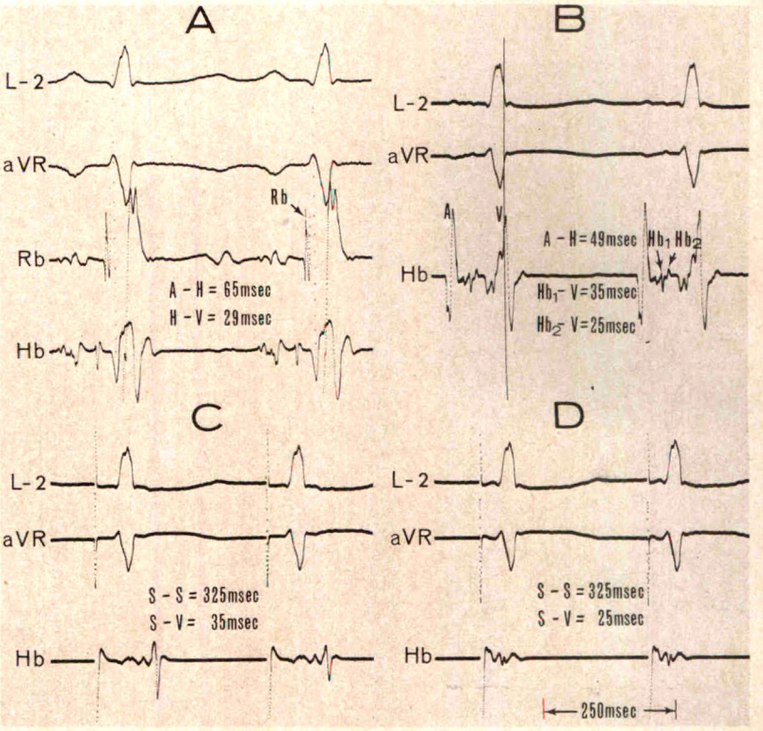

FIGURE 8. Experiment 10. **A,** control record obtained before ligation of the anterior septal artery. **B,** record obtained 60 minutes later illustrating splitting of the His potential into two deflections (Hb_1 and Hb_2) with slight lengthening of the H–V interval. Panels **C** and **D** represent His bundle pacing from the proximal and distal His deflections, respectively.

much less perceptible change in the pattern of incomplete right bundle branch block in the conventional leads. This figure thus illustrates a tachycardia-dependent complete right bundle branch block disturbance in the proximal right bundle branch system superimposed on a pattern of incomplete right bundle branch block due to the development of a constant degree of conduction delay in the right bundle. During the rapid heart rate, the H–V interval is slightly prolonged (from 33 to 39 msec) mainly as a result of a slight prolongation in the Hb_1–Hb_2 interval.

Figure 10, recorded 10 minutes later during constant atrial pacing at a slightly faster rate of 235/min, shows this phenomenon more clearly. Several spontaneous transitions from 1:1 A–V conduction to 2:1 A–V block and vice versa are observed with the block localized in the His bundle between the Hb_1 and Hb_2 deflections. Critical analysis of the H–V intervals during 1:1 A–V conduction showed a minimal increment of 5 to 10 msec before the blocked P wave which is mainly occurring between the Hb_1 and Hb_2 deflections (magnified sections). This arrangement reflects the presence of a Wenckebach type of conduction in the His bundle with an increment of only a few milliseconds.[14,15]

Figure 11, recorded 2 minutes after Figure 10, shows the effect of vagally induced cardiac slowing for 2,150 msec (rate 28 beats/min). A bradycardia-dependent complete right bundle branch block developed with disappearance of the Rb potential in the first conducted sinus impulse after the long pause. The H–V interval is significantly prolonged

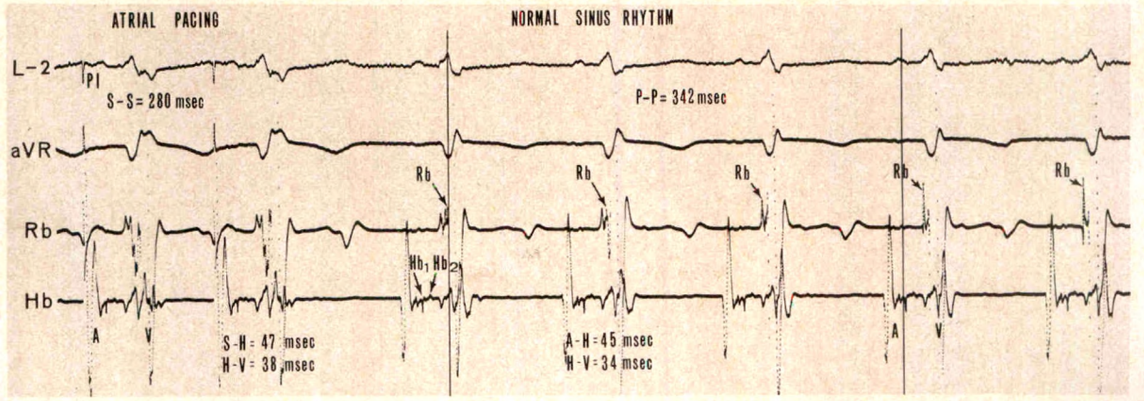

FIGURE 9. Experiment 10. Record obtained 125 minutes after ligation of the anterior septal artery showing incomplete right bundle branch block during normal sinus rhythm with a tachycardia-dependent complete block on atrial pacing. Note gradual movement of the right bundle potential (Rb) outside the V deflection after termination of pacing.

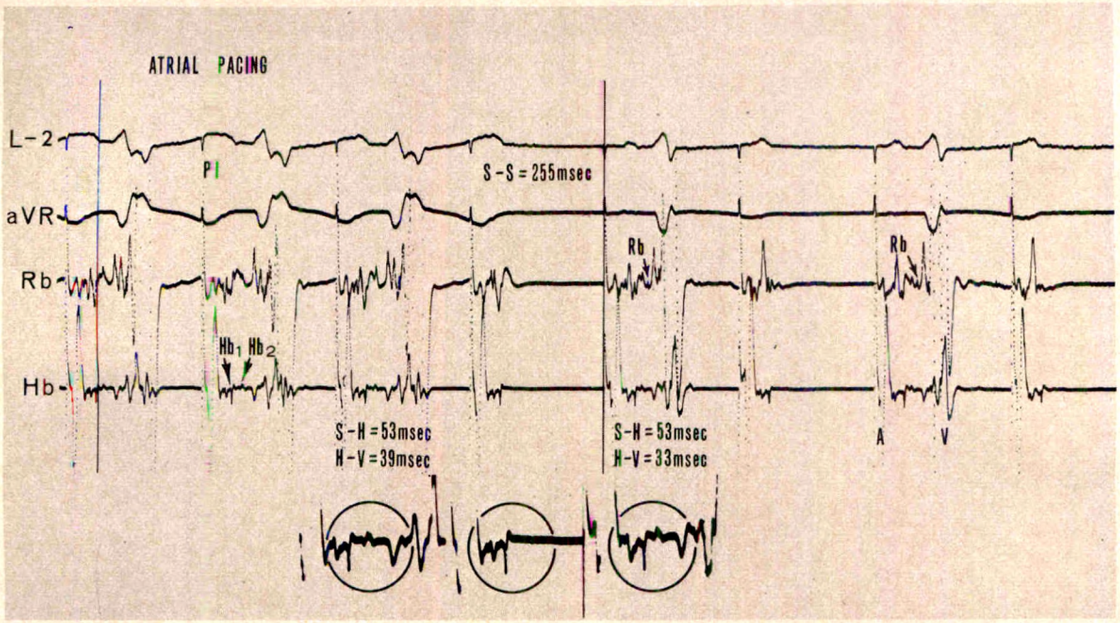

FIGURE 10. Experiment 10. Record obtained 135 minutes after ligation of the anterior septal artery showing constant atrial pacing at a rate of 235 beats/min. Note transition from 1:1 A–V conduction to 2:1 A–V block with the block localized in the bundle of His between the HB_1 and Hb_2 deflections. There is a Wenckebach arrangement with an increment of a few msec.

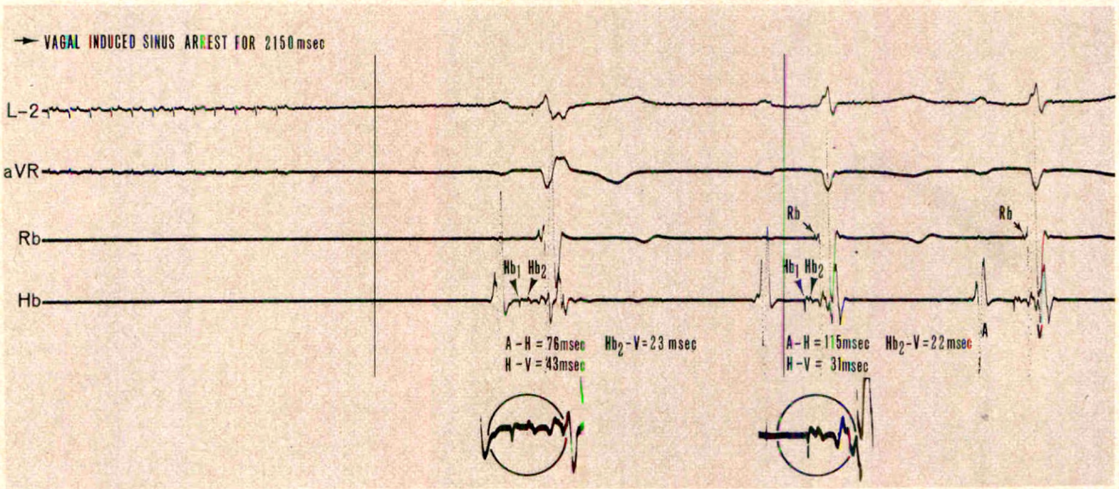

FIGURE 11. Experiment 10. Record obtained 2 minutes after Figure 10 showing a concomitant bradycardia-dependent first degree intra-His bundle block and complete right bundle branch block.

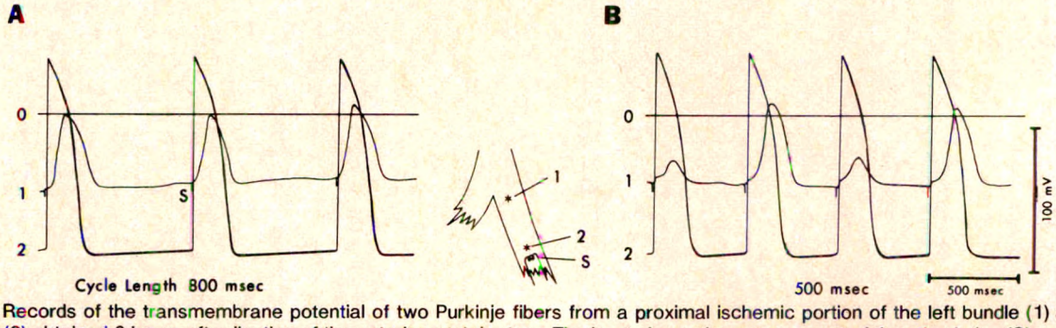

FIGURE 12. Records of the transmembrane potential of two Purkinje fibers from a proximal ischemic portion of the left bundle (1) and a distal normal zone (2) obtained 6 hours after ligation of the anterior septal artery. The inset shows the arrangement of the stimulating (S) and recording electrodes. In **A**, the proximal fiber has a low resting potential and a slowly rising action potential of small amplitude. In **B** there is a 2:1 time-dependent response of this fiber to an increase in the driving frequency. Although there is alternation of action potential amplitude, a significant conduction delay or block would be present in every cycle.

mainly because of lengthening of the Hb_1–Hb_2 interval (magnified sections). Figure 11 thus illustrates a bradycardia-dependent conduction disturbance in both the bundle of His and the right bundle branch system.

Critical analysis of Figures 10 and 11 reveals that 120 minutes after ligation of the anterior septal artery, a constant slight degree of conduction delay developed at both the bundle of His and the right bundle branch at intermediate heart rates. A tachycardia-dependent complete block at both sites could be elicited by atrial pacing. A bradycardia-dependent first degree intra-His bundle block and complete right bundle branch block could be illustrated by vagally induced cardiac slowing. A follow-up study for 7 days revealed complete correction of the intra-His bundle conduction disturbance but persistence of a tachycardia- and bradycardia-dependent right bundle branch block.

Discussion

General Considerations

Study of the onset and course of acute ischemic conduction disturbances in the canine proximal His-Purkinje system has shown the concomitant development of tachycardia- and bradycardia-dependent intermittent block both at the onset and before the termination of the transient conduction abnormality. The same electrophysiologic disturbance has been recently demonstrated in man.[8,9] The observation of tachycardia- and bradycardia-dependent bundle branch block several days after the ligation of the anterior septal artery in dogs and in some patients several months after the acute ischemic episode[8,9] suggests that this phenomenon is probably related to the electrophysiologic disturbances underlying intermittent conduction disorders in the His-Purkinje system in general. These disorders tend to occur at both rapid and slow heart rates with normal conduction at intermediate rates.

Our observations after ligation of the anterior septal artery in dogs strongly suggest that the experimental model is appropriate for study of conduction disturbances in the proximal His-Purkinje system after acute myocardial ischemia. The anatomic distribution of the His-Purkinje system in dogs and the canine blood supply are sufficiently similar to those of man to make the dog a suitable experimental animal. Direct extrapolation of the results of animal observations to the man should be made cautiously because the distribution of the septal arteries differs in the two species[16] and because in man lesions of the conduction system frequently antedate the acute infarction.[17] These differences, however, do not detract from the appropriateness of the animal model for study of the basic electrophysiologic disturbances after acute ischemic injury of the His-Purkinje system. Localization of the conduction disturbance in the proximal His-Purkinje system in our experiment is consistent with the anatomic distribution of the anterior septal artery in dogs. Ligation of the latter usually produces ischemia in the area of the muscular interventricular septum containing the distal portion of the A–V node, bundle of His and major portions of the right and left bundle branches.[18,19]

Demonstration of the transient nature of acute ischemic conduction disturbances in the canine proximal His-Purkinje system confirms the clinical experience of the temporary nature of many instances of A–V conduction disturbances and bundle branch block complicating acute myocardial infarction.[20,21] These observations are consistent with pathologic data in dogs[22] and man[23,24] suggesting relative immunity of the conducting tissue to ischemia at least in a morphologic sense. The relative sparing of the conduction fibers suggests that factors other than hypoxia itself may be responsible for the transient conduction disturbance.[24–27] These factors, released by the injured myocardial cells and other inflammatory cells, may accumulate and alter the ionic environment surrounding the conduction tissue and hence its electrophysiologic properties. They may be dissipated or washed out later on with the development of effective collateral circulation resulting in reversal of the conduction disturbance. The observation that collateral flow may not be sufficiently great to reverse the ischemic electrocardiographic changes probably reflects metabolic differences between contractile and conducting fibers.[24] An important factor implicated in acute ischemic rhythm disorders is the leak of large amounts of potassium ion from the intracellular to the extracellular space.[27]

Electrophysiologic Correlation

Correlation with in vitro studies: Our in vitro studies, revealing characteristic changes of the Purkinje fibers in the proximal His-Purkinje system involved in the acute ischemic process, are relevant to in vivo observations. Purkinje fibers in the proximal segment of the bundle branch system usually showed marked change in their action potentials. Partially depolarized fibers with a low resting potential, slowly rising phase zero and a diminished action potential amplitude were frequently seen (Fig. 12A). The electrical excitability and refractoriness of these fibers differed markedly from the properties of normal Purkinje fibers, and the duration of complete recovery of excitability was greater than that of the action potential. These fibers usually display a poor response to stimuli applied late in diastole after completion of the action potential (Fig. 12B). The fibers showed primarily a time-dependent rather than a voltage-dependent response to cycle length changes. This response is somewhat similar to the normal response of some cells in the sinoatrial and atrioventricular nodes.[28] Most of the electrophysiologic characteristics of these fibers can be explained by an increase in the extracellular potassium ion concentration in the ischemic zone. Previous studies of Purkinje fibers superfused with a high concentration of potassium ion revealed reduction in the resting potential, slowing of the upstroke velocity, decrease of the electrotonic spread and elevation of the threshold potential.[29,30] All of these factors can contribute to the reduction of conduction velocity.[30,31] Our observations suggest that the initial phase of tachycardia-

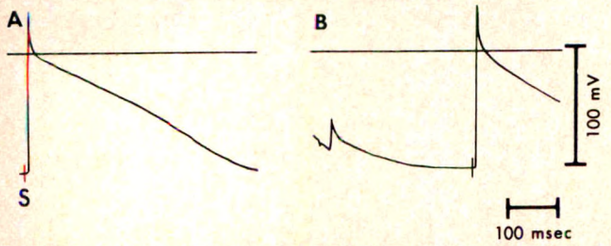

FIGURE 13. A, transmembrane potential recorded from a Purkinje fiber in the proximal portion of a canine right bundle branch 24 hours after ligation of the anterior septal artery. Note the prolonged action potential with characteristic changes of the voltage time course of the membrane potential during repolarization. **B,** stimulation at a cycle length of 300 msec showing 2:1 response. Note the very low action potential generated by stimulation during the terminal part of phase 3.

dependent block in the proximal His-Purkinje system is dependent on the characteristic response of the partially depolarized Purkinje fibers to shortening of the cardiac cycle.

We have demonstrated Purkinje fibers with prolonged action potentials in specimens obtained 24 hours after ligation. These fibers show a very characteristic change of the voltage time course of the membrane potentials during repolarization with shortening of phase 2, the early portion of phase 3 and a protracted terminal part of phase 3. These changes are particularly clear in cells showing full amplitude of resting and action potentials (Fig. 13A). In association with the altered action potential, these cells show evidence of reduced membrane responsiveness. Similar Purkinje fiber properties have been demonstrated in our laboratory[32] and by others[33] in the infarcted zone after ligation of the anterior descending artery, and we have shown that the action potential duration usually returns to normal within 3 to 4 days. These cells usually demonstrate a 2:1 response to shortening of the cycle length which can be explained by stimulation during the terminal part of phase 3, which results in a small action potential with a shortened duration so that the next stimulus usually falls outside phase 3 and thus conducts normally (Fig. 13B). The characteristic electrophysiologic response of these cells represents a voltage-dependent phenomenon and cannot explain the development of a 1:1 tachycardia-dependent bundle branch block. By contrast, partially depolarized Purkinje fibers may show an alternation of the action potential configuration at a certain degree of shortening of the cardiac cycle (Fig. 12B).In this case, however, a significant conduction delay is present in every cycle to give rise to a 1:1 pattern of complete bundle branch block. Thus, a time-dependent response of partially depolarized Purkinje fibers is probably the main electrophysiologic mechanism for tachycardia-dependent

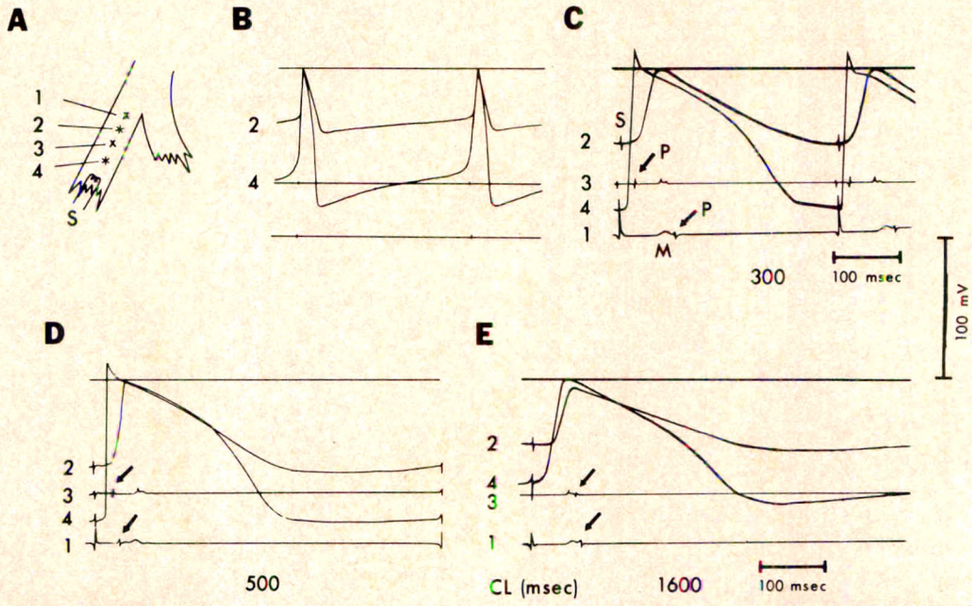

FIGURE 14. Records of the transmembrane potential of two Purkinje fibers from a proximal and a more distal portion of the left bundle branch system (2 and 4) and two electrograms (1 and 3). The specimen was obtained 5 hours after ligation of the anterior septal artery. Panel **A** shows the arrangement of the stimulating (S) and recording electrodes. Panel **B** shows spontaneous firing at a rate of 40/min. Note that the proximal fiber has a low resting potential and a slow rising action potential of small amplitude. The distal fiber shows slight reduction of resting potential and a "normal" slope of phase-4 depolarization. Panels **C to E** show the response of the two fibers to rapid (CL [cycle length] 300 msec), intermediate (CL 500 msec) and slow (CL 1,600 msec) driving frequencies. Note reduction of amplitude and upstroke velocity of action potential of the distal fiber at the slow driving rate. The transmembrane (M) potential of the proximal fibers shows lesser changes at different cycle lengths. Note that the downstream electrogram (1) shows delay of the Purkinje spike (P, marked by arrow) both at the rapid and slow driving frequencies as compared to the intermediate rate. Delay of the Purkinje spike will be reflected in the surface electrogram by the inscription of a bundle branch block pattern.

conduction disorders in the proximal His-Purkinje system under these experimental conditions.

Bradycardia-dependent block, phase 4 depolarization and extracellular potassium ion concentration: The concomitant demonstration of bradycardia-dependent block is particularly interesting since increased extracellular potassium ion is known to depress phase-4 depolarization. Two of our in vivo observations are particularly pertinent. The finding that long bradycardic intervals are usually necessary to illustrate bradycardia-dependent block suggests a normal or slowly rising rather than "enhanced" slope of phase-4 depolarization. On the other hand, the observation of long bradycardic intervals without pacemaker escape may point to a shift of the threshold potential toward zero. We have found that, when studied progressively distally along the bundle branch system, the Purkinje fibers show a lesser decrease of the resting potential and a normal or near normal slope of phase-4 depolarization (Fig. 14B). These cells can show a bradycardia-dependent conduction disturbance at slow driving frequencies, and the shift of the threshold potential rather than enhanced phase-4 depolarization may be the crucial factor in the display of bradycardia-dependent block. Such a shift in threshold potential permits gradual reduction of the membrane potential to levels at which significant decrement of conduction is likely to occur. This effect will be accentuated if there is an initial slight to moderate reduction in the resting potential of the kind expected to occur as a result of depolarization induced by a moderate increase in extracellular potassium ion. Another factor that can contribute to bradycardia-dependent block without marked enhancement of phase-4 depolarization is decrease of the membrane responsiveness.[34] Thus, bradycardia-dependent bundle branch block can be explained by the characteristic electrophysiologic alterations of Purkinje fibers at the periphery of the ischemic zone (distally located in the bundle branch system in our preparation) where the increase in extracellular potassium ion concentration is not as great as in the more ischemic proximally located zone. Figure 14, C to E, shows the characteristic response of two Purkinje fibers from a proximal and a more distal portion of the bundle branch system to rapid, intermediate and slow driving frequencies.

Concomitant tachycardia- and bradycardia-dependent block: In a recent series of papers, Rosenbaum's group[35–37] addressed themselves to the observation of concomitant tachycardia- and bradycardia-dependent bundle branch block. They hypothesized that tachycardia-dependent block can be explained by prolonged action potential duration of Purkinje fibers (phase-3 block), whereas bradycardia-dependent block is related to hypopolarization plus spontaneous diastolic depolarization (phase-4 block). Our in vivo and in vitro observations do not wholly support these recently published hypotheses. Tachycardia-dependent block in the proximal His-Purkinje system after acute myocardial ischemia was found to be related to a time-dependent rather than voltage-dependent response of partially depolarized Purkinje fibers. Hoffman[38] recently pointed to the difficulty of interpretation of tachycardia-dependent block based on marked prolongation of the action potential duration when durations of up to 1.8 seconds[37] sometimes have to be postulated. Although he indicated the possible role of prolonged action potentials recorded from Purkinje fibers 24 to 72 hours after occlusion, we[32] have demonstrated that this prolongation is limited both in value (a maximum of 750 msec) and duration (1 to 4 days after infarction). More significantly, we observed that these cells usually showed a 2:1 response to shortening of the cycle length which would not explain tachycardia-dependent bundle branch block.

Enhanced phase-4 depolarization and bradycardia-dependent block: Our observations suggest that the previously reported relation between enhanced phase-4 depolarization of the pacemaker cells and bradycardia-dependent conduction disturbances[5] is not applicable to our experimental findings. We found an absence of a relation between enhanced automaticity and bradycardia-dependent conduction disturbances, which is primarily related to the difference in behavior of the threshold potential. This was based on the following two observations: (1) In the early stage after acute ischemic injury when there was no enhanced automaticity, bradycardia-dependent block was usually demonstrated; (2) several hours after ligation of the anterior septal artery when enhanced automaticity began to be observed it was usually possible to illustrate that bradycardia-dependent block did not occur at rates significantly slower than the escape rate. Moreover, the escape rhythm did not necessarily arise from the site of maximal conduction disturbance in the bundle branch system. In relation to this point, we have demonstrated that in the presence of bradycardia-dependent conduction disturbance, escape rhythms arising from the A–V node, bundle of His, proximal portion of the diseased bundle or from the other bundle branch system may have exactly the same QRS configuration in conventional leads (Fig. 6). This clearly illustrates the limitation of attempting to localize the site of origin of escape rhythm from the conventional electrocardiogram.[39]

The electrophysiologic mechanisms underlying tachycardia- and bradycardia-dependent block in the proximal His-Purkinje system after acute myocardial ischemia may prove to be more complicated than those we have outlined. The possibility exists that in different clinical settings other mechanisms may be operating. Greater insight into the mechanisms of conduction disorders in the His-Purkinje system will probably have to await further electrophysiologic studies.

Let's face it. Conventional nitroglycerin is a notably unstable compound. It migrates from tablet to tablet, from tablet to cotton, from cotton to cap. Result: a wide variance in potency and therapeutic effect.

But with Nitrostat your angina patient gets a stabilized nitroglycerin. *Stabilized for uniform potency retention.* Thus, Nitrostat does the job that sublingual nitroglycerin is *supposed* to do. And does it *consistently*—providing the same pain-relieving potency, tablet after tablet. That's why more and more physicians are turning to Nitrostat.

Important facts to know whenever you're prescribing for a patient with a history of angina.

think nitroglycerin...write

Nitrostat®
(nitroglycerin tablets, USP)
Sublingual Tablets
0.6 mg (1/100 gr)
0.4 mg (1/150 gr)
0.3 mg (1/200 gr)

Because the pain-relieving potency is locked inside–this nitroglycerin tablet will work like the next–and the next–and the next.

The newest Ekoline 20A® features multi-parameter capability.

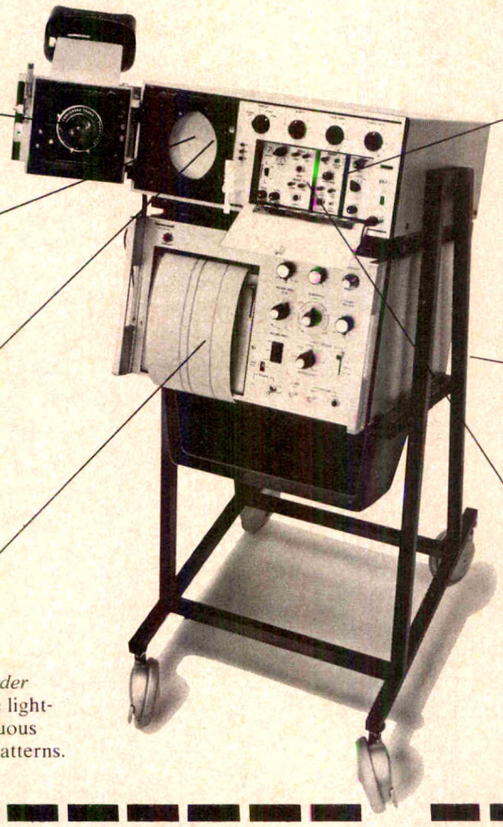
Two new modules give the Smith Kline Instruments Ekoline 20A® an unmatched multi-trace capability. The Isolated Sweep/EKG Module and the Multi-Parameter Amplifier Module enable the E20A Ultrasonoscope to produce traces for ultrasound, EKG, phono and carotid pulse or apex. Combine this with the Fiber-optic Recorder and the result is high quality, grey scale strip chart recordings of pertinent information—at a surprisingly low cost.

1. *New Oscilloscope Camera* features built-in electronic shutter release, uses high-speed 'Polaroid' film.

2. *New High-Resolution Oscilloscope* is standard on all 'Ekoline 20A' instruments, gives outstanding display of all echo patterns.

3. *New Long-Persistence Oscilloscope,* available as optional equipment, uses P7 phosphor to provide best possible display of M-mode echo patterns.

4. *New Fiber-Optic Line-Scan Recorder* utilizes fiber-optic CRT to expose light-sensitive paper, producing continuous "strip-chart" recordings of echo patterns.



5. *New Isolated Sweep/EKG System* Converts A-Mode echo display from a moving organ into M-Mode display. Features isolated, linear, and movable EKG.

6. *New Equipment Cart* conveniently houses 'Ekoline 20A' and Recorder. Permits complete system to be readily moved to any location throughout the hospital.

7. *New Multi-Parameter Amplifier Module* provides the capability for echo, EKG, phono and carotid pulse or apex traces.

Model 5000 Dyna-Gram® Recorder

The Model 5000 Dyna-Gram® Recorder for Holter Electrocardiography.

The Model 5000 is a new 24-hour cassette recorder with electronic timing and a digital patient clock for precise correlation of the ECG with patient activities and symptoms. The advanced design of the Model 5000 includes an exclusive circuit to minimize electrode artifact. The rechargeable Dyna-Gram® Power-Pack provides continuous 24-hour recording capability *without* turning the cassette. Compact and light weight, the Model 5000 Dyna-Gram® Recorder can be worn with a waist belt or a shoulder strap.

No purchase of costly processing equipment is required. Your recorded Dyna-Gram® cassettes will receive Cardio-Dynamics comprehensive analysis using the unique Dyna-Gram® III Analyzer System.

A quality line of cassettes, disposable electrodes, and related patient hookup supplies is available.

BLOOD FLOW

for clinical applications

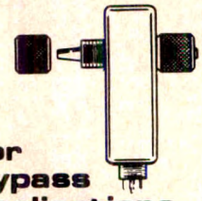
- Designed for clinical O.R. or cath lab use
- Easily applied handle-type probe
- Patient safety assured through isolation circuitry
- Simple to operate - minimum controls - direct meter readout in milliliters per minute

FLOW PROBES

for clinical applications

- Convenient, handle-type probe with positive capture slide
- Designed for O.R. and cath lab use
- For rapid analysis of flow through exposed blood vessels
- Use with Biotronex clinical blood flowmeter

FLOW PROBES



for bypass applications

- Use with heart-lung machine, artificial kidney or similar systems
- Iron core construction provides high sensitivity and accuracy
- Operates with BLI research and clinical blood flowmeters
- Available in sizes to fit most tubing

Announcing...

A Special Echocardiography Seminar and Workshop

THE BROADMOOR, April 15, 16 and 17, 1974
COLORADO SPRINGS, COLORADO

In view of the growing impact of ultrasound in cardiology and the lack of adequate training facilities, we are happy to announce a course in diagnostic echocardiography. This will be an informal seminar and workshop series to focus on the practical aspects, clinical uses and new techniques of diagnostic ultrasonics. Emphasis will be on the actual use of ultrasound and will provide supervised training conducted by physicians and technicians well versed in ultrasonic procedures. Only a limited number of registrations will be accepted to allow opportunities for participants to practice performing actual ultrasonic examinations.

For program and registration information, write or call:

ULTRASONIC SEMINAR
11122 E. 47th Avenue
Denver, Colorado 80239
(303) 343-8330

We'll lend your patient an ear... and you a hand.

Cardio-Dynamics Comprehensive Analysis of Holter Recordings for
• Clinical Practice • Research
• Drug Evaluation
• Multiphasic Screening

Your Holter recordings are processed by skilled Cardio-Dynamics analysts using the new and unique Dyna-Gram® III Analyzer System. Without having to purchase costly scanning equipment, you receive fast direct-mail service throughout the USA-including a telephone report of potentially ominous phenomena.

Cardio-Dynamics exclusive Dyna-Gram® Report gives counts of all ectopics *by morphology,* along with ECG strip documentation of each morphology. The Dyna-Gram® Report allows you to separately evaluate early cycle and late cycle ventricular ectopics, as well as any differential response to therapy.

Complete Holter ECG analysis is available for recorded cassettes from Cardio-Dynamics new 24-hour Model 5000 Dyna-Gram® Recorder, or for Avionics reel recordings.

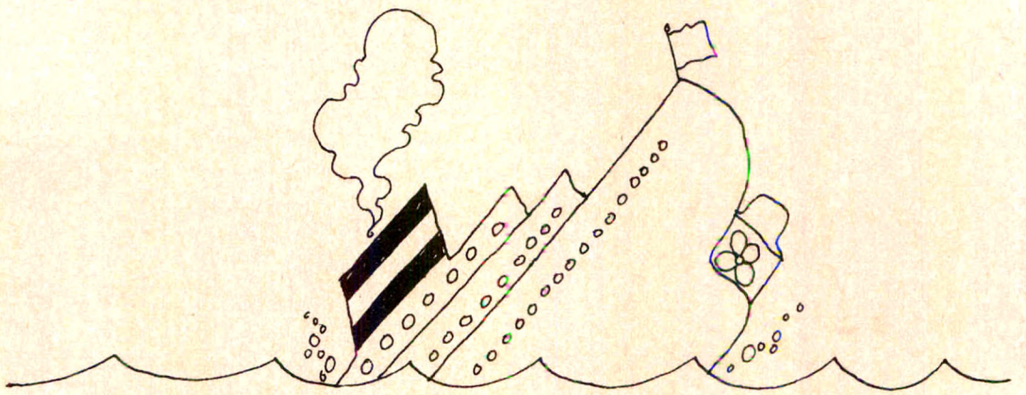
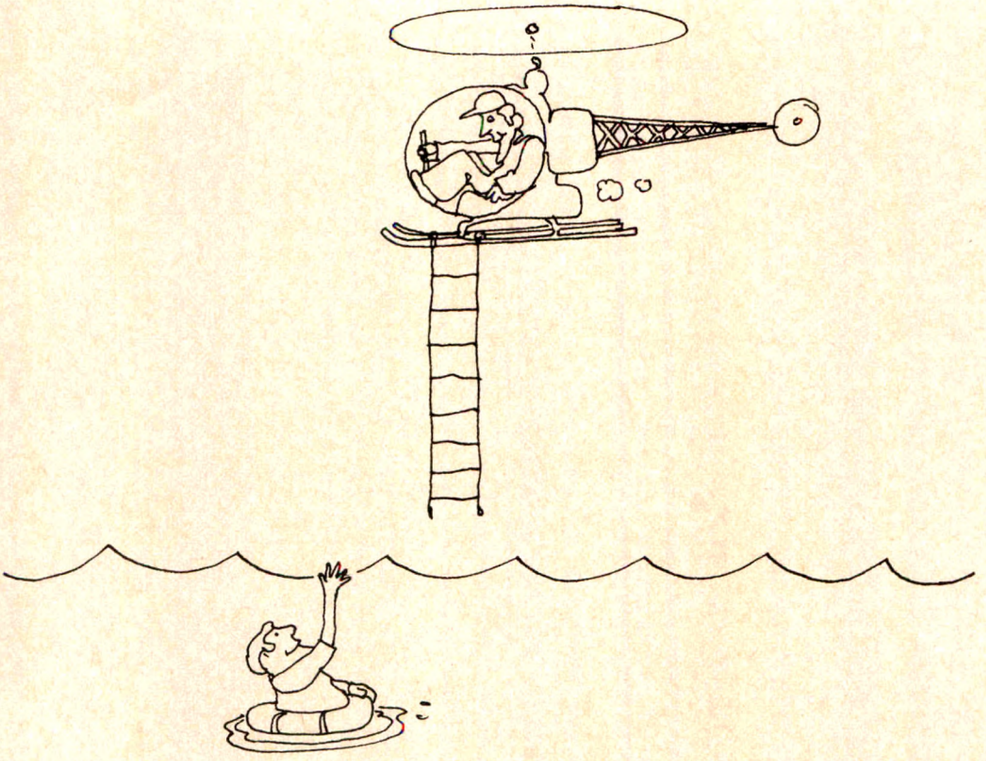
The sinking ship syndrome:



The cure:



Funny thing. Your brand-new patient monitoring system goes on stream for the first time, and everything's smooth sailing.

But if it goes down, you're sunk—unless you get help fast.

When your patient monitoring system is from B-D Electrodyne, you will.

B-D Electrodyne has field offices throughout the country, so there's bound to be one or two near you.

All our field offices have an around-the-clock/around-the-calendar answering service, a fully-stocked supply of parts and modules, and a complete repair shop.

B-D Electrodyne servicemen hold at least an associate's degree (or its equivalent) in electronics. Their cars are specially outfitted to make them traveling diagnostic and repair labs.

In addition, we give our servicemen schooling in hospital procedures, so they know *your* problems (as well as your equipment's). And we provide special training for your own service and maintenance engineers.

B-D Electrodyne. If your system goes down, we'll keep you from feeling sunk. May we tell you more? B-D ELECTRODYNE Division of Becton, Dickinson and Company, Sharon, Mass. 02067. (617) 828-9080.

The art of antianginal therapy

For centuries, treating the heart's ills has been the subtlest of arts. Even today, evaluating a drug for chronic angina pectoris involves the art of medicine as well as its science.

Persantine — over a decade of use

During more than a decade of clinical experience, compounding both science and art, Persantine has often been found useful in the long-term management of chronic angina pectoris.* It may:

eliminate or reduce the frequency of anginal attacks

improve exercise tolerance

reduce nitroglycerin requirements

Persantine — give enough — long enough

The recommended dosage: 50 mg. t.i.d. at least one hour before meals. *Give enough, long enough* — several weeks or longer of continuous therapy may be needed to see response.

Persantine® Tablets of 25 mg.
dipyridamole

the non-nitrate
coronary vasodilator

*INDICATIONS – Based on a review of this drug by the National Academy of Science-National Research Council and/or other information, FDA has classified the indication as follows:

"Possibly" effective: For long-term therapy of chronic angina pectoris. Prolonged therapy may reduce the frequency or eliminate anginal episodes, improve exercise tolerance, and reduce nitroglycerin requirements. The drug is not intended to abort the acute anginal attack.

Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS – No specific contraindications are known.

PRECAUTIONS – Since excessive doses can produce peripheral vasodilation, the drug should be used cautiously in patients with hypotension.

ADVERSE REACTIONS – Adverse reactions are minimal and transient at recommended dosages. Instances of headache, dizziness, nausea, flushing, weakness or syncope, mild gastrointestinal distress and skin rash have been noted during therapy. Rare cases of what appeared to be an aggravation of angina pectoris have been reported, usually at the initiation of therapy. On those uncommon occasions when adverse reactions have been persistent or intolerable, withdrawal of medication has been followed promptly by cessation of undesirable symptoms.

DOSAGE AND ADMINISTRATION – The recommended dosage is 50 mg. (2 tablets) three times a day, taken at least one hour before meals. In some cases higher doses may be necessary but a significantly increased incidence of side effects is associated with increased dosage. Clinical response may not be evident before the second or third month of continuous therapy.

For complete details, please see the full prescribing information.

Medieval Engraving
Engraving of a heart and the child Jesus, surrounded by cherubs. The transcription states, "Whoever holds Him in his heart is assured of eternal joy."

The engraving was made by "E.S." in 1467. It is in a collection of engravings in Berlin.

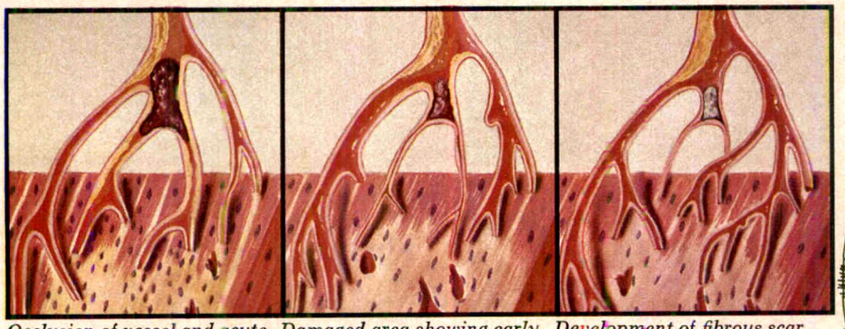
As the infarct heals,



Occlusion of vessel and acute infarct of the myocardium.

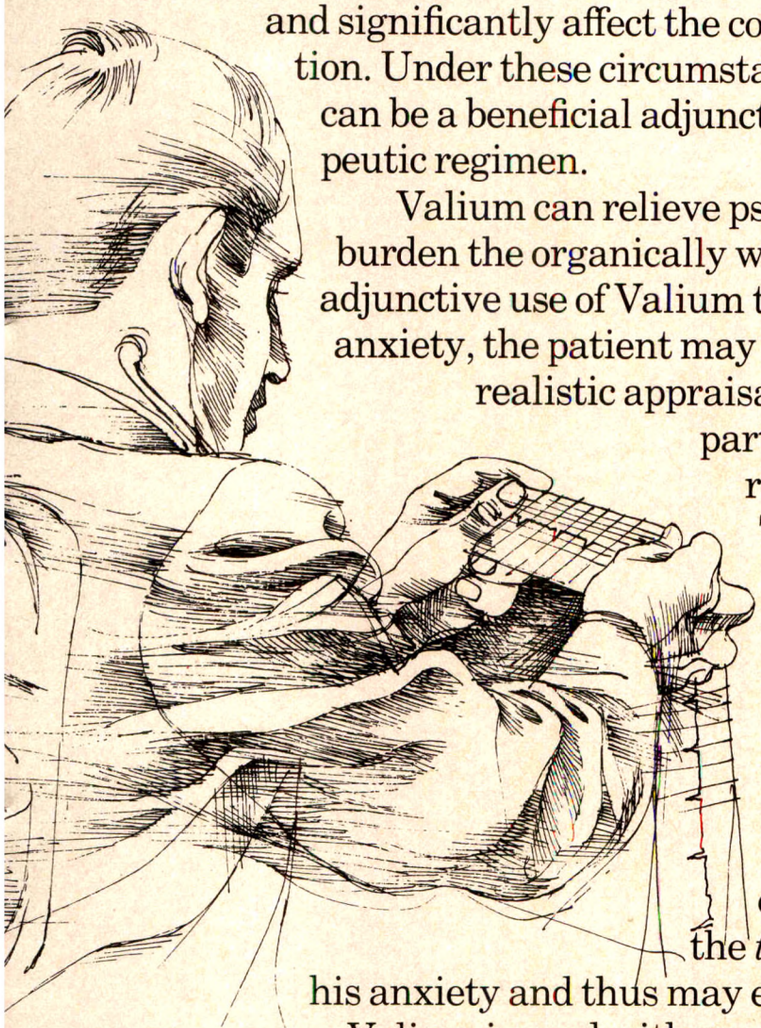
Damaged area showing early collateral vessel formation.

Development of fibrous scar and healing of infarcted area.

will psychic tension affect the patient's rehabilitation?

ROCHE

After the MI patient's acute episode has been successfully managed, a program of rehabilitation is begun. At times the overly tense cardiac patient may present a special problem. Although you continue to encourage a positive outlook through counseling and enlistment of support from the patient's family, psychic tension may remain, and significantly affect the course of rehabilitation. Under these circumstances, Valium (diazepam) can be a beneficial adjunct to the patient's therapeutic regimen.



Valium can relieve psychic tension that may burden the organically weak heart. As a result of adjunctive use of Valium to relieve unwarranted anxiety, the patient may be able to arrive at a more realistic appraisal of his situation and participate more fully with his rehabilitation program.

Therapy should normally be continued until the patient's anxiety has been reduced to tolerable levels.

Since the cardiac patient may be particularly prone to tension and anxiety at bedtime, the addition of an *h.s.* dose of Valium to the *t.i.d.* schedule can relieve his anxiety and thus may encourage sleep.

Valium is used with most classes of primary medications such as cardiac glycosides, diuretics, vasodilators, anticholinergics and antacids. The most commonly reported side effects have been drowsiness, fatigue and ataxia. Patients taking Valium should be cautioned against driving or operating dangerous machinery.

Valium®(diazepam)
2-mg, 5-mg, 10-mg tablets

when you consider it essential to keep the heart patient calm

Please turn page for a summary of product information.

When you consider it essential to keep the heart patient calm

- Valium (diazepam) can relieve psychic tension and anxiety that may burden the organically weak heart and interfere with the patient's course of rehabilitation.
- Valium works promptly in most patients. Significant improvement is usually noted during the first few days of therapy, although some patients may require more time to respond.
- Adjustments in dosage can alter clinical response. With appropriate titration, a regimen can be tailored to the patient's individual needs.
- Valium has a wide margin of safety in the usual oral dosage range and generally does not significantly affect respiration or pulse.

Valium® (diazepam)
2-mg, 5-mg, 10-mg tablets

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Tension and anxiety states, somatic complaints which are concomitants of emotional factors; psychoneurotic states manifested by tension, anxiety, apprehension, fatigue, depressive symptoms or agitation; symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology, spasticity caused by upper motor neuron disorders, athetosis, stiff-man syndrome, convulsive disorders (not for sole therapy).

Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.

Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms (similar to those with barbiturates and alcohol) have occurred following abrupt discontinuance (convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence. In pregnancy, lactation or women of childbearing age, weigh potential benefit against possible hazard.

Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.

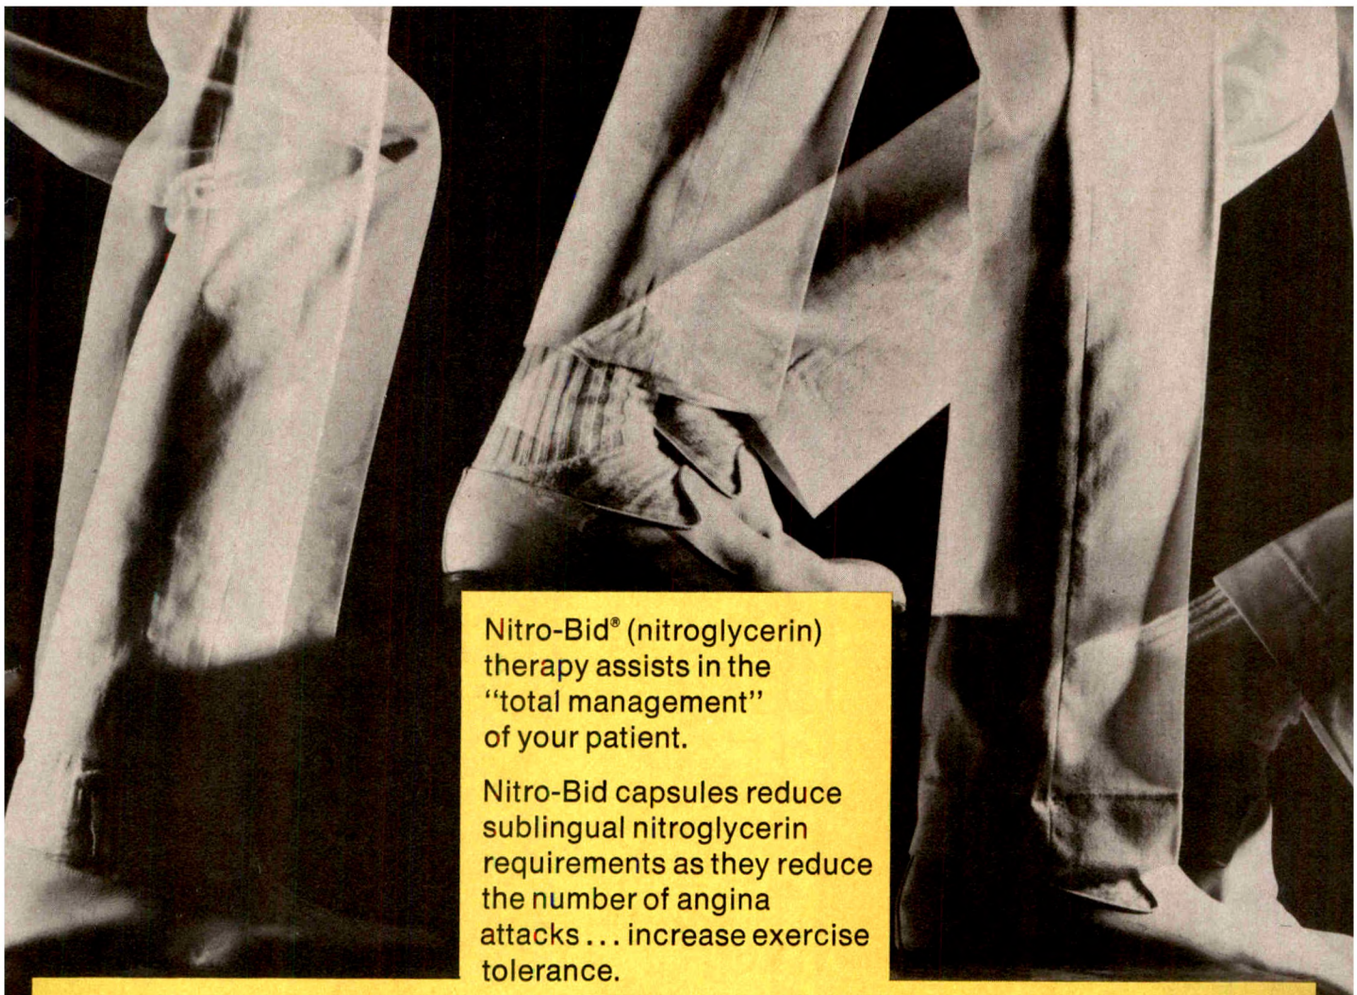
Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.

Dosage: Individualize for maximum beneficial effect. *Adults:* Tension, anxiety and psychoneurotic states, 2 to 10 mg b.i.d. to q.i.d.; alcoholism, 10 mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. to q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).

Supplied: Valium® (diazepam) Tablets, 2 mg, 5 mg and 10 mg; bottles of 100 and 500. All strengths also available in Tel-E-Dose® packages of 1000.

ROCHE

Roche Laboratories
Division of Hoffmann-La Roche Inc.
Nutley, N.J. 07110



The Third Step in Angina.*

After the classic "2-Step" Test aids in a diagnosis of angina, sustained-release Nitro-Bid® (nitroglycerin) is a logical third step. Here's why.

In angina secondary to arteriosclerotic heart disease, sustained-release Nitro-Bid® (nitroglycerin) therapy assists in the "total management" of your patient.

Nitro-Bid capsules reduce sublingual nitroglycerin requirements as they reduce the number of angina attacks . . . increase exercise tolerance.

Sustained-release Nitro-Bid Plateau CAPS® provide a metered sequence of medication during the night to protect against nocturnal angina attack.

In titrating dosage, availability of different strengths "...is quite an asset..."[1]

Nitro-Bid 2.5 and Nitro-Bid 6.5 capsules afford two dosage strengths for convenience in increasing or decreasing dose to accommodate patient symptoms.

NITRO-BID® 2.5
(nitroglycerin 2.5 mg) Plateau CAPS®

NITRO-BID® 6.5
(nitroglycerin 6.5 mg) Plateau CAPS®

INDICATIONS

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

*"Possibly" effective:
For the management, prophylaxis or treatment of anginal attacks.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Recent myocardial infarction, severe anemia, glaucoma, increased intracranial pressure, idiosyncrasy.
Precautions: For ORAL, not sublingual, use. If blurring of vision or dryness of mouth occurs, discontinue drug. Tolerance may develop on long-term usage.
Adverse Reactions: Occasional transient headaches. Overdose may cause flushing, headaches, tachycardia, dizziness.
Dosage: One capsule two or three times daily at 8 to 12 hour intervals.
Reference: 1. Master, AM: The management of angina pectoris. *Modern Medicine* **38**:92-100 (Feb 23) 1970.

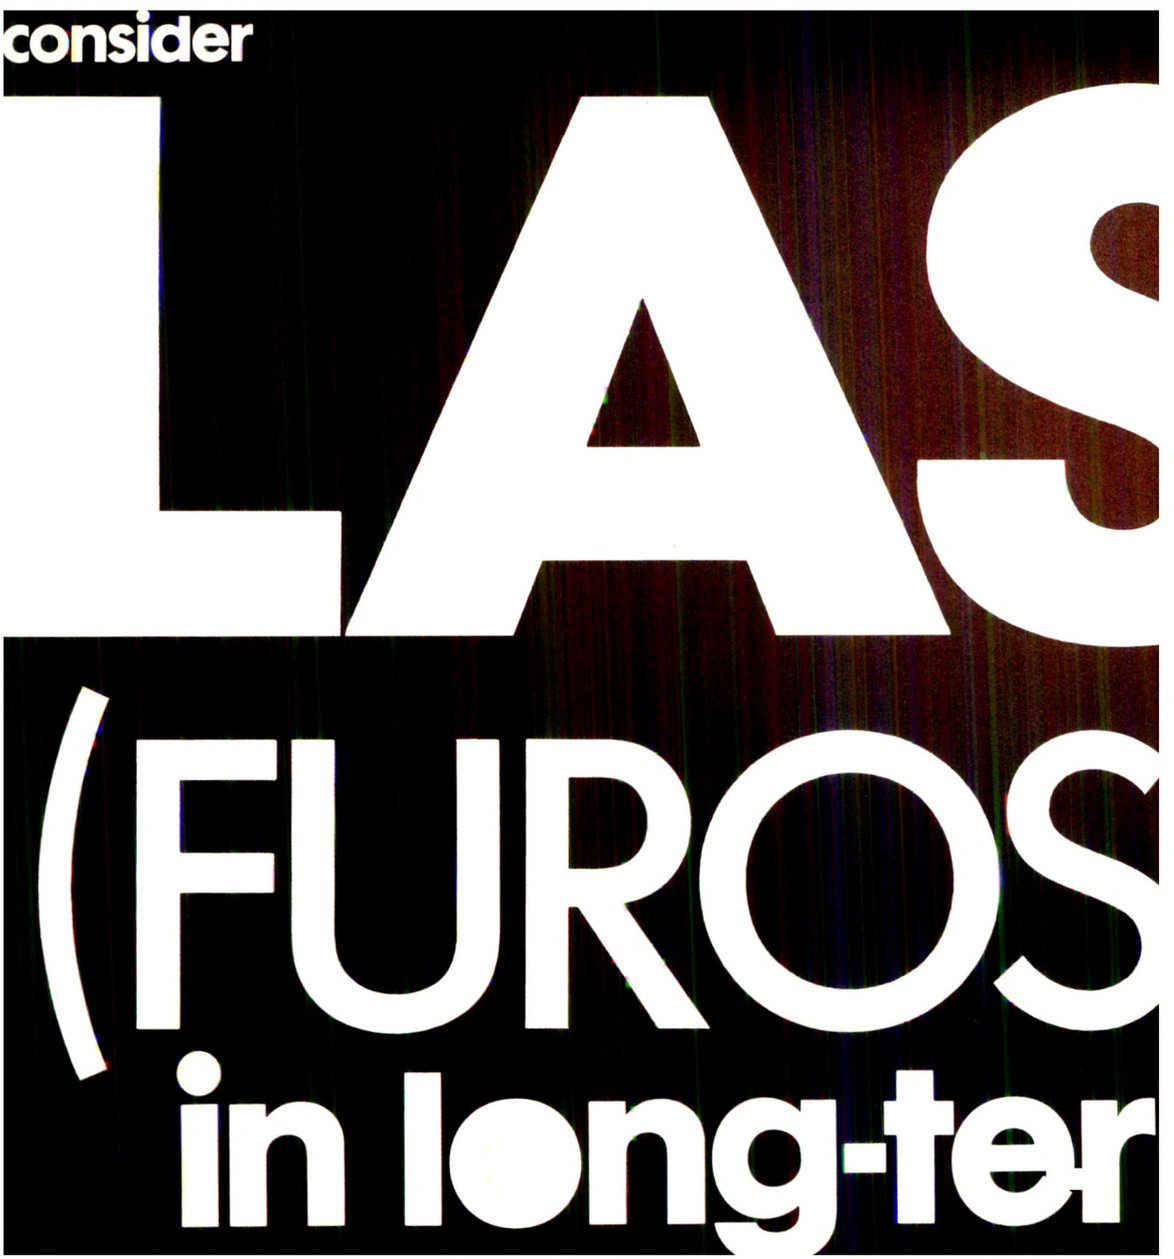
Your experience has
shown you the benefits
of Lasix® (furosemide)
in initial therapy of
cardiac edema.
Now...



consider
LAS
(FUROS
in long-ter

tablets
40 mg

X™

MIDE)

therapy

wide range of effectiveness allows you to treat most degrees of cardiac edema.

dry weight can be reliably and safely maintained by adjusting the dose to fit your patient's needs. With doses exceeding 80 mg /day and given for prolonged periods, careful clinical and laboratory observations are particularly advisable.

patient inconvenience is minimal since diuresis is usually complete within six to eight hours.

(See Lasix® [furosemide] prescribing information on last page of this

LASIX® (FUROSEMIDE)

TABLETS 40 mg

in long-term therapy

WARNING—Lasix (furosemide) is a potent diuretic which if given in excessive amounts can lead to a profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dose schedule have to be adjusted to the individual patient's needs. (See under "DOSAGE AND ADMINISTRATION".)

DESCRIPTION—Lasix is a diuretic, chemically distinct from the organomercurials, thiazides and other heterocyclic compounds. It is characterized by:

- a high degree of efficacy;
- a rapid onset of action;
- a comparatively short duration of action;
- a ratio of minimum to maximum effective dose higher than 1:10;
- the fact that it acts not only at the proximal and distal tubules but also at the ascending limb of Henle's loop.

Lasix is an anthranilic acid derivative. Chemically, it is 4-chloro-N-furfuryl-5-sulfamoylanthranilic acid.

INDICATIONS—Lasix is indicated for the treatment of the edema associated with congestive heart failure, cirrhosis of the liver, and renal disease, including the nephrotic syndrome. Lasix is particularly useful when an agent with greater diuretic potential than that of those commonly employed is desired.

Hypertension—Lasix may be used for the treatment of hypertension alone or in combination with other antihypertensive drugs. Hypertensive patients who cannot be adequately controlled with thiazides will probably also not be adequately controllable with Lasix alone.

CONTRAINDICATIONS—Because animal reproductive studies have shown that Lasix (furosemide) may cause fetal abnormalities, the drug is contraindicated in women of child-bearing potential. (See "ADDITIONAL INFORMATION".)

Lasix is contraindicated in anuria. If increasing azotemia and oliguria occur during treatment of severe progressive renal disease, the drug should be discontinued. In hepatic coma and in states of electrolyte depletion, therapy should not be instituted until the basic condition is improved or corrected. Lasix is contraindicated in patients with a history of hypersensitivity to this compound.

Until more experience is accumulated in the pediatric use of Lasix, children should not be treated with the drug.

WARNINGS—Excessive diuresis may result in dehydration and reduction in blood volume, with circulatory collapse and with the possibility of vascular thrombosis and embolism, particularly in elderly patients. Excessive loss of potassium in patients receiving digitalis glycosides may precipitate digitalis toxicity. Care should also be exercised in patients receiving potassium depleting steroids.

Frequent serum electrolyte, CO_2 and BUN determinations should be performed during the first few months of therapy and periodically thereafter, and abnormalities corrected or the drug temporarily withdrawn.

In patients with hepatic cirrhosis and ascites, initiation of therapy with Lasix (furosemide) is best carried out in the hospital. Sudden alterations of fluid and electrolyte balance in patients with cirrhosis may precipitate hepatic coma; therefore, strict observation is necessary during the period of diuresis. Supplemental potassium chloride and, if required, an aldosterone antagonist are helpful in preventing hypokalemia and metabolic alkalosis.

As with many other drugs, patients should be observed regularly for the possible occurrence of blood dyscrasias, liver damage, or other idiosyncratic reactions.

In those instances where potassium supplementation is required, coated potassium tablets should be used only when adequate dietary supplementation is not practical.

There have been several reports, published and unpublished, concerning nonspecific small-bowel lesions consisting of stenosis, with or without ulceration, associated with the administration of enteric-coated thiazides with potassium salts. These lesions may occur with enteric-coated potassium tablets alone or when they are used with nonenteric-coated thiazides, or certain other oral diuretics.

These small-bowel lesions have caused obstruction, hemorrhage, and perforation. Surgery was frequently required, and deaths have occurred.

Available information tends to implicate enteric-coated potassium salts, although lesions of this type also occur spontaneously. Therefore, coated potassium-containing formulations should be administered only when indicated, and should be discontinued immediately if abdominal pain, distention, nausea, vomiting, or gastrointestinal bleeding occurs.

Patients with known sulfonamide sensitivity may show allergic reactions to Lasix.

PRECAUTIONS—As with any potent diuretic, electrolyte depletion may occur during therapy with Lasix, especially in patients receiving higher doses and a restricted salt intake. Electrolyte depletion may manifest itself by weakness, dizziness, lethargy, leg cramps, anorexia, vomiting, and/or mental confusion.

In edematous hypertensive patients being treated with antihypertensive agents, care should be taken to reduce the dose of these drugs when Lasix is administered, since Lasix potentiates the hypotensive effect of antihypertensive medications.

Asymptomatic hyperuricemia can occur and gout may rarely be precipitated. Reversible elevations of BUN may be seen. These have been observed in association with dehydration, which should be avoided, particularly in patients with renal insufficiency.

When parenteral use of Lasix precedes its oral use, it should be kept in mind that cases of reversible deafness and tinnitus following the injection of Lasix (furosemide) have been reported. These adverse reactions occurred when Lasix was injected at doses exceeding several times the usual therapeutic dose of 20 to 40 mg.

Periodic checks on urine and blood glucose should be made in diabetics and even those suspected of latent diabetes when receiving Lasix. Increases in blood glucose, and alterations in glucose tolerance tests with abnormalities of the fasting and two-hour post-prandial sugar have been observed, and rare cases of precipitation of diabetes mellitus have been reported.

Lasix may lower serum calcium levels, and rare cases of tetany have been reported. Accordingly, periodic serum calcium levels should be obtained.

Patients receiving high doses of salicylates, as in rheumatic diseases, in conjunction with Lasix may experience salicylate toxicity at lower doses because of competitive renal excretory sites.

It has been reported in the literature that diuretics such as furosemide may enhance the nephrotoxicity of cephaloridine. Therefore, Lasix and cephaloridine should not be administered simultaneously.

Sulfonamide diuretics have been reported to decrease arterial responsiveness to pressor amines and to enhance the effect of tubocurarine. Great caution should be exercised in administering curare or its derivatives to patients undergoing therapy with Lasix, and it is advisable to discontinue Lasix for one week prior to any elective surgery.

ADVERSE REACTIONS—Various forms of dermatitis, including urticaria and rare cases of exfoliative dermatitis, erythema multiforme, pruritus, paresthesia, blurring of vision, postural hypotension, nausea, vomiting, or diarrhea, may occur.

Anemia, leukopenia, aplastic anemia, and thrombocytopenia (with purpura) may occur. Rare cases of agranulocytosis have occurred which responded to treatment.

In addition, the following rare adverse reactions have been reported; however, relationship to the drug has not been established with certainty: sweet taste, oral and gastric burning, paradoxical swelling, headache, jaundice, thrombophlebitis and emboli (see "WARNINGS"), and acute pancreatitis.

Lasix-induced diuresis may be accompanied by weakness, fatigue, lightheadedness or dizziness, muscle cramps, thirst, increased perspiration, urinary bladder spasm, and symptoms of urinary frequency.

As far as hyperglycemia is concerned, see "PRECAUTIONS".

DOSAGE AND ADMINISTRATION—The usual dose of Lasix is 40 to 80 mg given as a single dose, preferably in the morning. Ordinarily, a prompt diuresis ensues. Depending on the patient's response, a second dose can be administered 6 to 8 hours later. This dosage and dosage schedule can then be maintained or even reduced.

If the diuretic response with a single dose of 40 to 80 mg is not satisfactory; e.g., in a patient with congestive heart failure refractory to maximal doses of thiazides, the following schedule should be used: Increase this dose by increments of 40 mg not sooner than 6 to 8 hours after the previous dose until the desired diuretic effect has been obtained. This individually determined single dose should then be given once or twice daily (e.g., at 8:00 a.m. and 2:00 p.m.). The dose of Lasix may be carefully titrated up to 600 mg per day in those patients with severe clinical edematous states. Higher doses are currently under investigation.

The mobilization of edema may be most efficiently and safely accomplished by utilizing an intermittent dosage schedule in which the diuretic is given for 2 to 4 consecutive days each week. With doses exceeding 80 mg/day and given for prolonged periods, careful clinical and laboratory observations are particularly advisable.

Hypertension—The usual dose of Lasix is 40 mg twice daily both for initiation of therapy and for maintenance. Careful observations for changes in blood pressure must be made when this compound is used with other antihypertensive drugs, especially during initial therapy. The dosage of other agents must be reduced by at least 50 percent as soon as Lasix is added to the regimen to prevent excessive drop in blood pressure. As the blood pressure falls under the potentiating effect of Lasix, a further reduction in dosage, or even discontinuation, of other antihypertensive drugs may be necessary. It is further recommended, if 40 mg twice daily does not lead to a clinically satisfactory response, to add other hypotensive agents; e.g., reserpine, rather than to increase the dose of Lasix.

Until more experience is accumulated in the pediatric use of Lasix, children should not be treated with the drug.

HOW SUPPLIED—Lasix (furosemide) Tablets are supplied as white, monogrammed, scored tablets of 40 mg in amber bottles of 100 (6505-00-062-3336), 500 (6505-00-254-5546A), and Unit Dose 100's (20 strips of 5) 6505-00-117-5982).

Note: Dispense in dark containers. Exposure to light may cause slight discoloration which, however, does not alter potency.

Blood Flow Velocity Measured at the Mitral Valve of Man

KENNETH B. DESSER, MD
ALBERTO BENCHIMOL, MD, FACC

Phoenix, Arizona

Phasic mitral valve blood flow velocity was measured in 30 conscious persons with the Doppler ultrasonic flowmeter catheter. Mitral valve flow velocity is chracterized by a a large pandiastolic wave followed by a smaller systolic component. Deep inspiration resulted in a decline of peak mitral valve flow velocity; expiration had an opposite effect. The Valsalva maneuver produced a marked decline of peak flow velocity, which lasted for the duration of straining. Atrial and ventricular extrasystoles caused a diminution of peak mitral valve flow velocity, generally related to the duration of the extrasystolic coupling intervals. Brief episodes of ventricular tachycardia effected a decline of peak mitral valve flow velocity and the wave forms became completely irregular. These findings represent the first detailed description of phasic instantaneous mitral valve flow velocity in conscious man in a variety of physiologic and abnormal states.

Phasic blood velocity and volumetric blood flow have been measured at the mitral valve of experimental animals by means of surgically introduced electromagnetic flowmeters[1,2] and pressure differential techniques.[3] In these latter studies, estimation of mitral valve flow required general anesthesia, thoracotomy and incorporation of flowmeters into mitral valve prostheses[1] or the left atrial myocardium,[2] or direct insertion of pressure diffferential needles near the mitral valve ring.[3] We describe here instantaneous measurement of phasic mitral valve blood flow velocity in conscious man utilizing the Doppler flowmeter catheter technique.

Material and Methods

Thirty subjects comprised the study group. There were 22 men and 8 women whose ages ranged from 18 to 66 years (mean 49). Five patients had normal cardiac findings and 25 had heart disease. In this latter group 14 patients had coronary artery disease, and 11 had other forms of acquired or congenital heart disease. All diagnoses were made on the basis of complete right and left heart catheterization, selective coronary cineangiography and indicator-dilution curves. Normal subjects were studied because of the presence of chest pain or systolic murmurs originally thought to represent organic heart disease.

Mitral valve blood flow velocity was measured with a catheter tip[4] adaptation of Franklin's Doppler ultrasonic flowmeter.[5] This device has been utilized in our laboratory for the study of right atrial,[6] right ventricular,[7] aortic,[8] coronary arterial,[9] carotid arterial,[10] renal arterial[11] and superior mesenteric arterial[12] blood flow velocity patterns in man. The application of the Doppler flowmeter for the measurement of blood velocity in the left ventricle of man has recently been described.[13] With use of 1 percent lidocaine for local anesthesia, the right or left brachial artery and a medial antecubital vein were isolated. The flowmeter-tipped catheter was introduced into the artery and passed in retrograde fashion under fluoroscopic observation to the ascending aorta. The catheter was then advanced across the aortic valve into the left ventricle and positioned at the mitral valve (Fig. 1). Signals arising from mitral valve blood flow were identified by a predominant diastolic wave that was apparent on the oscilloscope display and will be described under Results.

The large diastolic component was evident during audible monitoring of the Doppler frequency shift. A saline-filled no. 7 or 8 bipolar Zucker catheter connected to a Statham P 23Db strain gauge was introduced into the vein for the purpose of obtaining right atrial, right ventricular or pulmonary arterial pressures. Flow velocity signals, right heart pressures, lead II of the electrocardiogram and at times external carotid arterial pulse tracings were simultaneously recorded on an Electronics for Medicine DR-12 oscilloscopic photographic recorder operated at various paper speeds. The flow velocity audio signals, voltage signals and other physiologic data were recorded on an eight channel Sanborn magnetic tape recorder.

Results

Blood flow velocity at the mitral valve during sinus rhythm: Blood flow velocity at the mitral valve was phasic, continuous and characterized by a large pandiastolic wave followed by a smaller and shorter peaked systolic component. The ascending limb of the diastolic wave was recorded rapidly, immediately after inscription of the dicrotic notch and second heart sound on the simultaneously recorded external carotid pulse tracing and phonocardiogram, respectively. The smaller systolic wave had a rapid upstroke and an early midsystolic downstroke. Peak systolic flow velocities usually attained levels which were 25 to 75 percent of the values for peak diastolic flow velocities and were recorded during the midsystolic *x* descent of simultaneous right atrial pressure recordings (Fig. 2). Signals obtained from other left ventricular cavity sites were characterized by larger systolic waves.[13] Differences between recordings obtained from the mitral valve area and other left ventricular sites were appreciated during careful withdrawal and advancement of the catheter tip under fluoroscopic control (Fig. 3). In 50 percent of cases, left atrial contraction resulted in a small presystolic flow velocity wave that peaked after the right atrial pressure *a* wave and a fourth heart sound on a simultaneously recorded phonocardiogram. This presystol-

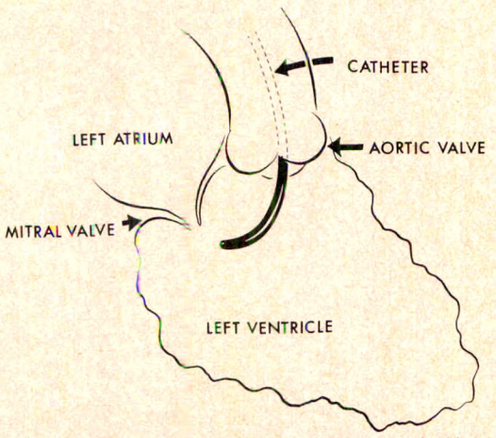

FIGURE 1. Schematic diagram demonstrating the position of the Doppler flowmeter catheter during measurement of mitral valve blood flow velocity.

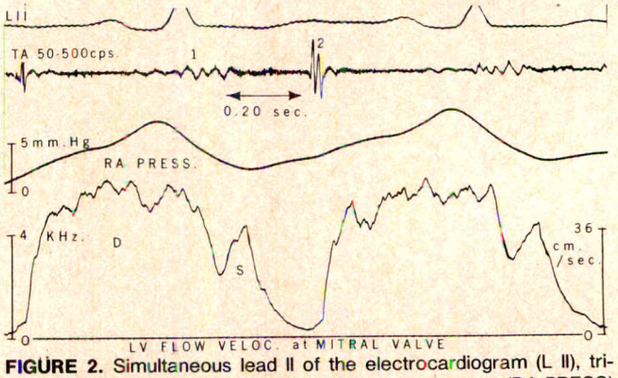

FIGURE 2. Simultaneous lead II of the electrocardiogram (L II), tricuspid area phonocardiogram (TA), right atrial pressure (RA PRESS) and mitral valve blood flow velocity recorded in a normal 65 year old woman. Note the rapid inscription of diastolic (D) flow velocity during concurrent recording of the second heart sound (2). The smaller systolic (S) wave occurs at the time of inscription of the first heart sound (1) and peaks during midsystole when the simultaneously recorded right atrial pressure is at its lowest level.

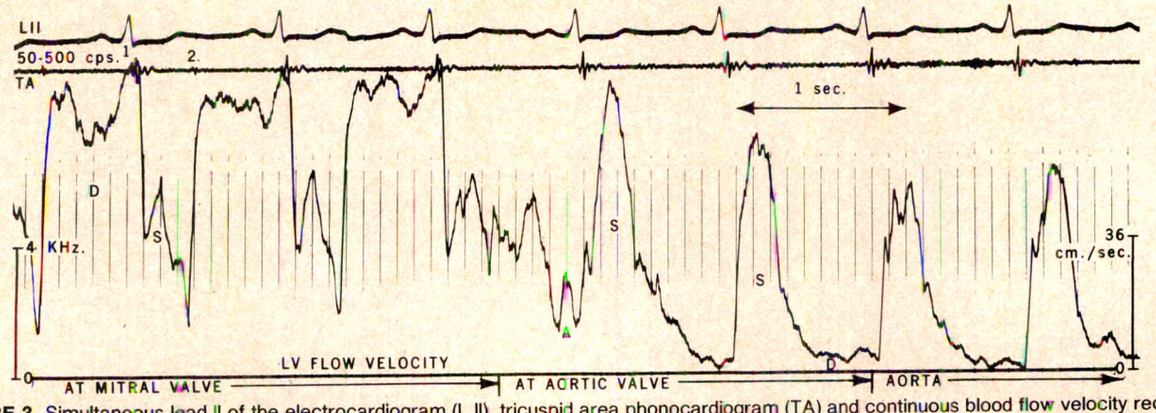

FIGURE 3. Simultaneous lead II of the electrocardiogram (L II), tricuspid area phonocardiogram (TA) and continuous blood flow velocity recorded during withdrawal of the Doppler catheter flowmeter tip from the mitral valve position toward the aortic valve in a 54 year old man with coronary artery disease. Note the decrease of diastolic flow velocity (D) and increase of systolic flow velocity (S) as the catheter tip is maneuvered to the left ventricular outflow tract and withdrawn across the aortic valve. LV = left ventricular; 1 = first heart sound; 2 = second heart sound.

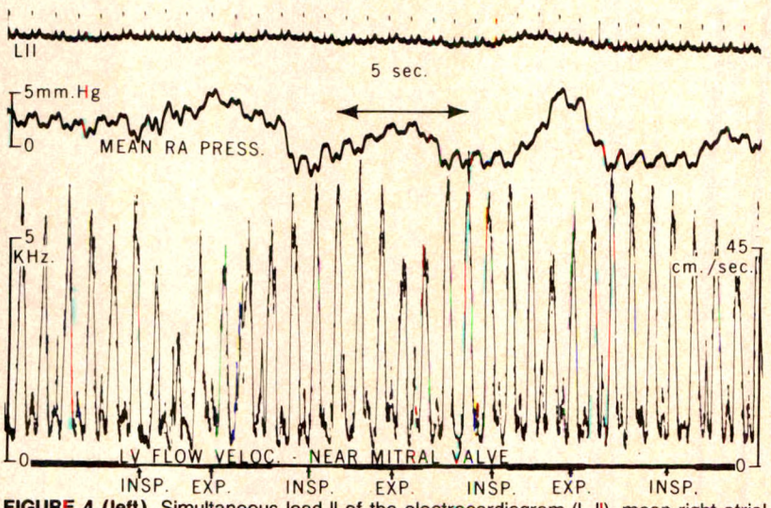
ic wave did not increase peak diastolic flow velocity at the mitral valve by more than 15 percent.

Effects of respiration and Valsalva maneuver: During deep inspiration and expiration, there were cyclic alterations of peak diastolic flow velocity at the mitral valve. Inspiration was associated with a decline of peak mitral valve blood flow velocity; lowest values for peak flow velocity usually corresponded to an increase of simultaneously recorded mean right atrial pressure. Expiration had exactly the opposite effects—an increase of peak diastolic flow velocity with concomitant decline of mean right atrial pressure (Fig. 4). The Valsalva maneuver resulted in a marked reduction of peak mitral valve blood flow velocity, which lasted as long as the straining continued (Fig. 5).

Effects of arrhythmias: Atrial premature beats resulted in reductions of peak flow velocity at the mitral valve that were generally dependent on the preceding extrasystolic coupling interval; the shorter the coupling interval, the greater was the diminution of peak flow velocity. In a single subject with atrial bigeminy, reductions of peak systolic and diastolic mitral valve blood flow velocity were always associated with the atrial extrasystoles, resulting in persistent alternation of recorded wave forms (Fig. 6). Similarly, ventricular extrasystoles produced a decrease of peak mitral valve blood flow velocity, with greater



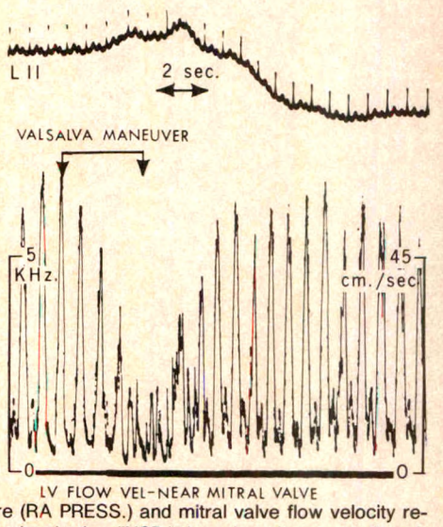


FIGURE 4 (left). Simultaneous lead II of the electrocardiogram (L II), mean right atrial pressure (RA PRESS.) and mitral valve flow velocity recorded in a 28 year old woman with minimal mitral insufficiency during deep respiration. During inspiration (INSP.) there is a decrease of peak mitral valve blood flow velocity and an increase in mean right atrial pressure. During expiration (EXP.), peak mitral valve flow velocity increases when mean right atrial pressure declines.

FIGURE 5 (right). Simultaneous lead II of the electrocardiogram (L II) and mitral valve blood flow velocity recorded in a 28 year old woman with a mild degree of mitral insufficiency. During execution of the Valsalva maneuver, there is a marked reduction of peak mitral valve blood flow velocity. LV = left ventricular; VEL = velocity.

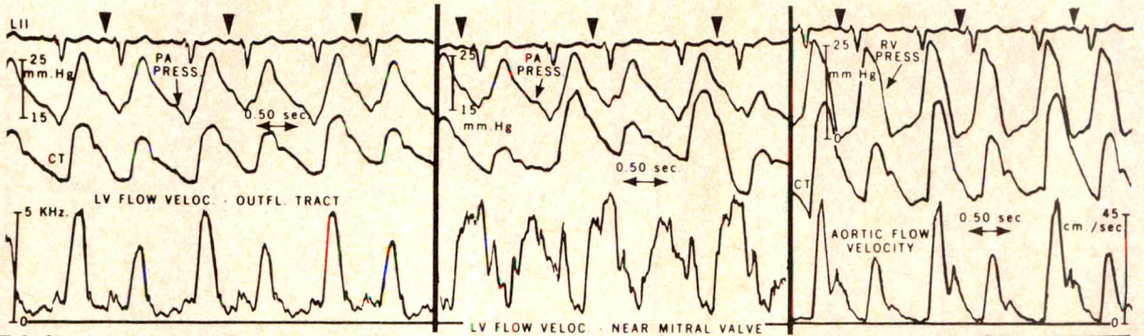

FIGURE 6. Simultaneous recordings of lead II of the electrocardiogram (L II), right heart pressure, external carotid pulse tracing (CT) and blood flow velocity at various sites in a 59 year old woman with essential hypertension and atrial bigeminy. The atrial premature beats are marked by **arrows. Left,** atrial extrasystoles result in reduced pulmonary arterial pressures and decreased amplitude of both external carotid pulse and left ventricular outflow tract blood velocity wave forms. **Middle,** atrial extrasystoles effect reduced peak diastolic mitral valve flow velocities followed by increased systolic components associated with the succeeding sinus beats. **Right,** reductions of peak aortic flow velocity and concordant changes in peak right ventricular (RV) pressures are induced by atrial extrasystoles.

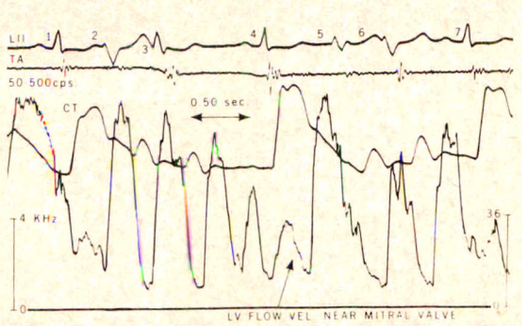

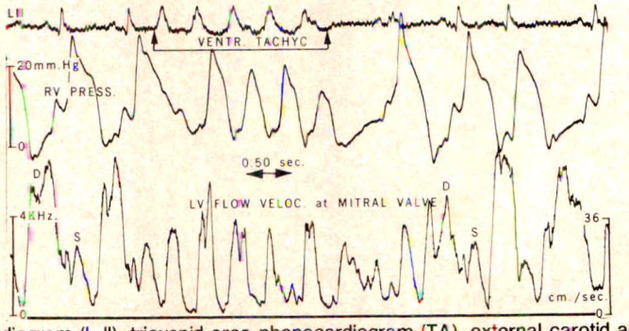

FIGURE 7 (left). Simultaneously recorded lead II of the electrocardiogram (L II), tricuspid area phonocardiogram (TA), external carotid arterial pulse tracing (CT) and mitral valve blood flow velocity in a 54 year old man with coronary artery disease during catheter-evoked ventricular extrasystoles. Ventricular extrasystoles (numbered 2, 3, 5, and 6) result in reduced peak mitral valve blood flow velocity, generally related to extrasystolic coupling intervals. An "overshoot" of peak mitral valve flow velocity and external carotid pulse tracing amplitude during sinus beat 4 is preceded by a longer postextrasystolic interval. LV = left ventricular; VEL = velocity.

FIGURE 8 (right). Simultaneous lead II of the electrocardiogram (L II), right ventricular pressure (RV PRESS.) and mitral valve flow velocity recorded in a 59 year old man with coronary artery disease. During an episode of ventricular tachycardia there is a decline of peak mitral valve blood flow velocity which is paralleled by a reduction in systolic and end-diastolic right ventricular pressure levels. D = diastolic; LV = left ventricular; S = systolic; VELOC. = velocity.

flow velocity reductions related to prematurity of the ectopic beats. Postextrasystolic beats preceded by longer R–R intervals resulted in peak mitral valve flow velocity "overshoot" (Fig. 7). Ventricular tachycardia effected a marked reduction of peak mitral valve flow velocity and the recordings during this arrhythmia were completely irregular. During most beats of the tachycardia, there were concomitant reductions of simultaneously recorded systolic and end-diastolic right ventricular pressures (Fig. 8).

Discussion

The mitral valve diastolic blood flow velocity patterns described here resemble trapezoidal shaped mitral flow wave forms previously recorded in experimental animals by Nolan et al.[1] A continuous blood flow velocity at the mitral valve throughout the cardiac cycle indicates that significant hemodynamic alterations occur at this cavity site during isovolumic relaxation and contraction. The rapid rise of mitral valve flow velocity at the time of the second heart sound may be related to a downward displacement of the mitral valve leaflets before valvular opening. Most descriptions of blood flow profiles at the mitral valves of experimental animals indicate a sharp increase of flow in early diastole.[1,2] During this period, continuing relaxation of the left ventricle and increasing left atrial pressure produce a rapidly rising atrioventricular energy gradient.[3] Careful cineangiographic investigation has also demonstrated major left atrial emptying[14] and left ventricular filling[15] early in the diastolic period.

Left atrial contraction maintains but does not appreciably augment mitral valve blood flow velocity during sinus rhythm. A secondary, smaller acceleration of volumetric mitral flow after atrial depolarization has been noted in animals with implanted ball valve electromagnetic flowmeters,[1] and supplementary left ventricular filling due to atrial contraction is usually no more than 10 to 15 percent of stroke volume.[3] However, Williams et al.,[2] utilizing a flowmeter incorporated into the atrial side of the mitral valve ring in animals, found that peak mitral valve flow occurred at the time of P wave inscription. This latter finding may reflect differences in the anatomic site of flow measurement by various investigators. The sharply inscribed systolic mitral flow velocity wave noted in our study is probably due to left ventricular ejection. However, it is likely that upward movement of the mitral valve during isovolumic contraction[16] results in early systolic reverse flow velocity that is sensed by the flowmeter.

Declining mitral valve flow velocity during exaggerated inspiration and the Valsalva maneuver can be attributed to increased pulmonary arterial blood flow or decreased systemic and pulmonary venous return,[17] which occur during these two respective physiologic maneuvers. The reduction of mitral valve blood flow velocity observed during inspiration can be contrasted with left ventricular outflow tract blood velocity, which increases during this period of the respiratory cycle.[13]

The alterations of mitral valve flow velocity during extrasystoles and ventricular tachycardia are particularly noteworthy. Some experimental evidence[1] suggests that rapid right atrial stimulation reduces mitral forward stroke output and enhances stroke power loss across the valve. This decrease of mitral valve blood flow may be a result of diminished pulmonary venous return, lesser left atrial volumes, reduced left atrial contraction or mitral insufficiency. At present, there are no adequate data in experimental animals with intact mitral valves that might indicate the relative importance of each of these variables. The adverse clinical consequences resulting from diminished mitral valve flow velocity in man during cardiac tachyarrhythmias are evident. Reduced mitral valve flow velocity would effect diminished left ventricular volume and reduce stroke output.

Limitations of the technique: The Doppler flowmeter catheter utilized in our study did not distinguish between forward and reverse flow velocities. It has been demonstrated that a minor degree of net reverse flow does occur in experimental animals[2] and human subjects with intact mitral valves, particularly during isovolumic contraction[2,16] and early diastole.[15] Furthermore, we have recorded substantial net reverse blood flow velocity at the left ventricular inflow tract of man.[18] Currently, the bidirectional Doppler flowmeter cannot be properly maneuvered for positioning at the mitral valve of man as described here.

Advantages of the technique: The Doppler flowmeter catheter is currently the only device that can directly measure phasic instantaneous blood flow velocity at the mitral valve of conscious man. The major advantage of this technique is a capability for characterizing mitral valve flow velocity under a variety of physiologic and pathologic conditions.

Large Dose Furosemide Therapy for Hypertension

Long-Term Use in 22 Patients

WILLIAM J. MROCZEK, MD
MICHAEL DAVIDOV, MD
FRANK A. FINNERTY, Jr., MD, FACC

Washington, D. C.

A retrospective study of 22 hypertensive patients receiving large oral doses of furosemide (80 to 640 mg daily for 32 ± 7 months) and standard antihypertensive therapy was performed. All patients had moderately severe or severe hypertension. The substitution of furosemide for the previous diuretic agents resulted in a 22 percent average reduction in arterial pressure and significant improvement in the clinical status of 15 patients. The addition of furosemide allowed a reduction in the dose of antihypertensive medication in four patients. Besides preventing the sodium retention and extracellular fluid volume expansion associated with standard antihypertensive agents, large doses of furosemide may have exerted an additional antihypertensive effect. The combination of orally administered furosemide and standard antihypertensive therapy permitted better control of arterial pressure than that obtained with previous diuretic-antihypertensive combinations in the patients studied. The overall safety of large dose furosemide therapy for extended periods of time appears to be relatively good.

Studies from this laboratory have demonstrated the effectiveness of intravenously administered furosemide as an antihypertensive agent[1] and in the management of congestive heart failure.[2,3] Our experience in a large outpatient population and studies of other workers[4,5] have documented the effectiveness of orally administered furosemide in the management of hypertensive patients. The dose-response curve of furosemide is unusually broad,[6] and the drug is effective in increased doses in the presence of renal insufficiency.[7–10] Relatively few serious side effects have been reported after administration of large doses for short periods[11–14]; however, data are not available on the effectiveness or safety of large doses given for extended periods. Furosemide has been used as a diuretic agent and as an adjunct to antihypertensive therapy in our clinic since 1964. A retrospective analysis of results in patients receiving large dose, long-term furosemide therapy forms the basis of this report.

Methods

A review of the records of patients attending the Hypertension Clinic at the District of Columbia General Hospital revealed that 22 patients had received at least 80 mg of furosemide daily for at least 24 consecutive months. All patients were considered to have essential hypertension on the basis of family history, serum electrolyte determinations and a rapid sequence intravenous pyelogram. All 22 patients were Negro, and 8 were male. The average age was 50 ± 10 years (36 to 70 years). Before initiation of furosemide therapy two patients (Cases 4 and 19) had clinical evidence of congestive heart failure despite digitalization and full doses of antihypertensive and diuretic agents. All patients had electrocardiographic evidence of left ventricular hypertrophy. No patient was uremic; however, six had mild azotemia (blood urea nitrogen 20 to 40 mg/100 ml). Twelve patients had accelerated hypertensive retinopathy (flame-shaped hemorrhages and cotton wool exudates); three of these had papilledema. The remainder of the patients had either grade I or II Keith-Wagener-Barker changes.

From the Georgetown University Medical Division, District of Columbia General Hospital, Washington, D. C. Manuscript accepted July 25, 1973.

Address for reprints: William J. Mroczek, MD, Box 355, District of Columbia General Hospital, Washington, D. C. 20003.

All patients had previously received other diuretic agents for at least 3 months: hydrochlorothiazide, 100 mg daily (13 patients); hydrochlorothiazide, 100 mg, plus triamterene, 200 mg daily (6 patients); hydrochlorothiazide, 100 mg, plus spironolactone, 100 to 250 mg daily (3 patients). They had also received standard antihypertensive agents administered in full doses (methyldopa, 2 g; hydralazine, 300 mg; reserpine, 0.50 mg daily). Furosemide was initially substituted for the previous diuretic agent at a dose of 40 mg twice daily, by mouth. This dose was increased if arterial pressure could not be adequately controlled with the maximal dose of the standard antihypertensive agent, or if the patient had evidence of sodium retention or congestive heart failure. Treatment was continued using the same dose of antihypertensive medication as that previously administered. All patients were receiving a "no added salt diet" which, in the population studied, represents a daily intake of 5 to 10 g of sodium chloride.

Patients were examined in the Hypertension Clinic at weekly, biweekly or monthly intervals. At each clinic visit the patients were questioned as to possible side effects, and body weight was measured. Arterial pressure was determined with a mercury sphygmomanometer with the patient in the sitting position and after 2 minutes of quiet standing. The sitting and standing arterial pressure values from three consecutive clinic visits were averaged and rounded off to the nearest 5 mm Hg. Mean arterial pressure was calculated as the diastolic pressure plus one third of the pulse pressure. Blood pressure control was deemed adequate if there was at least a 10 percent reduction in mean arterial pressure and the diastolic pressure was maintained at 100 mm Hg or less. Blood for laboratory analysis, by methods described elsewhere,[1] was obtained at biweekly or monthly intervals. Supplemental potassium was administered as a 25 percent potassium chloride solution if the serum potassium level was below 3.5 mEq/liter or if electrocardiographic or clinical signs of hypokalemia were present.

Results

Table I shows the effect of large doses of furosemide and commonly used antihypertensive agents on arterial pressure and weight. The patients were followed up for an average of 32 ± 7 months. Table II shows the various doses of furosemide administered. The average reduction in mean arterial pressure at the end of almost 3 years of this combination therapy was 16 percent (from an average of 193/124 to an average of 163/104 mm Hg). Fifteen patients had decreases in mean arterial pressure ranging from 13 to 46 percent (average 22 percent). The reduction in mean arterial pressure was less than 10 percent in five patients, and two patients (Cases 5 and 12) had net increases in arterial pressure. In four patients (Cases 2, 10, 15 and 19) the substitution of furosemide for the previously used diuretic agent allowed a reduction in the dose of antihypertensive medication. The hypertensive retinopathy markedly decreased in all 12 of the patients with grade III or IV retinopathy (Keith-Wagener-Barker classification), and papilledema disappeared within 2 months (Table III).

The average weight decreased from 202 ± 40 lb to 194 ± 38 lb after 32 months of therapy. Seventeen patients lost an average of 15 ± 11 lb. The initial responses to furosemide therapy were increased diure-

TABLE IV

Laboratory Studies After Long-Term Large Dose Furosemide and Antihypertensive Therapy (mean values in 22 patients treated for 32 months)

	Before	After
Hematocrit	38 ± 5	41 ± 5
Blood urea nitrogen (mg/100 ml)	21 ± 7	21 ± 12
Fasting blood glucose (mg/100 ml)	94 ± 34	101 ± 25
Sodium (mEq/liter)	143 ± 4	142 ± 3
Potassium (mEq/liter)*	4.0 ± 0.4	3.9 ± 0.4
Uric acid (mg/100 ml)	7.8 ± 2.4	10.3 ± 2.2
SGOT (units/ml)	14 ± 6	16 ± 8
Alkaline phosphatase (Bessy-Lowry units)	1.5 ± 0.6	1.9 ± 0.8

*Five patients received supplemental potassium during furosemide therapy.

SGOT = serum glutamic oxaloacetic transaminase.

sis, weight loss and, in 2 patients, clearing of congestive heart failure. Although no patient had clinical evidence of sodium retention, it was necessary to increase the dose of furosemide to more than 80 mg/day to maintain adequate control of arterial pressure in all patients. With subsequent increases in dose, the potentiation of the antihypertensive effect was repeatedly noted; however, weight loss and diuresis were not consistent and did not appear to be related to the antihypertensive response. No differences in antihypertensive response were noted between men and women.

Table IV shows the effect of furosemide on blood chemistry values. There were no significant changes except for an increase in uric acid observed in all 22 patients. Three patients (Cases 6, 8 and 11) had an average increase of 18.5 mg/100 ml in blood urea nitrogen; however, three others (Cases 4, 19 and 21) had an average decrease of 14.2 mg/100 ml. Two patients had diabetes mellitus before institution of furosemide therapy; one of them required an increased dose of orally administered hypoglycemic agents. In addition, three patients who had no history of diabetes manifested clinical diabetes while receiving furosemide therapy. The condition of these patients was controlled with diet and orally administered hypoglycemic agents. Five patients (Cases 3, 5, 11, 18 and 21) required supplemental potassium administration because of a serum potassium level below 3.5 mEq/liter. No patient had symptoms of hypokalemia.

Discussion

Despite maximal doses of antihypertensive agents and diuretic agents, the arterial pressure of the patients studied was inadequately controlled before treatment with furosemide. The substitution of furosemide for the previous diuretic agent permitted adequate control of arterial pressure in 15 patients; in 4 of these patients control of arterial pressure was accomplished with reduced doses of antihypertensive agents. Seven patients had no significant improvement in arterial pressure or clinical status although there was no obvious clinical difference between these patients and the 15 who responded to therapy.

Mechanism of beneficial effects of furosemide therapy: Data from previous studies in our laboratory may help to explain the beneficial effects of furosemide in these patients. Most antihypertensive drugs have sodium-retaining properties that can be associated with expansion of the plasma and extracellular fluid volumes, and these volume changes may account for either decreased responsiveness to antihypertensive agents or the development of apparent drug resistance.[15] It is possible that the large doses of antihypertensive agents administered to the patients in this study necessitated the increased doses of furosemide to overcome this effect. It seems logical to hypothesize that the previously administered diuretic agents were not potent enough to prevent the sodium retention caused by the maximal doses of the antihypertensive agents. The potency of furosemide and its increased potency in larger doses blocked the sodium-retaining properties of the antihypertensive agents, thus allowing the latter to exert their full antihypertensive effect. Recent studies by Dustan et al.[16] emphasize the importance of precise volume control in maintaining blood pressure reductions during antihypertensive treatment.

During the initial stages of furosemide therapy, all patients lost weight (average 4.5 ± 2.1 lb during the first week of therapy). This initial weight loss was thought to represent diuresis and loss of body fluids. The weight change over the remaining 32 months could not be entirely accounted for by a net fluid loss and probably represented changes in caloric balance. When furosemide is given intravenously, its antihypertensive effects are unrelated to weight loss and diuresis.[1] In this study we repeatedly noted that subsequent increases in the dose of furosemide resulted in an additional antihypertensive effect that was apparently unrelated to either diuresis or weight loss. This

antihypertensive action usually occurred with oral doses of 200 to 600 mg daily. Our findings are in agreement with those of Hutcheon and Leonard,[4] who observed that the antihypertensive action of orally administered furosemide in doses of 100 to 200 mg daily was independent of diuresis. The mechanism of this antihypertensive action of large doses of furosemide could have been related to changes in fluid volume or to a decrease in cardiac output, as originally postulated by Wolfer et al.,[17] since these variables were not measured in our study. The possibility exists that the large doses of furosemide had an antihypertensive action independent of diuresis, as found by Hutcheon and Leonard,[4] since there was no change in body weight on a week to week basis when the dose of furosemide was increased to more than 100 mg daily.

Side effects: Although the average value for blood urea nitrogen did not change in the 22 patients, an increase was noted in 3. Investigation of this azotemia revealed no pre- or postrenal origin, and this deterioration of renal function was thought to represent progression of the underlying hypertensive disease process. A rise in serum uric acid levels was noted in all patients. Four patients were receiving probenecid before furosemide therapy and in two additional patients, clinical gout developed during the study. In one of the two patients with known diabetes it was necessary to increase the dose of tolbutamide from 1 g daily to 2 g daily. Clinical diabetes, which became apparent in three other patients receiving furosemide therapy, was effectively treated with diet and 500 mg of tolbutamide administered twice daily. It is not known if the previous administration of thiazide diuretic agents or the large doses of furosemide alone accounted for the high rate of diabetes mellitus in these patients. Therefore, in addition to monitoring of serum electrolytes and blood urea nitrogen, it seems advisable to monitor blood glucose levels at frequent intervals in patients receiving large doses of furosemide.

Clinical implications: Our study demonstrated that large doses of furosemide (80 to 640 mg daily) administered over 2 1/2 years produced no toxic effects and had side effects similar to those of thiazide diuretic agents (hypokalemia, hyperglycemia and hyperuricemia). When combined with standard antihypertensive agents, furosemide not only prevents their sodium-retaining properties, thus allowing them to exert their full effect, but also may exert an additional antihypertensive effect. The combination of standard antihypertensive agents with large doses of furosemide appears to permit better control of arterial pressure than that obtained with other diuretic-antihypertensive combinations in patients with moderately severe or severe hypertension.

Experiments on the Mitral Valve (Stricker, 1883)

SAUL JARCHO, MD

New York, New York

At present it can be discerned that, from the viewpoint of historical development, cardiac surgery is a composite of techniques variously applied to various components of the heart, these techniques having markedly different origins.

Surgery of the valves originated with 19th century European physiologists and pathologists, such as Julius Cohnheim (1839–1884), Edwin Klebs (1834–1913) and Ottomar Rosenbach (1851–1907), who was Cohnheim's pupil. Their contributions have been discussed in previous issues of this Journal.[1–4]

Directly in the line of development is Salomon Stricker (1834–1898), a student of histology, experimental pathology and philosophy. The following excerpts have been translated from Stricker's Vorlesungen über Allgemeine und Experimentelle Pathologie (Lectures on General and Experimental Pathology, Vienna, Braumüller, 1883, pp. 805 ff). This book is dedicated to Carl von Rokitansky, the illustrious Austrian pathologist.

Excerpt from Stricker's Lecture

Let us now illustrate the conditions as they shape themselves in some pathological states of the heart. Let us posit the case that the atrioventricular valves—specifically the mitral valve—are insufficient.

With normal atrioventricular valves the intracardiac pressure begins to rise with the onset of systole. According to dominant doctrine it must increase until it is able to overpower the aortic pressure and open the semilunar valves.

If the mitral valve suddenly becomes insufficient, in the moment in which the ventricle begins to become smaller the blood must be shunted toward the atrium, where the pressure normally is much lower than in the aorta.

If the exit through the atrioventricular orifice were large enough to let the blood be shunted to such a degree when the ventricle becomes smaller, one would have to surmise that the semilunar valves do not open until the pressure in the left atrium is greater than the pressure in the aorta and that the ventricular blood encounters less resistance at the semilunar valves than at the atrioventricular ostium and left atrium.

This study was based on research assisted by the National Institutes of Health (Grant HL-10948).

Address for reprints: Saul Jarcho, MD, 35 E. 85th St., New York, N. Y. 10028.

This speculation was aroused by a chance observation. In the course of their comparative investigations on the pressures in the two circulations, Openchowsky and Wagner on one occasion came upon an animal in which the pressure in the pulmonary artery was somewhat higher than in the aorta. The autopsy revealed the presence of mitral insufficiency. Now if in certain degrees of mitral insufficiency the pressure in the pulmonary artery were actually greater than that in the aorta, one would have to surmise that the pressure in the left atrium also was abnormally high and that during systole in the moment in which a new quantum of blood is thrown into the atrium, the pressure there rises as much as is necessary to open the semilunar valves.

The symptom complex that is observed in cases of mitral insufficiency is not incompatible with this hypothesis. The hypertrophy of the right ventricle and the accentuation of the second heart sound at the pulmonic area make us suspect elevation of pressure in the lesser circulation.

Skoda, the discoverer of accentuation, has also evaluated this phenomenon in the same way. On the other hand, in severe mitral insufficiency the arterial pulse is usually small and easily compressible.

Thus, when the clinical evidence allows one to surmise that the pressure in the pulmonary artery rises and the aortic pressure falls, it would be admissible to suspect that that chance observation in a dog corresponds to the state of affairs in mitral insufficiency. Meanwhile a correctly arranged experiment did not give the expected answer to the questions that have been raised here.

When I open the thorax of a large dog by resecting a few ribs on the left side, I can very readily introduce a suitable cannula* through the left auricle and advance it into the ventricle. Then I tie it to the auricle so as to make the communication between ventricle and atrium continuous. After the introduction and attachment of a cannula of this kind, you can see how the atrium and auricle fill with each ventricular systole. By placing a finger over the left atrium you can also feel a distinct whirr, a sure sign that the ventricle is discharging part of its contents into the atrium.

In one instance the experiment gave the following result. Before the insufficiency was produced, the pressure in the pulmonary artery was very low (about 20–25 mm of mercury); the pressure in the aorta was 160. Now the staying power of the left ventricle was tested by interruption of respiration. After this test the aortic pressure sank to 110 mm during regular respiration. Now the insufficiency was produced. The aortic pressure fell another 40 mm; naturally, I

* The cannula is provided with several holes at its sides; the end can be occluded by a tap.

cannot tell whether this was due to the insufficiency or to bad handling of the ventricle. The pressure in the pulmonary artery did not rise. The recording was continued for an additional 15 minutes. At the end of the experiment the pressure in the pulmonary artery was about as high as at the beginning. After the insufficiency was established I interrupted the respiration once more. The pressure in the aorta rose to 180 mm in 40 to 50 seconds. There was a scarcely perceptible elevation of pressure in the pulmonary artery.

In the few experiments which I have carried out after this one, the conditions were not always the same. For example, in one experiment, after the establishment of insufficiency the aortic pressure was not higher than the pulmonic.* With the interruption, however, the aortic pressure rose very considerably; thus conditions were produced such as I have already described.

In the last mentioned experiment in the presence of low aortic pressure the whirr (the systolic backflow of blood into the atrium) was very weak; it became distinctly stronger when the aortic pressure increased. Thus the regurgitating stream must increase with increasing aortic pressure. This fact is especially important.

We know that, especially in mild cases, mitral insufficiency is well tolerated as long as the patient leads a quiet life but that when any strenuous work is performed—e.g., stair-climbing—dyspnea and palpitation occur. Patients who have severe insufficiency do relatively well only when they are in bed; even walking about in the bedroom arouses agitation of the heart.

What is the reason for this?

I stated previously that every muscular action is associated with elevation of blood pressure. In mitral insufficiency the causes of the elevation do not cease, since the elevation is dependent on contraction of the small blood vessels. But the task of the ventricle increases when the mitral valve is insufficient, in another relation than exists when the valve is normal. When the aortic pressure is increased, the opening of the semilunar valve becomes more difficult and the blood regurgitates in greater amount against the *locus minoris resistentiae,* i.e., into the atrium. Indeed it would flow there entirely if there were not some sort of compensation, by which the semilunar valve is nevertheless opened. But of what does this compensation consist? For the present I can only answer speculatively.

I have here a model in which the heart is represented by a rubber ball. This ball is open at two sides. On one side it leads to a system of tubes equipped with a manometer. This opening has a valve which opens the way the semilunar valve opens, i.e., toward the system of tubes. By means of a screw I can regulate the outflow from the system of tubes. I can make it narrower or wider and I can close it off altogether. In this way I can imitate the changes in the lumina of the small arteries. The other opening of the ball leads to a reservoir. This opening has no valve. The reservoir represents the atrium together with the lesser circulation, against which the ventricle has no valve—i.e., even less than an insufficient valve.

Now when I squeeze the ball rhythmically in imitation of ventricular systoles, I drive the water, which is dyed blue and which fills my reservoir and the balloon, into the blindly† ending system of tubes until it is itself under a certain pressure. As soon as this pressure has been reached, no more fluid passes into the system of tubes. Compression empties the balloon just as before, but the fluid goes back into the reservoir. However I can also drive fluid immediately into the system of tubes when I compress the ball more quickly than before. If I increase the speed of compression I also increase the filling of the system of tubes despite the continually increasing pressure, despite the insufficiency or despite the open communication with the reservoir, which is under lower pressure.

Doubtless in the heart with an insufficient mitral valve the same possibility exists of driving the blood into the aorta despite the fact that a much higher pressure prevails there than in the atrium. By turning speed into pressure the ventricle must only contract with corresponding speed in order to produce the pressure necessary to open the semilunar valve.

In this work, however, a greater task is imposed on the heart. When the pressure suddenly rises further, the ventricle must contract more rapidly in order to be able to open the semilunar valves. In the presence of this greater task quicker exhaustion is intelligible.

The experimental study that I have reported on this occasion concerns only insufficiency that arises acutely; there can be no question of compensation such as is found in man. When we find hypertrophy of the right heart in the presence of mitral insufficiency and, still more distinctly, in the presence of stenosis of the left atrioventricular orifice, this hypertrophy is doubtless the sequel of prolonged restriction of the outflow of blood from the lesser circulation.

Meanwhile I have noticed, not unintentionally, that 15 minutes after establishment of the insufficiency the pressure in the pulmonary artery has not yet risen. This experiment, I wish to suggest, gives us no conclusion as to how rapidly complications and compensations go into effect.

Physicians assert that insufficiency which takes onset acutely can quickly lead to death. Experiment gives us no conclusion as to this also. From the course of the pressure curve in the first 15 minutes after the establishment of insufficiency it cannot be inferred that the circulation must become fatigued. Hence it is permissible to surmise that in cases in which insufficiency arising acutely leads rapidly to death, the fatal result is caused not by insufficiency alone but by other complications. For example, when myocarditis is present and the heart muscle cannot permanently cope with the new burden that is put upon it by the insufficiency, a cause of death might very well be present. Large masses of exudate in the pericardial cavity might also act in the same way as myocarditis, inasmuch as they make pressure against the muscle of the heart and the heart cannot dilate when it is burdened by external pressures.*

Comment on Excerpts from Stricker

The foregoing passages, a small excerpt from a large book, contain several aspects that deserve comment. We notice first that knowledge of physiology had reached a degree of development such that it had become possible to consider the functions of individual chambers of the heart and to study these func-

* In this instance the pressure was very low before the insufficiency. In addition, the communication between the ventricle and the atrium was very wide, since I had modified the cannula.

† I draw the blind end through the screw-clamp; this is useful for the present experiment.

* For the heart of the frog Morro and Pagliani have shown that a pressure of 20 cc of water is sufficient to prevent diastolic filling. Francois-Franck introduced fluid into the pericardial cavity under slight pressure and found that very important deleterious effects occurred, e.g., diminution of the arterial pressure and elevation of the venous pressure.

tions quantitatively. Unlike some of the earliest workers who had been content to measure carotid arterial pressures alone during experiments on valves, Stricker made simultaneous determinations of pressure in the pulmonary artery and aorta. Second, it is observable that clinical reasoning had attained a comparable degree of sophistication, as is shown by the remarks about the pathogenesis of pulmonic accentuation.

We may notice also that Stricker's observations on canine cardiac physiology were made with constant reference to conditions found in human disease. For example, Stricker was obviously aware that in mitral disease of intermediate severity the patient is tolerably comfortable at rest but readily becomes dyspneic on exertion. He also was familiar with the clinical picture produced by myocarditis and with that produced by large pericardial exudates.

It is further of interest that Stricker illustrated his lecture by means of a rather elaborate model, consisting of a rubber ball, tubes, valves and a reservoir. These models have a long history, in association with which we might mention the names of von Basch and MacCallum. It is even possible that something similar may be traceable in the writings of the iatrophysicists who followed Galileo.

Paroxysmal Atrioventricular Block Related to Phase 4 Bilateral Bundle Branch Block

GIANNI CORRADO, MD
RAÚL J. LEVI, MD
GERARDO J. NAU, MD
MAURICIO B. ROSENBAUM, MD

Buenos Aires, Argentina

Repeated episodes of paroxysmal atrioventricular (A–V) block were recorded from a 78 year old woman with Stokes-Adams seizures. After a single or occasionally two consecutive and conducted atrial extrasystoles, all the succeeding P waves were blocked. Normal A–V conduction was resumed only when a P wave fell within a certain time interval after a ventricular escape beat. Three A–V conduction phases were identified: an early phase of A–V block, a late phase of A–V block and an intermediate phase during which A–V conduction was preserved. Within the phase of preserved A–V conduction, three intraventricular conduction subphases were found: an early phase of incomplete left bundle branch block, an intermediate phase of normal intraventricular conduction (mixed with incomplete right bundle branch block) and a late phase of high grade right bundle branch block. Thus, conduction was initially impaired more or only in the left bundle and, as the R–P intervals increased, conduction deteriorated progressively in both bundle branches but at a higher rate in the right bundle, until conduction failed totally in both bundle branches. This case, a complex variant of paroxysmal A–V block, seems to be the first reported instance of enhanced diastolic depolarization occurring in both bundle branches simultaneously and giving rise to phase 4 bilateral bundle branch block.

Phase 4 paroxysmal atrioventricular (A–V) block is a variety of A–V block in which normal A–V conduction is suddenly interrupted whenever an atrial impulse falls relatively late in diastole.[1] Normal A–V conduction is reestablished only after a ventricular escape beat, provided a P wave falls within a limited interval immediately after this beat. This form of A–V block has been related to the existence of hypopolarization and spontaneous diastolic depolarization in one population of cells of the affected fascicle. However, another population of cells may show prolonged recovery, giving rise at the same time to phase 3 A–V block.[1] Thus, in such cases two phases of A–V block tend to occur: an early phase of tachycardia-dependent or phase 3 block and a late phase of bradycardia-dependent or phase 4 block. Normal A–V conduction occurs between these phases.[1] In most cases, the paroxysmal A–V block is precipitated by sinoatrial slowing when a delayed P wave falls late during phase 4 block. In some cases, the paroxysmal A–V block is triggered by a premature beat when the postextrasystolic P wave falls sufficiently late. Most commonly, the lesions responsible for the paroxysmal A–V block occur in one bundle branch when there is total interruption of conduction in the contralateral branch.[1]

In this report we analyze a case of paroxysmal A–V block in which hypopolarization and spontaneous diastolic depolarization seemed to occur simultaneously in both bundle branches. This event gave rise, in addition to paroxysmal A–V block precipitated by atrial extrasys-

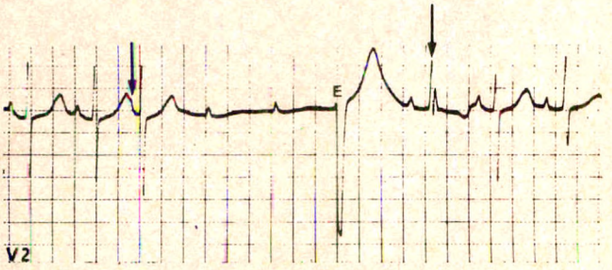

FIGURE 1. Typical episode of paroxysmal A–V block. The first two beats show 1:1 A–V conduction, with a P–R interval of 0.16 second and a normal QRS configuration. An atrial extrasystole **(first arrow)**, with an R–P interval of 0.28 second is conducted with a P–R interval of 0.10 second and a pattern of incomplete left bundle branch block. The next two P waves are blocked and, after an interval of 1.76 seconds, an escape beat (E) occurs (with a pattern of left bundle branch block) and 1:1 A–V conduction is reestablished. The first beat after the escape beat shows high grade right bundle branch block **(second arrow)**.

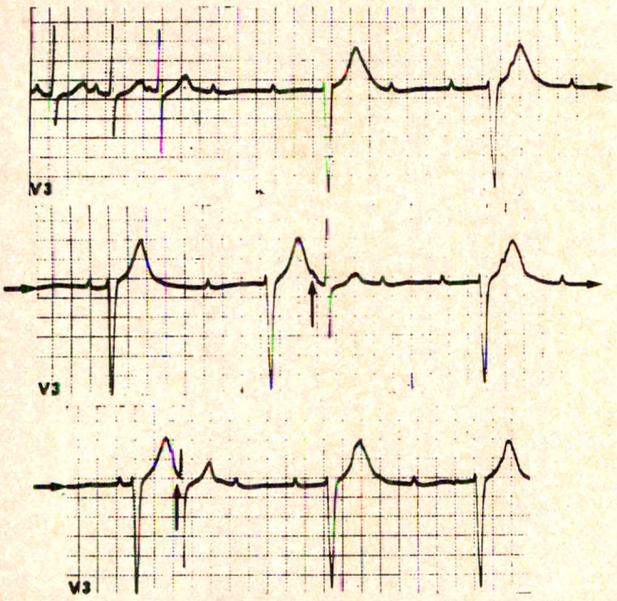

FIGURE 2. Episode of paroxysmal A–V block of longer duration. The three strips are continuous. The A–V block is preciptated by a single atrial extrasystole (third beat). All the P waves are blocked, except for two **(arrows)** that fall at an appropriate distance after the idioventricular beats.

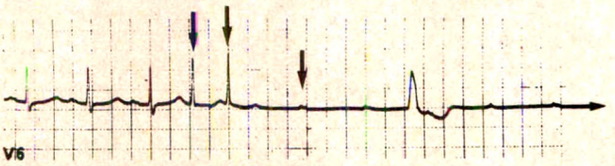

FIGURE 3. Paroxysmal A–V block precipitated by two consecutive atrial extrasystoles. The first three beats are of sinoatrial origin, with 1:1 A–V conduction. Then, two atrial extrasystoles occur **(arrows)**, the first, with an R–P interval of 0.32 second, and the second, with an R–P interval of 0.28 second. Both are conducted with a short P–R interval of 0.13 second. The paroxysmal A–V block begins with the first postextrasystolic P wave **(third arrow)**.

toles, to a complex array of conducted impulses showing different degrees of right or left bundle branch block with different degrees of prolongation of the P–R interval.

Report of Case and Analysis of Electrocardiograms

A 78 year old woman was hospitalized because of Stokes-Adams seizures of short duration, which had started 4 days previously. No other clinical or laboratory abnormalities were present. A long electrocardiographic tracing revealed a sinoatrial rhythm with a rate of approximately 100/min, a changing P–R interval and a QRS complex with a pattern ranging from normal to incomplete right bundle branch block. In addition, there were atrial extrasystoles, most of which precipitated episodes of paroxysmal A–V block. Twenty episodes were recorded and, with slight variations, all began and ended in the same way. Figures 1 to 3 illustrate three episodes. In Figure 1, the paroxysmal A–V block is precipitated by an atrial extrasystole that is conducted to the ventricles with a pattern of incomplete left bundle branch block (first arrow). The block is of short duration because A–V conduction reestablished in the first P wave after the first escape beat. The first beat reestablishing A–V conduction shows a pattern of right bundle branch block (second arrow). In Figure 2 the paroxysm is also provoked by a single atrial extrasystole, but is of longer duration because the P waves after the escape beats are not conducted except for the two marked by arrows. In Figure 3 the episode is triggered by *two* consecutive atrial extrasystoles, both conducted (first two arrows). This figure demonstrates that, if it is sufficiently late, the P wave after an atrial extrasystole actually initiates the paroxysmal A–V block. In all the episodes, whenever a single P wave is

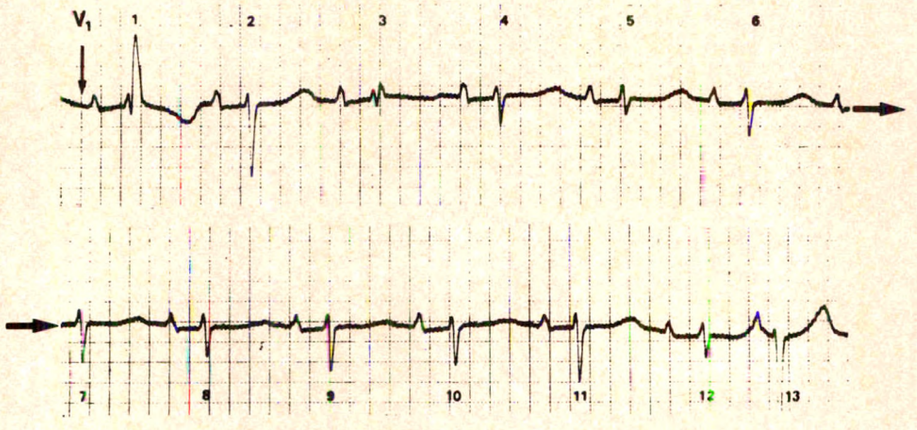

FIGURE 4. Different types of intraventricular conduction. The two strips are continuous and were recorded at a paper speed of 50 mm/sec and with a calibration of 20 mm/mv. Beat 1 shows a high degree of right bundle branch block; beat 3 shows a lesser degree, and beats 4, 5 and 12 a still lesser degree, which can only be recognized by comparison with the normal beats (6 to 10). Beats 2 and 13, and perhaps also beat 11, show different degrees of incomplete left bundle branch block.

blocked, all the succeeding P waves are also blocked. Figures 1 to 3 also show that all the P waves that fall either early or late after the escape beats are blocked, whereas P waves falling at an intermediate distance are conducted. The QRS configuration of the conducted beats varies according to the atrial rate or the coupling of the premature impulses or the R–P interval after the escape beats. Thus, several different QRS patterns, ranging from normal to different degrees of right and left bundle branch block, can be observed in a single tracing (Fig. 4).

The P–P, R–R, P–R and R–P intervals were measured and the latter were correlated with both atrioventricular and intraventricular conduction (Fig. 5). The most important findings were as follows: (1) All atrial impulses with an R–P interval shorter than 0.28 second were blocked (first arrow). (2) Atrial impulses with an R–P interval of 0.28 to 0.40 second were conducted to the ventricles with a relatively short P–R interval (0.10 to 0.14 second) and a pattern of incomplete left bundle branch block (second arrow). (3) Atrial impulses with an R–P interval of 0.41 to 0.48 second were also conducted, but with an average P–R interval of 0.165 second and a QRS pattern varying between normal and incomplete right bundle branch block (third arrow). (4) Atrial impulses with an R–P interval of 0.50 to 0.68 second were conducted with an average P–R interval of 0.18 second and a pattern of high grade or complete right bundle branch block (fourth arrow). (5) Some atrial impulses with an R–P interval of 0.56 to 0.68 second and all atrial impulses with an R–P interval greater than 0.68 second were again totally blocked (fifth arrow).

Ranges of A–V conduction: Figure 5 shows that both early and late atrial beats were blocked; intermediate atrial impulses were conducted to the ventricles. Thus, three A–V conduction phases were present: (1) a phase of early A–V block (black bar to the left), (2) a phase of late A–V block (black bar to the right), and (3) an intermediate phase of preserved A–V conduction (white bar). This distribution is similar to that described in paroxysmal A–V block[1] as well as in intermittent bundle branch block,[2] thus suggesting participation of the same electrophysiologic mechanisms. Accordingly, the black bar to the left corresponds to phase 3 block, and the black bar to the right corresponds to phase 4 block.[1,2] Moreover, an "accordion effect" which so well describes the fact that the two phases of block seem to compress the intermediate conduction range has also been

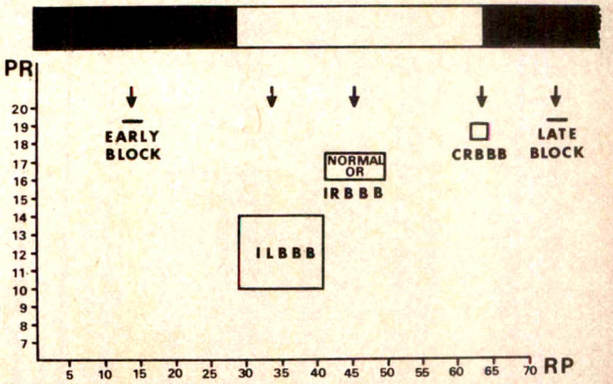

FIGURE 5. Relation between R–P **(abscissa)** and P–R intervals **(ordinate)**, in hundredths of a second. Total A–V block occurs after the shortest **(first arrow)** and after the longest **(fifth arrow)** R–P intervals. In addition, the R–P intervals are correlated with the type of intraventricular conduction. CRBBB = high grade or complete right bundle branch block; ILBBB = incomplete left bundle branch block; IRBBB = incomplete right bundle branch block. The **bar** at the top represents the accordion effect. See text.

documented.[1–3] The difference in the present case was that, during the intermediate phase of A–V conduction, the P–R intervals were not constant and increased slightly and progressively from left to right.

In addition, within the intermediate phase of A–V conduction, three subphases could be demonstrated: (a) an early phase of incomplete left bundle branch block, (b) an intermediate phase of normal intraventricular conduction intermingled with incomplete right bundle branch block, and (c) a late phase of high grade or complete right bundle branch block. These three subphases coincided with a progressive increase of the P–R interval. Thus, it appeared that initially A–V conduction was impaired only or more in the left bundle; thereafter, conduction deteriorated progressively in both bundle branches, but more rapidly in the right bundle, until conduction was totally interrupted in both bundle branches.

Ranges of intraventricular conduction: Figure 6 represents an attempt to explain these conduction abnormalities in terms of recovery of excitability and impulse propagation or the possible configuration of the action potentials of the injured fibers in the bundle branches. Thus, early or

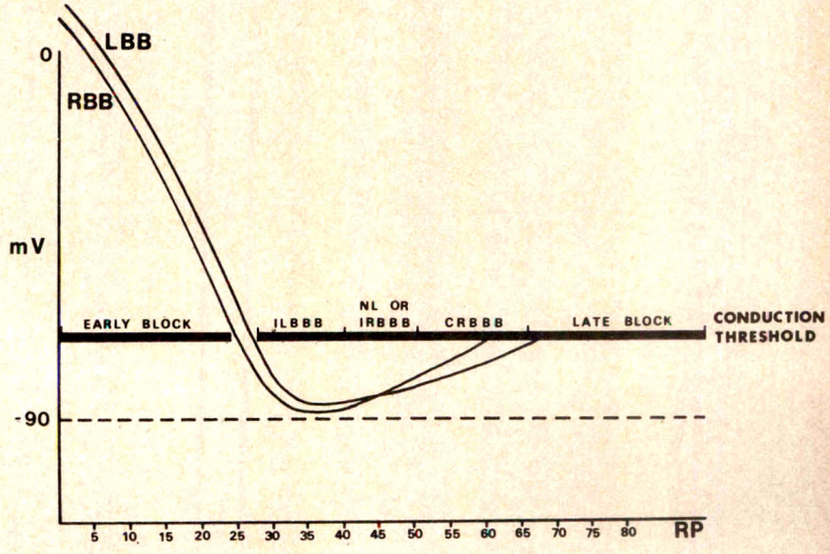

FIGURE 6. Diagrammatic representation of the findings of Figure 5. RBB and LBB represent the recovery curves of the right and left bundle branch, respectively. The two bundle branches are assumed to be hypopolarized and to show an increased rate of diastolic depolarization. The slope of diastolic depolarization is steeper in the right than in the left bundle branch. The **horizontal bar** designated "conduction threshold" corresponds to the critical level of transmembrane potential that separates conduction from total block, during both repolarization and diastolic depolarization. R–P intervals and phases of atrioventricular and intraventricular conduction as in Figure 5. See text.

phase 3 A–V block was related to incomplete recovery in both bundle branches, whereas late or phase 4 A–V block was related to enhanced diastolic depolarization, also in both bundle branches. The subphase of incomplete left bundle branch block was attributed to the duration of the recovery period, which was slightly longer in the left than in the right bundle. The subphase of right bundle branch block was attributed to the slope of diastolic depolarization, which was steeper in the right than in the left bundle. The subphase of normal intraventricular conduction probably corresponded to the moment when the two curves tended to overlap. The beats showing incomplete left bundle branch block were accompanied by an extremely short P–R interval, thereby suggesting that recovery in the right bundle was complete at that moment. The occurrence of only incomplete left bundle branch block of slight degree indicated that recovery in the left bundle was nearly complete. The fact that the P–R interval increased progressively along the A–V conduction range suggested that diastolic depolarization began to increase very early in both bundle branches.

Discussion

Our present case is a peculiar variant of phase 4 paroxysmal A–V block. As in all previously reported cases,[1] the A–V block began when an atrial impulse fell late in diastole; A–V conduction was reestablished only after an escape beat. The basic electrophysiologic mechanisms were also well represented by an accordion effect, with an early or phase 3 A–V block, late or phase 4 A–V block, and an intermediate A–V conduction phase. However, whereas in all previous cases[1] the intermediate phase was a range of *normal* A–V conduction with a constant P–R interval and QRS pattern, in our case it was a phase of *preserved* A–V conduction, during which the P–R interval increased gradually and the QRS pattern changed successively from one of incomplete left bundle branch block to normal, then to incomplete right bundle branch block and finally to high grade right bundle branch block.

In previous cases,[1] paroxysmal A–V block occurred when prolonged recovery, hypopolarization and enhanced diastolic depolarization took place in one fascicle in the presence of total interruption of the remaining fascicles: hence, an intraventricular conduction system was abnormally transformed into a "monofascicular" system. In our present case, these alterations occurred at the same time in the two main bundle branches, and no fascicle was totally interrupted. Thus this case has important academic value. Indeed, if the described physiologic abnormalities could occur in one single fascicle, it was natural and even necessary that they could occur simultaneously in both bundle branches. Thus, our case is a necessary link in the chain of suggested mechanisms.[1,2]

In paroxysmal A–V block, the critically injured region responsible for the A–V block has almost invariably been infranodal.[1] The same was true in our present case; moreover, the occurrence of phase 4 right and left bundle branch block in the same patient gave rise to a peculiar variety of bilateral bundle branch block. All previously reported cases of bilateral bundle branch block were examples of phase 3 block.[4] The present case seems to be the first reported example of "phase 4 bilateral bundle branch block."

Although phase 4 block was clearly present in both bundle branches, there was less certainty about phase 3 block. Thus, although the early phase of A–V block was attributed to incomplete recovery in both bundle branches, it is possible that early atrial impulses were blocked in the A–V node. In addition, even if recovery was prolonged, the prolongation was necessarily slight. This is not surprising since in this type of process the greater the injury and hypopolarization, the shorter can be the action potential duration.[1,2] Perhaps for this reason many of the atrial extrasystoles were readily conducted to the ventricles (Fig. 3).

Injury seemed to be slightly greater in the right than in the left bundle for the following reasons: (1) The slope of diastolic depolarization was steeper in the right bundle and, probably for the same reason, the escape beats showed a left bundle branch block pattern (Fig. 1 to 3), thus suggesting a possible site of origin of escape and ectopic beats in the critically injured area of the right bundle. (2) Recovery was completed first in the right bundle. (3) The spontaneous diastolic depolarization seemed to start earlier in the right bundle; however, injury was also important in the left bundle since both depolarization slopes began and reached critical levels for total block very early.

When diastolic depolarization is enhanced, ectopic beats and reentry may occur, although not always and not necessarily. In another report[5] we analyze why increased automaticity and depressed conduction (which are so commonly interrelated) may become dissociated or demonstrate a lack of synchrony.

The gradual increase in the P–R interval during the phase of preserved A–V conduction is interesting because this progression may draw a parallel to the slope of diastolic depolarization, and because it was not seen in other clinical cases of paroxysmal A–V block.[1] However, such progression has been documented in paroxysmal A–V block provoked experimentally in the canine heart (unpublished observations).

Aneurysm of the Left Atrium

THOMAS J. HOUGEN, MD
DONALD G. MULDER, MD, FACC
MICHAEL T. GYEPES, MD
ARTHUR J. MOSS, MD, FACC

Los Angeles, California

Congenital left atrial aneurysm is a rare anomaly that has been reported only five times previously. The usual presenting features include an abnormal chest roentgenogram, an apical systolic murmur and supraventricular tachycardia. Even with cineangiocardiography the diagnosis is uncertain, and the lesion is commonly confused with cardiac tumor. Aneurysmectomy is the preferred treatment and has been successful in all patients undergoing operation. The presence of thrombi in the aneurysm necessitates circulatory assistance during excision.

Aneurysms of the left atrium may be congenital or acquired in origin. They are considered congenital when no predisposing cardiac condition is present. Acquired aneurysms may be secondary to rheumatic mitral insufficiency or stenosis, tuberculosis, syphilitic myocarditis or other conditions leading to abnormal atrial pressures or weakened myocardium.[1–5] Congenital aneurysms involve either the atrial wall (left atrial aneurysm) or the appendage of the atrium (left atrial appendage aneurysm). Five cases of the former[6–10] and 11 of the latter have been recorded.[11–19] Aneurysms of the left atrial appendage are often associated with a pericardial defect and, although more common, are probably of less significance. Since the case to be presented is that of an aneurysm of the left atrial wall, discussion will be limited to this type of lesion.

Case Report

The patient, a 13 year old girl, presented initially at age 1 year with congestive heart failure. Cardiomegaly was noted on the chest roentgenogram, and the electrocardiogram showed left atrial and left ventricular hypertrophy. Cardiac catheterization and angiocardiography revealed a large left atrium with no associated valvular or septal defects. Diminished cardiac pulsations were observed. The diagnosis could not be established with certainty, but it was presumed that the child had endocardial fibroelastosis.

The heart failure responded to decongestive measures, and the patient's condition remained stable for several months. However, because of persistent cardiomegaly and exercise intolerance, cardiac catheterization was repeated at age 2 years. A large left atrium was again demonstrated, but this time overt mitral insufficiency was present. Although the patient's clinical condition remained satisfactory, a reassessment of her cardiac status at age 9 was believed indicated. The previous findings were confirmed with no new observations. It was elected to discontinue administration of digoxin at that time.

One year later the patient complained of episodes of palpitation followed by syncope. She was hospitalized, and supraventricular tachycardia was documented. The arrhythmia responded promptly to treatment with digoxin, and she was discharged on maintenance dosage. There were numerous recurrent episodes of arrhythmia (atrial fibrillation and supraventricular tachycardia) and in four instances, these were severe enough to require hospitalization. These were treated by adjusting the dose of digoxin and adding oral propranolol.

At age 13 years, calcification in the area of the mitral valve was observed on roentgenogram (Fig. 1) which, in retrospect, could be seen in the films obtained 4 years previously. She was admitted to the hospital for further evaluation.

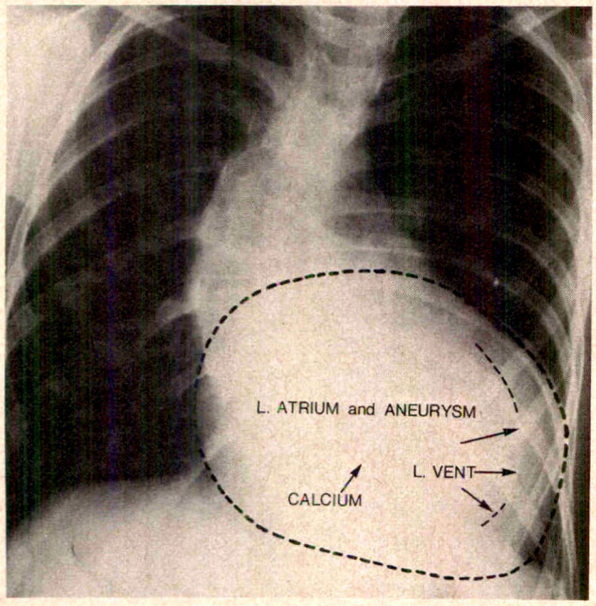

FIGURE 1. Posteroanterior chest roentgenogram. Moderate scoliosis is noted. Most of the cardiac shadow is made up by the enlarged left atrium and the large left atrial aneurysm **(outer dotted line).** The **single arrow** points to the small inner calcification. The **inside curvilinear dotted line (triple arrows)** indicates the site of the bottom of the left ventricle which was later confirmed by angiocardiography and surgery. L. = left; VENT = ventricle.

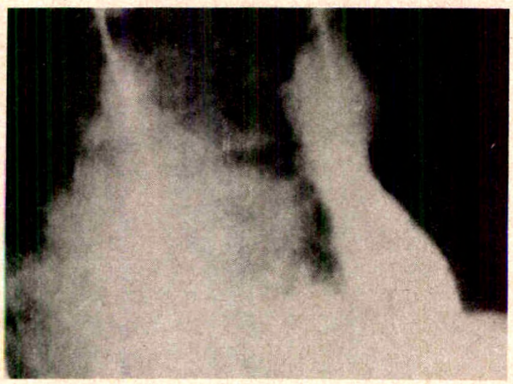
Physical examination on admission revealed a thin adolescent girl with a blood pressure of 90/65 mm Hg. Apical pulse rate was 70/min. The chest was clear to percussion and ausculation. Cardiac examination revealed a regular rhythm with no thrill or abnormal impulse. The first heart sound was soft and the second sound was widely split with the pulmonic component louder than the aortic. A grade 3/6 harsh holosystolic murmur was audible at the apex and radiated into the left axilla. A grade 2/6 early diastolic murmur of low intensity also was heard at the apex. No clicks or extracardiac sounds were audible. There was severe dextroscoliosis of the thoracic spine. Since the possibility of a cardiac tumor could not be excluded, a fourth cardiac catheterization with cineangiocardiography was performed. The findings confirmed the presence of mild mitral insufficiency and demonstrated what was believed to be an aneurysm or tumor of the left ventricle (Fig. 2). The cardiac catheterization findings are summarized in Table I.

Operation was recommended. A median sternotomy was performed, and upon opening the pericardium, an 8 by 12 cm saccular aneurysm of the left atrium was found (Fig. 3). Under cardiopulmonary bypass, the thin-walled aneurysm was opened. No thrombi were present. The atrial appendage was normal and the mitral valve leaflets were slightly thickened. The aneurysm was resected and a 0.5 by 4 cm spicule of calcium arising from the endocardium of the posterior wall of the atrium was debrided. The patient had an uneventful postoperative course. No medications were prescribed on discharge.



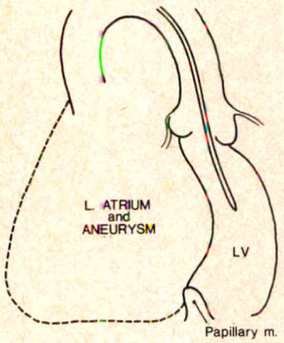


FIGURE 2. Left ventricular angiocardiogram and drawing. The root of the aorta and the left ventricle, visualized by retrograde introduction of the catheter and injection of contrast material, are well delineated. This frame is from the lateral series and clearly shows a very large structure filled with contrast medium that lies directly behind the left ventricle, indenting the ventricular septum. This turned out to be the left atrium and a large left atrial aneurysm. L. = left; LV = left ventricle; m. = muscle.

TABLE I

Cardiac Catheterization Data

	Age 1 Year	Age 2 Years	Age 10 Years	Age 13 Years
	Pressures (mm Hg)			
Left ventricle	NR	92/6	96/11–14	91/13
Ascending aorta	86/54	NR	84/60	85/52 (66)
Pulmonary wedge	NR	16/14	(17)	NR
Pulmonary artery	36/16	33/13	36/20 (22)	25/15
Right ventricle	46/0	37/1	28/1–5	28/7
Right atrium	9–12/3	8/4–12/9	*a* 5; (4) *v* 4	*a* 6; (3.5) *v* 4
Cardiac index (liters/min per m²)	NR	1.8	3.46	4.5

Figures in parentheses indicate mean pressures.
a = *a* wave; NR = not recorded; *v* = *v* wave.

Pathologic examination of the specimen revealed a 5 by 7 cm saccular structure about 1 mm thick. The atrial wall fibers were attenuated with thick fibrous epicardium and hypertrophy of the sparse myocardial fibers (Fig. 4).

In the 6 months since operation, the patient has remained asymptomatic with no episodes of arrhythmia. Serial roentgenograms have shown decreasing cardiomegaly and electrocardiograms show no evidence of recurrence of the arrhythmia.

Discussion

There are several previous reports[1–5,20] of left atrial aneurysm in patients with acquired valvular or myocardial disease. The presence of myocardial disease or chronically increased left atrial pressure, as seen in severe mitral stenosis secondary to rheumatic heart disease,[3] can predispose to development of an aneurysm. The appearance of left atrial aneurysm in early childhood in the absence of any recognized predisposing causes such as congenital heart disease, acquired inflammatory changes or other pathologic processes in the myocardium indicates a congenital origin.

Clinical findings: The clinical data in the six recorded cases (including that reported here) of congenital left atrial aneurysm are summarized in Table II. There were five children (aged 2 to 13 years) and one adult (aged 64 years). Roentgenographic evidence of cardiomegaly or a mediastinal mass was present in each case, and arrhythmia was observed at some time during the course of the disease in five. The origin of the arrhythmia is not known. It may be caused by tension on the conduction system from the enlarged atrial muscle mass, a circus movement phenomenon or a congenital defect in the conduction tissues.[7]

A systolic murmur was present in five cases, the location being apical in four[7,8,10] and not indicated in the one.[6] Two of these patients also had diastolic murmurs[10] suggesting real or relative mitral stenosis; one patient had no cardiac murmur.[9] Lack of angio-

cardiographic evidence of significant mitral insufficiency suggests that aneurysms are probably not secondary to malfunction of the mitral valve.[7,8]

The preoperative diagnosis was cardiac or mediastinal tumor in four of five cases.[6,7,9] One patient had a preoperative diagnosis of left atrial appendage aneurysm,[21] but at operation a left atrial aneurysm was found.[8] Semans and Taussig[10] described a patient who was not operated upon and subsequently died. All five patients treated by resection of the aneurysm recovered from operation and had no further episodes of arrhythmia.

Differential diagnosis: Although children with congenital mitral insufficiency may present features similar to those of left atrial aneurysm, there are some subtle differences. Supraventricular tachycardia with congenital mitral insufficiency is not common. In 33 reported cases of congenital mitral insufficiency,[22–24] the electrocardiogram demonstrated supraventricular tachycardia in only 3. Thus the presence of supraventricular tachycardia and the murmur of mitral insufficiency should lead one to suspect the possibility of left atrial aneurysm. In addition, the degree of enlargement of the cardiac silhouette is usually more striking in the patient with an aneurysm.

Intracardiac tumors, particularly left atrial myxomas, present commonly with cardiomegaly, arrhythmia and a cardiac murmur.[25–31] In 46 cases of cardiac tumors in children,[25,29,30,32,33] 81 percent of the patients had an abnormal cardiac silhouette and 40 percent had cardiomegaly. Cardiac calcifications were noted in 16 percent. There were eight instances of arrhythmia (18 percent): One patient had atrioventricular block,[29] one had nodal extrasystoles,[32] two had ventricular tachyarrhythmias,[30] two had supraventricular tachycardia,[25,30] and in two the type was not described.[33] A systolic murmur, usually apical, was present in 24 of the 46 cases (52 percent). Nineteen patients (41 percent) had both systolic and diastolic murmurs. Systemic embolization, a common presenting sign of cardiac tumor, was documented in 19 (41 percent) patients.

The type of arrhythmia may prove helpful in distinguishing left atrial aneurysm from cardiac tumor. It seems that supraventricular arrhythmias are more often associated with left atrial aneurysm, and ventricular arrhythmias are more often associated with ventricular tumors.

Angiocardiography is the most accurate means of distinguishing left atrial aneurysms from isolated congenital mitral insufficiency or cardiac tumor. Even with these studies, the diagnosis in some instances can be established only by operation.

Complications and management: Left atrial aneurysm is a potentially lethal disease even in the asymptomatic patient. The threat of embolization is always present and, although no instance of embolization has been recorded, the presence of thrombi in two patients indicates that this is a potential hazard. Serious arrhythmias do occur in most patients with this condition and are potentially fatal. Spontaneous rupture of the left atrium has not been reported, but it seems reasonable to assume that a huge atrial aneurysm is vulnerable to either spontaneous or traumatic rupture.

Operative excision, even in the asymptomatic patient, is the treatment of choice. Cardiopulmonary bypass is essential for the excision of left atrial aneurysm since it involves a major portion of the atrial chamber and mural thrombi may be present. This is in contrast to treatment of appendage aneurysms which can be amputated without use of circulatory support. The risk of operation is low, and the probability of eliminating future embolic episodes and arrhythmas is good.

Addendum

Eleven months after operation, the patient experienced two episodes of tachycardia highly suggestive of paroxysmal atrial tachycardia without electrocardiographic documentation. Repeat heart catheterization and angiography demonstrated mild mitral stenosis and mild mitral insufficiency. The patient was discharged without medication and continues to do well.

Acute Dissecting Aortic Aneurysm Resulting from Retrograde Brachial Arterial Catheterization

Successful Operative Intervention

HARRY A. WELLONS, Jr., MD
RAJINDAR SINGH, MD

Charlottesville, Virginia

A case of type I aortic dissection occurring as a complication of retrograde catheterization of the right brachial artery is described. The problem was immediately identified and, after appropriate studies were performed, operative intervention was successfully carried out. Although this lesion is an extremely rare complication of the catheterization procedure, the possibility of its occurrence must be kept in mind. Prompt recognition, accurate diagnostic evaluation and immediate operation can result in a successful outcome.

Dissecting aneurysm of the aorta resulting from retrograde cardiac catheterization is a rare complication. Several prospective and retrospective studies[1–8] have documented the incidence of major and minor complications of catheterization and angiographic procedures. Although localized aortic dissection and subintimal injections of contrast material have been reported, little mention has been made of dissections of surgical significance. The following case is presented to emphasize this potential hazard and the importance of its immediate recognition and prompt treatment.

Case Report

A 55 year old white man was admitted to the University of Virginia Hospital on November 1, 1970 for evaluation of recurrent episodes of chest pain and syncope. In the year before admission his symptoms gradually increased in frequency; an evaluation by his local physician revealed a cardiac murmur suggestive of aortic stenosis.

Physical examination revealed a well developed, well nourished white man. Blood pressure was 160/100 mm Hg, pulse 80/min and regular. Examination of the heart revealed a thrill at the upper right sternal border and a grade 4/6 systolic murmur in the aortic area. Peripheral pulses were strong and equal bilaterally; no bruits were present.

An electrocardiogram revealed sinus tachycardia and evidence of left ventricular hypertrophy. A chest roentgenogram was noncontributory (Fig. 1A), but fluoroscopic examination revealed calcification in the area of the aortic valve.

The initial clinical diagnosis was calcific aortic stenosis and possible coronary artery disease. On November 4, 1970 the right brachial artery was catheterized with a no. 7F National Institutes of Health catheter. As the catheter was advanced into the area of the innominate artery, the vessel was noted to be extremely tortuous. In an attempt to delineate the course of the artery before advancing the catheter, small amounts of contrast material were injected and appeared within the wall of the subclavian artery. Almost immediately, the patient complained of severe chest pain requiring administration of narcotic agents. Because further fluoroscopic observation suggested widening of the superior mediastinum, the procedure was terminated. Although pain continued, the patient's vital signs remained stable. A chest roentgenogram confirmed widening of the mediastinum and suggested a double shadow of the aortic knob. The pain persisted and radiated to the back. Four hours later, hypotension developed and a repeat chest roentgenogram showed further widening of the mediastinum (Fig. 1B). Aortic dissection with developing cardiac tamponade was suspected, and a retrograde femoral aortogram was

immediately performed. This revealed a dissection of the aorta beginning at the aortic root and extending throughout the length of the thoracic and abdominal aorta (Fig. 2). The presence of intraluminal extravasation and dissection into the innominate artery suggested that the dissection originated in this area. Because of continued hypotension and paradoxical pulse, immediate operation was performed.

Exploration through a median sternotomy revealed blood in the pericardial sac and tamponade. After appropriate cannulation, cardiopulmonary bypass was begun, and the ascending aorta was cross-clamped just proximal to the innominate artery. The aorta was opened and transected at the level of the intimal tear. The distal end of the aorta was oversewn with a running suture, obliterating the false lumen. The aortic valve was congenitally deformed and heavily calcified, although only mildly stenotic. The dissection had detached the right coronary cusp, and it was believed that repair would not result in a satisfactorily functioning valve. A no. 13 Starr-Edwards aortic prosthesis was inserted and aortic continuity restored by interposition of a short segment of woven Teflon® graft. Perfusion of the left coronary artery had been maintained throughout the procedure, and cardiopulmonary bypass was discontinued

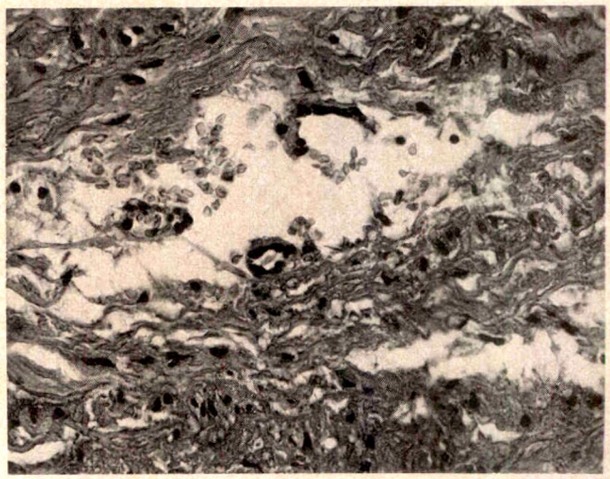

FIGURE 3. Photomicrograph of aortic media showing cystic medial degeneration with hemorrhage from ruptured vasa vasorum. The basophilic ground substance, easily seen in the slide, is not evident in the black and white photograph. Hematoxylin-eosin ×520, reduced by 26 percent.

without difficulty. In the immediate postoperative period, the patient's course was complicated by an episode of pericardial tamponade that required opening the lower end of the incision and evacuation of collected blood. The patient's condition then stabilized, and the remainder of the postoperative course was uneventful. He was discharged on the 11th postoperative day in satisfactory condition and has had no recurrent episodes of syncope or chest pain since discharge. On his last visit, 18 months postoperatively, he was doing well.

Pathologic examination of the resected specimen of aorta revealed atherosclerosis and focal mucoid degeneration in the media (Fig. 3). Examination of the aortic valve revealed thickening and calcification.

Discussion

In a cooperative, prospective study involving 12,367 catheterization procedures, there was a 3.6 percent prevalence of major complications.[1] Of the arterial complications, the most common was thrombosis. Only seven cases of dissection occurred.[2] Three local coronary arterial dissections resulted in two myocardial infarctions and one death[3]; of four localized dissections of the intrathoracic great vessels, only one required operation for obstruction. A report of 53 complications of left heart catheterization over a 36 month period noted 12 episodes of local peripheral arterial dissection of which 3 required repair,[8] two for occlusion of a peripheral vessel. Lang[4] reported a survey of 11,402 percutaneous retrograde angiographic procedures revealing a major complication rate of 0.7 percent. Local dissection is mentioned only as a causative factor in peripheral arterial obstruction. As a minor complication, intramural or subintimal injection of contrast medium was frequently reported, having occurred in 136 instances without sequelae. In several other large series reviewed, no mention is made of dissection as a major complication.[5–7]

In 1972, Cooley et al.[9] reported successful treatment of an ascending aortic dissection that occurred during coronary angiography. In their case, catheterization of the left brachial artery was followed by pain and resistance at the level of the innominate artery. After removal of the catheter, coronary angiograms obtained by the percutaneous femoral approach, disclosed severe coronary artery disease and the patient was referred for operative intervention. At operation, a dissection of the ascending aorta was found and repaired with a Dacron® patch. Saphenous vein bypass grafts from the prosthesis to the right coronary artery and the left anterior descending vessel were also performed. The patient had an uneventful recovery.

The mechanism of spontaneous aortic dissection is not established but is dependent on preexisting degenerative disease in the aortic media. The event is probably started by hemorrhage into an area of medial necrosis with extension of the dissection developing in part by expansion of the hematoma. Alternatively, the hematoma may rupture through the intima and allow the entrance of blood under pressure to extend the dissection. Experimental studies have demonstrated that separation of the media in a normal aorta requires such high injection pressures that it can be concluded dissection cannot occur in the absence of medial disease.[10] Dissection has been produced experimentally in dogs with a normal aorta, but the clinical appearance and course were not similar to those observed in man.[11]

Since subintimal injections frequently occur in catheterization procedures without significant complications or dissection, it seems reasonable to assume that degenerative medial disease is a prerequisite for dissection. This was the situation in the case reported here since pathologic examination revealed focal mucoid degeneration, a finding typically seen in cystic medial necrosis. Presumably the process is initiated by subintimal injection of contrast material. If a vessel diseased by degenerative changes is involved, this may be enough to start the dissection. The dissection may be self-limiting or, as demonstrated in our case, an intimal tear may occur and result in progressive and complete aortic dissection.

Clinical implications: As an increasing number of patients with advanced atherosclerosis undergo catheterization for evaluation of coronary artery disease, the existence of diseased and tortuous peripheral vessels must be appreciated. If a difficult catheterization occurs, extreme care must be taken in manipulation of the catheters and careful hand injections of small volumes of contrast material utilized to assess the situation. In spite of adherence to the principles of careful technique, aortic dissection can occur. It is imperative that the problem be recognized immediately and that appropriate diagnostic studies be obtained. Typical signs and symptoms of a dissecting aneurysm may be observed. Serial chest roentgenograms should reveal the appearance of a double shadow in the area of the aortic knob or progressive mediastinal widening. Once the diagnosis is suspected, angiograms must be obtained for confirmation. Surgical intervention should be considered if the appropriate indications are present. These include pericardial tamponade, severe aortic insufficiency, progressive pain, persistant hypotension or major peripheral vascular obstruction. Prompt and aggressive surgical intervention can be effective and life-saving. The case we have described and that reported by Cooley et al.[9] demonstrate that simultaneous correction of a coexisting problem such as valve replacement or coronary artery bypass grafting can be performed successfully.

Successful Total Repair of Interrupted Aortic Arch Associated With Ventricular Septal Defect and Large Patent Ductus Arteriosus

JACQUES G. LOSMAN, MD
HYMIE S. JOFFE, MB, ChB
WALTER BECK, MSc, FRCP
CHRISTIAAN BARNARD, MD, FACC

Cape Town, South Africa

Successful total repair in one procedure was performed in a case of interrupted aortic arch associated with ventricular septal defect and large patent ductus arteriosus. The surgical technique is described and results of postoperative angiography are analyzed. The literature and results of previous surgical attempts at correction are reviewed.

The complex malformation of interrupted aortic arch associated with ventricular septal defect and large patent ductus arteriosus feeding the descending aorta is a rare condition that has seldom been successfully repaired.[1–3] A case, in a young 8 year old boy, presented an opportunity to review the literature on this defect and evaluate recent progress in treatment.

Case Report

A cardiac lesion was detected in a boy soon after birth after a full-term, normal pregnancy and delivery. The weight at birth was only 2.5 kg, and growth was slow and marked by repeated chest infections. Later the child experienced shortness of breath while playing or running, and was constantly underweight in relation to his age and size. In 1968 at age 5 years he was admitted to the hospital for treatment of a respiratory tract infection.

On examination the child was markedly underweight and was in considerable respiratory distress. There was no cyanosis or clubbing. The blood pressure in the right arm was 160/110 mm Hg; all pulses were equally palpable. Examination of the lungs revealed consolidation of the left lower lobe and crepitation in both lungs. A fairly prominent central sternal bulge was present, and cardiac examination showed signs of gross cardiomegaly with left and right ventricular hypertrophy. There was a systolic thrill over the precordium; a grade 5/6 pansystolic murmur was maximal at the lower left sternal border, and a grade 2/4 mid-diastolic rumbling murmur at the apex. The second heart sound was not split, but it was markedly accentuated. The electrocardiogram showed biventricular hypertrophy and the chest X-ray film marked cardiomegaly, considerable pulmonary plethora and left lower lobe consolidation. The clinical diagnosis was ventricular septal defect with a large left to right shunt and marked pulmonary hypertension. The increased blood pressure was attributed to peripheral vasoconstriction. The pneumonia responded to medical treatment.

Cardiac catheterization: One year later data obtained at cardiac catheterization revealed a ventricular septal defect with a left to right shunt of 44 percent and a right to left shunt of 19 percent. The pressure in the right ventricle was equal to that in the descending aorta but only half that in the left ventricle. The pulmonary vascular resistance was normal, but angiograms showed an interruption of the aortic arch (Fig. 1) between the left carotid and left subclavian arteries (Celoria and Patton[4] type B) (Fig. 2). A patent ductus arteriosus was connected to the descending aorta, and there was a small bidirectional shunt through the ductus. The aortogram showed large,

tortuous internal mammary arteries feeding the left subclavian artery through collateral vessels. There was delayed filling of the aorta through these connections. Contrast material refluxed into the patent ductus during diastole, and during systole the flow appeared to be from the ductus to the descending aorta (Fig. 1C).

Subsequently, the child was readmitted twice for upper respiratory tract infections and it was noticed that signs of congestive cardiac failure had developed and the blood pressure had increased. The pressure in the right arm was now 200/100 and in the left arm 100/65 mm Hg. There was no radial femoral pulse delay. The patient was treated with digitalis and diuretic agents and underwent surgical correction.

Surgical repair: At operation a left posterolateral thoracotomy was performed to divide the ductus arteriosus and to make an end to end anastomosis between the descending aorta and a 1/2 inch Dacron® vascular graft. A median sternotomy was performed (Fig. 3). The patient was placed on total cardiopulmonary bypass, and the ventricular septal defect was closed with a 1 1/2 by 2 1/2 cm Teflon® felt patch. During rewarming the Dacron vascular graft was pulled into the anterior mediastinum, through a window in the pericardium above the left phrenic nerve, and was anastomosed end to side to the proximal part of the ascending aorta (Fig. 3). Bypass was discontinued. The patient was routinely ventilated for the first 24 hours after operation.

The child made an uneventful recovery apart from severe systemic hypertension in the early postoperative period, with a systolic blood pressure increasing at times to 260 mm Hg. This condition was treated medically and was

abolished completely 12 days postoperatively. When the patient was discharged, the blood pressure was 140 to 150/85 mm Hg in the right arm and the cardiovascular status was normal. The femoral and left brachial pulses were all present but weaker than the right brachial pulse.

Before the patient's discharge an aortogram was performed by way of the right brachial artery; the film showed good, rapid filling of the graft, with backflow from the graft into the left subclavian artery and the major collateral vessels (Fig. 4). No significant gradient could be found, and it was postulated that the relative weakness of the femoral pulses resulted from the damping effect of the long, rigid Dacron graft.

Discussion

Fewer than 200 cases of interrupted aortic arch have been reported, fewer than 20 patients have been operated on successfully, and only three or four total corrections of the interrupted arch and associated anomalies have been performed (Table I).

Despite anatomic similarities with coarctation of the aorta, extension of interruption and associated lesions make this syndrome one of the most rapidly lethal forms of congenital malformation; 95 percent of infants affected die in the first year of life and most of them in the first days or weeks.[5] Van Praagh,[6] in a study of 174 consecutive autopsies of neonates, reported that this syndrome was the commonest cause of death (31 percent) from all congenital heart diseases in the first month of life.

Natural survival beyond infancy is related to the extent of the obstruction to blood flow through a segment of aorta and the associated anomalies. Our patient fulfilled two of the three prerequisites for successful tubular grafting outlined by McNamara and Rosenberg [2]—aortographic evidence of adequate collateral vessels and a significant systolic pressure gradient between proximal and distal aortic segments.

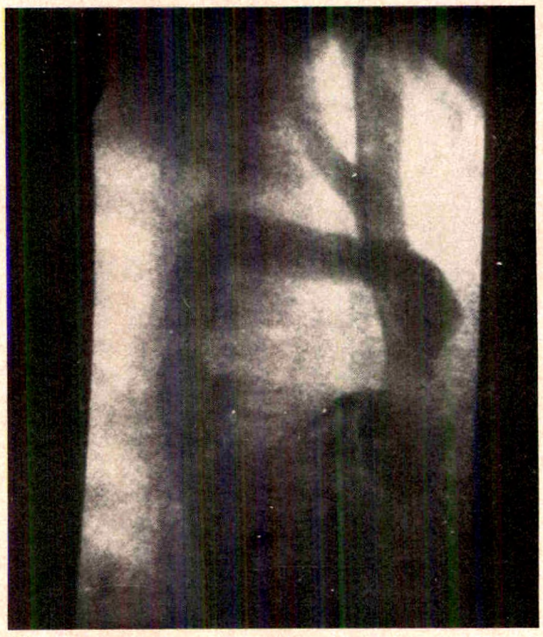

FIGURE 4. Postoperative aortic angiogram. Injection just above aortic valve showing the ascending aorta, Dacron graft and descending aorta.

The various forms of the syndrome have been classified by several workers, in particular Celoria and Patton,[4] who divided interruptions of the aortic arch according to the site of interruption (Fig. 5). In type A, complete interruption of the aorta occurs distal to the left subclavian artery. In type B, the defect is localized between the left carotid and left subclavian arteries, and in type C it is proximal to the left carot-

Present case	1973	8 yr	M	B	PDA and VSD; graft from ascending to descending aorta; division of PDA and closure of VSD

ASD = atrial septal defect; A–V = atrioventricular; LPA = left pulmonary artery; MPA = main pulmonary artery; PA = pulmonary artery; PDA = patent ductus arteriosus; RPA = right pulmonary artery; TGAs = transposition of great arteries; VSD = ventricular septal defect.

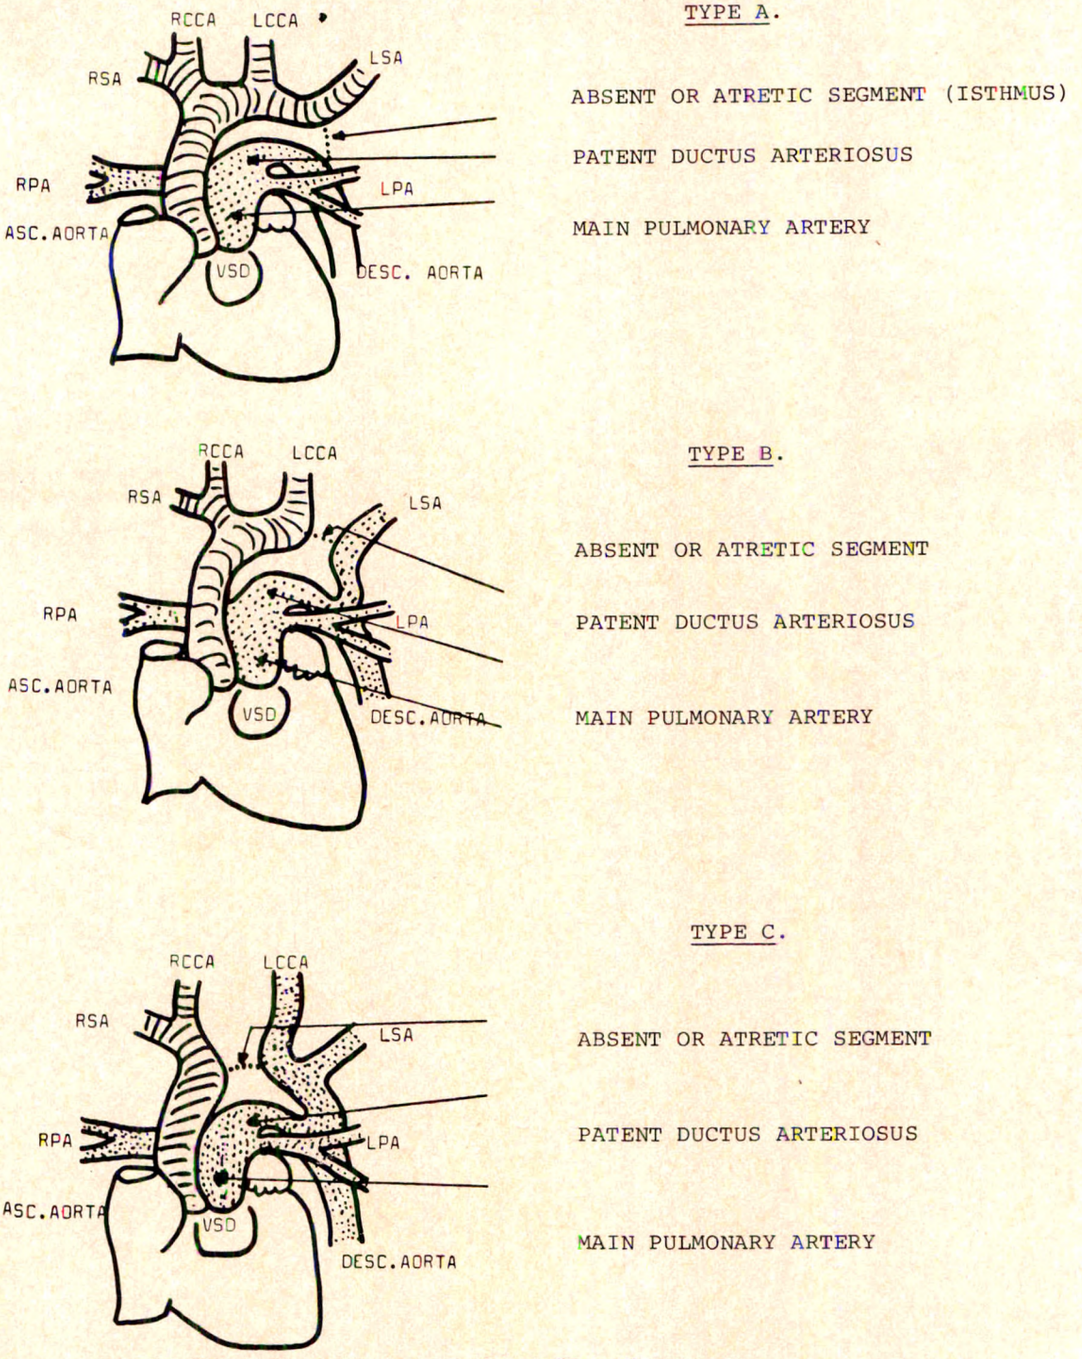

FIGURE 5. Diagrams illustrating the three types of interrupted aortic arch. PA = pulmonary artery.

id artery. Roberts et al.[7] reported prevalence rates of 44 percent for type A, 52 percent for type B and 4 percent for type C in their series. Multiple associated abnormalities were the rule, commonly ventricular septal defect and patent ductus arteriosus. Other defects included bicuspid aortic valve with subvalvular stenosis, multiple abnormalities of the great vessels arising from the arch, and complex intracardiac anomalies. The embryologic process leading to interrupted aortic arch differs from that resulting in coarctation of the aorta. The complex developmental changes in the embryo, which eventually result in the normal aortic arch, involve processes of reabsorption and growth of the primitive double arch. Interrupted aortic arch is due to hypoplasia of some of the elements constituting the arch.

The poor results of previous attempts at correction were related to the severity of the associated anomalies, the degree of disability of the child, and the use of surgical procedures that only partially corrected

the defects present (banding of the main or left and right pulmonary arteries, reestablishment of a large shunt between the main pulmonary artery and the descending aorta). However, with recent progress in surgery total corrections in one procedure may be performed successfully. Even in neonates the prognosis of interrupted aortic arch, which until recently was extremely poor, will be reversed because of new developments in neonatal resuscitation and the use of deep hypothermia with short periods of extracorporeal circulation.

LETTERS TO THE EDITOR

HEART RATE IN ACUTE MYOCARDIAL INFARCTION

The article entitled "Deleterious Effects of Increased Heart Rate on Infarct Size in the Conscious Dog" by Shell and Sobel[1] presented data obtained in the fastidious manner one has come to expect from that laboratory. It is not my intention to discuss the problem of the extent to which creatine phosphokinase levels mirror actual changes in infarct size, but rather to consider the significance of their findings for the prehospital phase of the patient with acute myocardial infarction. I have, with one exception, no problem with what the authors stated but rather with what they didn't state.

The one exception is related to their reference to "routine administration of atropine to prevent ventricular arrhythmias . . .," as if this, in fact, might have been contemplated. No one that I am aware of, least of all the undersigned, has proposed such a *routine* use of atropine. It would, I believe, be foolish to do so. Nor do I see any rational basis for increasing the heart rate of the in-hospital infarct patient with bradycardia whose condition is stable and who does not exhibit ectopy, hypotension or signs of congestive failure.

On the other hand, the authors might wish to express their views about the relevance of their findings to the use of atropine when bradycardia is present in the first 30 minutes of acute myocardial infarction in light of the recent findings in the valuable study of Webb et al.[2] In that study, half of the patients observed in the first 30 minutes had heart rates of 60/min or less. Of those who had such bradyarrhythmia, four of five had a systolic pressure of 100 mm Hg or less, and every second patient had a systolic pressure of 80 mm Hg or less.

It seems self-evident that the maintenance of coronary perfusion pressure is a fundamental requirement of an ongoing circulation. If one adds to this the great likelihood that flow to the peri-infarcted myocardium (marginal area) will depend to a substantial extent on flow through collateral vessels, the maintenance of an adequate coronary perfusion pressure seems essential not only to the longevity of the patient but also to limitation of the ultimate size of the infarct.

In short, do the authors deduce from their data that an increase in bradycardic heart rates is undesirable in the presence of hypotension in the early phase of acute myocardial infarction? Or would they consider the use of atropine appropriate in such circumstances in view of the findings that atropine, when so used, almost uniformly elevates hypotensive levels of arterial pressure in addition to inducing an increase in heart rate?

Stanley J. Sarnoff, MD, FACC
Survival Technology, Inc.
Bethesda, Maryland

REPLY

Dr. Sarnoff's interest in our work is most appreciated. In the study to which he refers, we demonstrated that "infarct size" can be determined objectively, antemortem, under controlled conditions in conscious dogs with coronary occlusion and that infarct size in this model is augmented when heart rate is accelerated by ventricular pacing or administration of isoproterenol or atropine. Our study was *not* directed toward the prehospital phase of acute myocardial infarction in man per se. However, as underscored by Dr. Sarnoff's own work and fundamental contributions, elucidation of phenomena with clinical implications often requires parallel experimental explorations under rigorously controlled conditions. We have recently shown that analysis of serial changes in serum creatine phosphokinase activity after experimental and spontaneous myocardial infarction provides an index of infarct size.[1,2] Further, it is becoming increasingly clear that infarct size is an important determinant of prognosis.[2,3] Under specific conditions in which atropine increases infarct size, such as those described in our investigation, administration of the agent is deleterious. Extension of these findings to the more complex clinical situation should not be undertaken lightly. In fact, our investigation was designed in part to develop a means for gathering objective information on the effect of atropine and other interventions on infarct size and, hence, prognosis under specified experimental and clinical conditions.

Available clinical evidence regarding the value of atropine early after infarction is equivocal. Bradycardia is common in patients with posterior acute myocardial infarction and is often associated with hypotension.[4] Atropine frequently reverses both. However, it is not clear that infarct size or mortality is adversely influenced by the transient bradycardia. It remains to be shown that vigorous treatment of bradycardia early after infarction will significantly improve survival.[5] Despite Dr. Sarnoff's explicit admonitions against the routine use of atropine, there has been a tendency among some to embrace this measure uncritically or overenthusiastically. In addition to the data in our study, other experimental results attest to deleterious effects of accelerated heart rate when the heart is ischemic. For example, the extent of myocardial injury detected electrocardiographically is increased.[5,6] Although ischemia or bradycardia alone increases temporal dispersion of refractoriness, acceleration of heart rate induced by atropine in the presence of ischemia accentuates the temporal dispersion of refractoriness associated with ischemia alone, thus facilitating reentrant dysrhythmias.[7] In addition, both the threshold for ventricular fibrillation and the occurrence of "malignant" ectopic activity in the ischemic heart are increased by atropine.[7]

In patients, injudicious doses of atropine may precipitate ventricular tachycardia.[4] Accordingly, it is particularly important to identify subsets of patients with acute myocardial infarction who may be benefited by treatment with atropine in the prehospital phase.

As pointed out by Dr. Sarnoff, bradycardia associated with acute myocardial infarction is often associated with hypotension. Presumably, under these circumstances infarct size would be increased as a function of the duration and severity of diastolic hypotension sufficient to compromise coronary flow. On the other hand, since myocardial oxygen requirements are undoubtedly reduced when heart rate is decreased, transient bradycardia may decrease the disparity between myocardial oxygen requirements and myocardial oxygen supply associated with a given coronary perfusion pressure. We concur that hypotension associated

with bradycardia and responsive to augmentation of heart rate with atropine should be corrected promptly by judicious administration of this agent to patients with acute myocardial infarction. However, administration of atropine to all patients with transient bradycardia associated with infarction would be justified only if it were established (1) that bradycardia was invariably responsible for hypotension responsive to the drug and sufficiently prolonged to jeopardize myocardium, or (2) that bradycardia consistently contributed to development of major dysrhythmias, a point not substantiated by recent experimental data.[8] We do not believe that either of these premises is justified on the basis of present information. Acceleration of heart rate induced by atropine augments infarct size when preexisting hypotension is absent, as shown in our report. Thus, in our view the use of atropine as a therapeutic modality generally applicable to patients with acute myocardial infarction in the prehospital phase, even those with transient bradycardia, is not presently justified and requires further exploration in carefully controlled studies.

Methods such as those described in our report should allow objective assessment of the effect of potentially therapeutic interventions on infarct size, an important determinant of prognosis in patients with acute myocardial infarction. The complex issues addressed in Dr. Sarnoff's letter can best be resolved by both clinical investigation and rigorous experimental assessment of the effect of alteration of heart rate on hemodynamics, dysrhythmias, infarct size and mortality.

ACADEMIC VS. COMMUNITY SURGEONS

A recent editorial by Dr. Effler in this Journal[1] sharply criticized the academic segment of the surgical establishment and praised the high order of surgical practice in some community hospitals. Effler specifically mentioned my own community of Flint, Michigan, where a large number of saphenous vein bypass grafts have been performed with low mortality. As a practicing cardiac surgeon, I was pleased that our community had received this recognition.

On close examination, Effler was giving us a back-handed compliment: The academic surgeons are so bad that even the community surgeons look good. Effler proposed that an external auditor should evaluate the competency of each cardiac catheterization laboratory and each surgical team.

I am not sure whether this would help the academic surgical community, but I am quite certain that it would be detrimental to the cardiac surgical teams in the smaller centers that Effler seems to admire. What is clearly needed are more unbiased statistics, more carefully evaluated indications for surgery, and more critically examined results. I suspect we need more heretics and fewer evangelists in this field at the moment. Oneupmanship is practiced at the community level as in academic centers. I doubt that putting more uncritical reports in print from community hospitals would be of help to anyone. Unlike Effler, I would encourage the editors of our journals to be even more critical of statistical material and I implore our academic colleagues to be even more demanding of our surgical efforts in this field.

Lloyd H. Hudson, MD
McLaren General Hospital
Flint, Michigan

REPLY

The purpose of my editorial was not to give anybody a compliment, but simply to state the facts as I see them. There is considerable opposition on the part of cardiologists to revascularization surgery in any form, and the dismal results that have been published in many of our academic centers are used constantly as ammunition against this current surgical trend.

Having been in this business for quite a while, I am convinced that the surgical treatment of coronary disease would be best handled by those who get the best results. After my tour of duty on the Coronary Committee of the I.C.D.H., I was impressed by the fact that many of our surgical leaders have no idea of what is going on in this business. Like Dr. Hudson, I am a firm believer in presenting the profession at large with "unbiased statistics and critically examined results." Each year we publish the Cleveland Clinic results, but these are usually cast aside as being unrepresentative of what can be accomplished in the United States. There are still a few people who should know better who believe the Cleveland Clinic Hospital is constructed with the tusks of large male elephants, and that we are able to accomplish things that cannot be accomplished on the outside. The point of my editorial was to state simply that this is not the fact and that many community hospitals are achieving results that are comparable to ours. . . . It was not my intent to suggest that academic surgeons are awful and that community surgeons look good as a result. I did state quite frankly that the aura of the academic center may not be entirely justified on the basis of its surgical results, and this I believe to be true.

Donald B. Effler, MD
Cleveland Clinic
Cleveland, Ohio

Calendar of Continuing Medical Education Programs

The National Committee for Continuing Medical Education, William Likoff, MD, FACC, Chairman, announces the following calendar of programs.

Each program is designed to enlarge knowledge and clarify the endlessly changing frontiers which mark scientific achievements in the recognition and treatment of cardiovascular disease. Although the disciplined objective of each program as well as its content, format and faculty are primarily determined by the Program Director, the National Committee for Continuing Medical Education always exercises the prerogative of final review and approval, whether the program is sponsored solely by the College or in collaboration with universities, colleges, hospitals and other professional societies.

Subject matter reflects national interest and needs in the fields of patient care, research and teaching. The program structures vary in method of education.

The National Committee for Continuing Medical Education of the College earnestly solicits the interest of member and nonmember physicians alike in continuing education for the clear reason that participation provides a unique opportunity to deepen one's understanding of heart disease, the most formidable and challenging health problem of our time.

Programs and faculty are subject to change. For further information write Mary Anne McInerny, Director, Department of Continuing Education Programs, American College of Cardiology, 9650 Rockville Pike, Bethesda, Md. 20014.

APRIL TO JUNE 1974

APR. 1–10 **Cardiology for the Consultant: A Clinician's Retreat.** E. Grey Dimond, FACC, director. Rancho Santa Fe Inn, Rancho Santa Fe, Calif.

APR. 4–6 **Advances in Clinical Cardiology.** Lawrence S. Cohen, FACC, director and Alfred L. Aronson, William W. L. Glenn, FACC, Allan V. N. Goodyer, FACC, Norman S. Talner, FACC and Steven Wolfson, FACC, co-directors. Yale University School of Medicine, New Haven, Conn.

APR. 17–19 **Core Curriculum—Vectorcardiography (A Basic Workshop).** Alberto Benchimol, FACC, director. Scottsdale Hilton Hotel, Scottsdale, Ariz.

APR. 22–25 **Current Concepts in Cardiology—1974.** Philip R. Akre, director and John A. Bowers and Masato Takahashi, FACC, co-directors. MGM Grand Hotel, Las Vegas, Nev.

MAY 6–9 **The Recognition and Management of Coronary Syndromes.** J. Willis Hurst, FACC and Robert C. Schlant, FACC, directors. Royal Coach Motor Hotel, Atlanta, Ga.

MAY 9–11 **The Ventricular Ectopic Beat: Heart-throb or Harbinger of Death.** Bernard Tabatznik and J. O'Neal Humphries, FACC, directors. Cross Keys Inn, Baltimore, Md.

MAY 15–17 **Clinical Auscultation of the Heart.** W. Proctor Harvey, FACC, director. Georgetown University School of Medicine, Washington, D. C.

MAY 17–19 **Core Curriculum: Rational Drug Therapy in Cardiovascular Disease.** Robert J. Lee, PhD., director. The Nassau Inn, Princeton, N. J.

MAY 23–25 **Cardiologist's Appraisal of Operable Heart Disease.** Arthur Selzer, FACC and Keith E. Cohn, FACC, directors. St. Francis Hotel, San Francisco, Calif.

JUNE 6–8 **Core Curriculum in Echocardiography: New Developments in Cardiac Ultrasound.** Arthur D. Hagan, director and Robert A. O'Rourke, FACC, co-director. Town and Country Hotel, San Diego, Calif.

VIIth WORLD CONGRESS OF CARDIOLOGY

The VIIth World Congress of Cardiology will be held in Buenos Aires, Argentine Republic, September 1 to 7, 1974. The Buenos Aires Sheraton Hotel will be the headquarters for sessions and exhibitions.

The scientific meetings will consist of Principal Sessions, Round Tables, Conferences, Free Communications, Luncheon Panels and Talks with Experts. In addition to the scientific program and scientific, commercial and industrial exhibitions, a full social program with scheduled tours and visits to museums and shows has been planned.

For further information, write the Secretary General, Dr. Bernardo Malamud, Avda. Roque S. Pena 1110, 2º piso, Buenos Aires, Argentina. Cables: CENIBAIRES.

INSTRUCTIONS FOR AUTHORS

The editors and publishers of THE AMERICAN JOURNAL OF CARDIOLOGY welcome concise articles devoted to cardiovascular disease. Articles must be contributed solely to THE AMERICAN JOURNAL OF CARDIOLOGY and become the property of the Publisher. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced in any form without the written permission of the Publisher. Statements in articles are the responsibility of the authors. Authors will assist the editors in the prompt processing of manuscripts if these instructions are followed:

THE WHOLE PAPER

- **Address manuscript** to Simon Dack, MD, American Journal of Cardiology, 666 Fifth Ave., New York, NY 10019.
- **Submit two copies** of all elements of the article: text, references, legends, tables and figures.
- **Arrange the paper** in this order: (1) title page; (2) abstract; (3) text; (4) references; (5) legends; (6) tables; and (7) figures.
- **Number all pages** in above sequence, beginning with title page as 1, abstract as 2, etc.
- **Type all matter:** (1) on 8½ × 11 opaque white bond paper; (2) in duplicate; (3) on **one side** of each sheet only; (4) double-space; (5) leave wide margins, all four sides.

THE TITLE PAGE

- **Number title page** as page 1.
- **Include first names,** degrees and, where applicable, FACC for all authors.
- **Insert at bottom:** name and address of institution from which work originated plus information about grants.
- **Add at bottom** the phrase "Address for reprints: . . ." followed by full name and address with zip code.

THE ABSTRACT

- **Limit words as follows:** 100 to 250 words for major articles; 50 to 100 words for case reports.
- **Add at end of abstract:** an alphabetical list of 2 to 6 key words and subjects for indexing.

THE TEXT

- **Number pages** in sequence after abstract.
- **Type in duplicate;** double-space.
- **Do not use abbreviations** such as SVC, WPW: write out; superior vena cava, Wolff-Parkinson-White.

Abbreviate measurements (mm, kcal and the like) as recommended in the Style Manual for Biological Journals, American Institute of Biological Sciences, 3900 Wisconsin Avenue, N.W., Washington, D. C.

- **Cite in numerical** order every reference, figure and table. (Order of mention in text **determines the number** given to each.)
- **Place acknowledgments** at end of text, before references.

THE REFERENCES

- **Type in duplicate;** double-space.
- **Place immediately** after text, and number pages in sequence after text page numbers.
- **Number the references** in order in which they are mentioned in text.
- **Follow the general** arrangement, abbreviations and punctuation styles shown below.

THE FIGURE LEGENDS

- **Start at top** of new page.
- **Type in duplicate;** double-space.
- **Number pages** in sequence after last page of references.
- **Identify at** the end of each legend and **in alphabetical order** all abbreviations in the figure described.

THE TABLES

- **Start each** table at top of new page.
- **Type in duplicate;** double-space.
- **Number pages** in sequence after last page of legends.
- **Give each table** a number (in roman numerals: Table I, II, etc.) and a title. Number the tables in order in which they are mentioned in the text.
- **Provide a footnote** to each table—identifying **in alphabetical order** all abbreviations used.

THE FIGURES

- **Submit 2 glossy prints** (not originals) of each photo and drawing.

Please note that art work of published articles will not be returned.

- **Use black ink** for all charts (line drawings). Make decimals, broken lines, etc. strong enough for reproduction.
- **Use arrows** to designate special features.
- **Crop photomicrographs** to show only essential field.
- **Identify figures** on back by number and author's name.
- **Number figures** in order in which they are mentioned in the text.
- **Indicate top** of each figure.
- **Submit written permission** from publisher and author to reproduce any previously published figures.
- **Limit figures** to number necessary for clarity. The publisher allows a limited sum toward reproduction.

Examples of Styles of References

For periodicals, follow INDEX MEDICUS:

31. Bellet S, Feinberg LJ, Sandberg H, et al: The effects of caffeine on free fatty acids and blood coagulation parameters of dogs. J Pharmacol Exp Ther 159: 250-254, 1968

(Author: please note that no periods are used after authors' initials.)

For books (edited by other than author of article):

28. Schiebler GL, Van Mierop LHS, Krovetz LJ: Diseases of the tricuspid valve, chap 20. In, Heart Disease in Infants, Children and Adolescents (Moss AJ, Adams F, ed). Baltimore, Williams & Wilkins, 1968, p 134

For books (with identical author and editor):

36. Berne E: Principles of Group Treatment. New York, Oxford University Press, 1966, p 26

(Author: all book references should have specific page numbers)

why settle for less

THAN A COMPLETE CARDIAC DIAGNOSTIC SYSTEM?

Why indeed! Medcraft's CDC 70 System is a real workhorse. Use it.

- *for stress testing*
- *as an ambulatory patient monitor*
- *for routine office ECG's.*

Doesn't it make a lot of good sense to have *one* sophisticated, yet rugged instrument for all your cardiac testing needs. A Cardiac Diagnostic System that is versatile enough to be kept in use all day? The all solid-state CDC 70, Cardiac Diagnostic System, is easy to use, compact, and smartly styled. It offers a memory scope display and tracing printout for ECG . . . digital heart rate display . . . low-cost ambulatory patient monitoring recorders with *cassette* tape recording (up to 16 hours per cassette) . . . switchable 5-lead resting or stress test ECG . . . and a host of other wanted features and optional capabilities.

To learn more, call, write, or use the coupon below to receive our latest brochure describing the CDC 70 System. You'll be surprised at the sophisticated, years-ahead design and the low cost of owning

THE CDC SERIES 70 SYSTEM by HITTMAN Medcraft

Lifeguard 1500 portable defibrillator saves you headaches while saving patient's lives.

When you need a quick reaction lifesaving tool for ECG monitoring and defibrillation, you need the Lifeguard LG 1500 from Gould, the portable, battery operated defibrillator with built-in cardioscope and synchronizer for cardioversion.

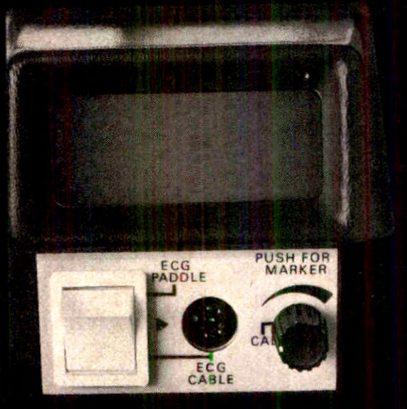
Easy to use.

Everything about the LG 1500 is designed for fast, effective action. For "quick look" or emergency monitoring, you can

obtain the ECG signal through the paddle electrodes. Standard ECG electrodes and cables, which are stored in pockets built into the lid, may also be used.

The built-in monitoring cardioscope produces clear, readable ECG traces even in bright ambient light conditions.

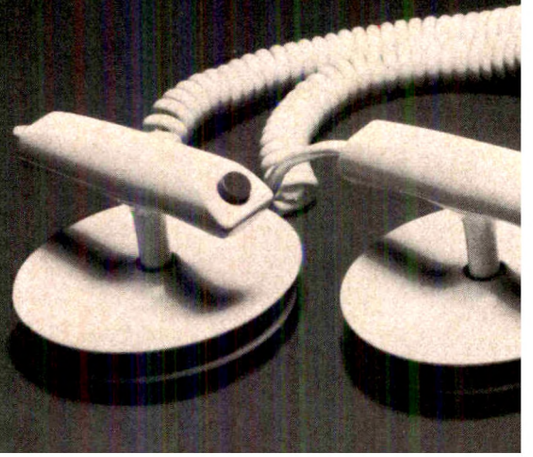
The panel controls and indicators are logically located and arranged for people in a hurry. All switches are positive



action and clearly labeled. A large, illuminated meter shows the energy level in both delivered and stored energy units. If the operator selects an energy level higher than desired, he can

simply lower it to the proper level by pressing a clear button. This also saves battery energy.

Paddles have handles like pistol grips so the operator can get a firm grip when removing paddles from their holders and pressing them against a patient's chest. To give precise control of discharge timing, there is a pushbutton on each handle.



he LG 1500 is easy
o carry. It's a trim, 25
ounds. Just a little
rger than an
ttache case. The
ase is thin and the
andle is balanced,
o you can carry
naturally and
asily, without
training your arm
r banging it into
our leg.

Outstanding safety features.

Take the paddles, for example. They have dual insulating rings

path between the handles and the electrodes. The bottom ring insulation prevents contact with the electrode and contact gel. The top ring, which is larger in diameter, is contoured so even if the operator's hand or fingers slip, they won't touch the electrodes.

The discharge control device—unique all-electronic Plasatron—eliminates circuit "ringing" due to contact bounce, which could cause deadly refibrillation. It also assures a virtually pure Lown waveform.

All high voltage circuits are isolated and the front panel controls and case are non-conductive. For maximum patient safety, the ECG input circuits are also isolated to minimize leakage to less than 10 microamps.

Chances of a premature discharge are minimized because of the location of the pushbuttons they have to be pressed simultaneously.

Superior performance and reliability.

The hermetically sealed, all-electronic Plasatron device is unexcelled for reliability. It has no moving parts and no contacts to pit, corrode, bounce or weld shut. Life expectancy is more than 100,000 operations, many times greater than electro-mechanical devices.

For maximum effectiveness, the LG 1500 provides infinitely selectable delivered energy levels from 10 to 320 watt-seconds, with up to 90 maximum-energy discharges from a fully charged battery.

An output connector permits graphic recording of ECG. It also provides an FM signal for transmitting ECG by radio or telephone.

What's more, the LG 1500 is rugged and durable. It will take rough handling, bumps and jars in stride.

Simple to service.

All the critical circuit components for the LG 1500 are on plug-in p.c. boards for quick, easy replacement.

A true value.

When you consider all you get with the LG 1500, you'll probably be pleasantly surprised at its low cost. For complete details and specifications, write today for our new, free brochure.

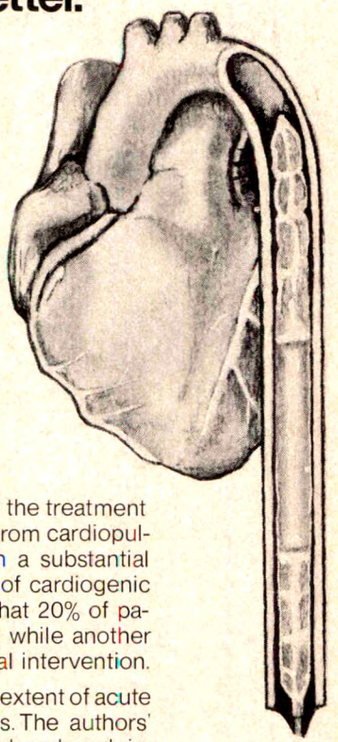
"a life-saving measure in a substantial minority of patients"[1]

The Avco Intra-Aortic Balloon Pump* ...and the Sooner, the Better.

The rationale of intra-aortic balloon pump (IABP) therapy in low-cardiac output conditions is widely accepted. By lowering pressure in the proximal aorta at the beginning of systole, myocardial work load is lessened. Also, by augmenting pressure during early diastole, pumping improves coronary perfusion and can open dormant collaterals. Thus a better balance between myocardial oxygen demand and consumption is obtained.



Documented effectiveness

The IABP's effectiveness is clinically proven in the treatment of cardiogenic shock and in weaning patients from cardiopulmonary bypass. It is a "lifesaving measure in a substantial minority of patients who would otherwise die of cardiogenic shock."[1] Braunwald and Maroko[2] estimate that 20% of patients who would otherwise die can be saved, while another 20% can be stabilized for diagnosis and surgical intervention.

IABP "significantly reduced the magnitude and extent of acute myocardial ischemic injury"[3] in animal studies. The authors' preliminary clinical results also demonstrated reduced ischemia as well as hemodynamic improvement.

Time a critical factor

Hemodynamic criteria to determine if a patient who seems to be going into cardiogenic shock is responding to treatment have been developed by Leinbach.[4] These criteria are a major contribution to the effective application of IABP treatment since *early use* of the system greatly increases the chances of success. Buckley and associates[5] used the IABP in 27 heart-surgery patients who went into shock upon termination of cardiopulmonary bypass. Eighteen survived; 13 are long term survivors. Best results occurred with initiation of IABP therapy early in the postoperative period.

*Developed by Avco Corporation and manufactured for Roche Medical Electronics Division.

The IABP versus drugs

Dunkman and others[6] have concluded that "catecholamines may actually increase ventricular dysfunction and necrosis" whereas the IABP's enhancement of coronary perfusion and reduction of oxygen-consuming work in the left ventricle can save patients if applied before about 40% of the left ventricle is irretrievably damaged. Moreover, IABP permits safe use of drugs if needed.

AVCO, the most experienced system

The internal counterpulsation system most widely used clinically is the Avco IABP. There are some very practical reasons for this dominance.

Patented 3-chamber balloon design prevents end occlusion.

QRS triggered synchronization with normal and abnormal rhythms.

Automatic reset for changes in interval or loss of R wave.

Safety engineering with fail-safe venting, self-initiated trouble identification, and emergency compressor with independent power supply.

Nationwide on-site service.

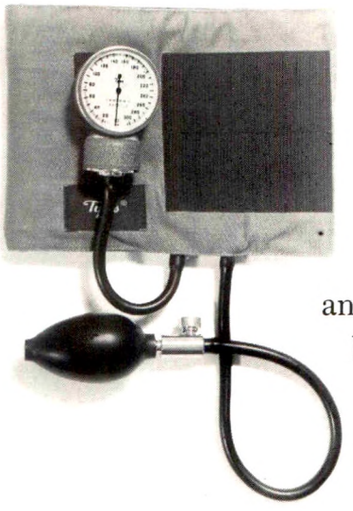
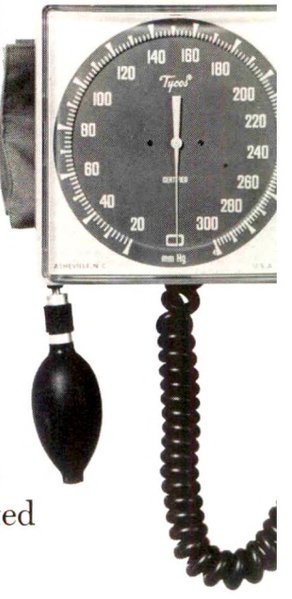
Three Sphygs for perfectionists.



For over 65 years Tycos® has set the standard for exc in precision aneroids. The fact that there are ove million Tycos sphygs in use today attests to their unsu accuracy, design and reliability.

The big wall sphyg, featuring a large 6¼″ dial, is ic mounting between two beds anywhere in the hospital. The swivel bracket and large white numerals assure easy reading from anywhere in the room.



The hand and pocket aneroids are recognized everywhere as fine diagnostic instruments. Their compactness and light weight make them easy and comfortable to carry either in pocket or bag.

All three sphygs have the exclusive Tycos visual check for accuracy and are backed by the famous Tycos 10-year warranty. For the practitioner who demands perfection, they can be counted upon to give top performance for many, many years.

PHILIPS®

® TM N.V. Philips of Holland

Mobile Image Intensifier System

With improved image quality and handling ease

A mobile image intensifier used in the operating room, should always be a welcome assistant but never an intrusion. This is indeed the case with the Philips BV21, which has been designed to do its job quietly, quickly and unobtrusively.

Draping is accomplished simply and the x-ray tube can be positioned outside of the sterile field, while still retaining more than enough travel to scan the area of interest with little or no fuss.

The BV21 was designed by engineers who are well aware that the height of a surgical table is adjustable over a wide range and so, therefore, is the height of the BV21.

Enhanced image quality is indeed impressive and will be appreciated for all procedures, including hip pinnings, pacemaker implantations and foreign body location.

Laragh's Hypertension Manual

Edited by John H. Laragh, M.D., of the College of Physicians and Surgeons, Columbia-Presbyterian in New York.
A classic treatise for understanding, diagnosing and treating hypertension.

Chapters by:

- ☐ John Laragh on The Renin System in Causation and on Evaluation of Hypertensive Patients.
- ☐ Sir George Pickering on Definitions, Natural Histories and Consequences.
- ☐ Louis Tobian on Experimental Mechanisms
- ☐ Arthur Guyton on Control Mechanisms
- ☐ Edward Freis on Why, When, and How to Treat.
- ☐ Edward Biglieri on Diagnosis of Adrenocortical Hypertension
- ☐ Harriet Dustan on Hemodynamic Mechanisms
- ☐ Jay Cohn on Hypertension and the Heart
- ☐ Hans Brunner on Renin as a Risk Factor

Approximately 900 pages, 150 illustrations.
Price: $37.00
Ready January, 1974.

Partial list of contributors:

John H. Laragh	J. C. Hunt
Sir George Pickering	F. R. Buhler
E. A. Lew	E. G. Biglieri
E. D. Freis	D. R. LaBarthe
H. R. Brunner	K. Engelman
A. C. Guyton	J. E. Sealey
L. Tobian, Jr.	C. R. Ayers
H. P. Dustan	J. A. Wilber
J. N. Cohn	J. Koch-Weser
V. DeQuattro	P. Kincaid-Smith
J. Giese	F. A. Finnerty
A. R. Christlieb	E. D. Vaughan
A. F. Lever	

Dr. Laragh's Hypertension Manual will undoubtedly become the standard reference work in Hypertension. Use the attached form to place your order. When cardiac complaints occur in the absence of organic findings, underlying anxiety may be one factor

The influence of anxiety on heart function

Excessive anxiety is one of a combination of factors that may trigger a series of maladaptive functional reactions which can generate further anxiety. Often involved in this vicious circle are some cardiac arrhythmias, paroxysmal supraventricular tachycardia and premature systoles. When these symptoms resemble those associated with actual organic disease, the overanxious patient needs reassurance that they have no

---

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Relief of anxiety and tension occurring alone or accompanying various disease states.

Contraindications: Patients with known hypersensitivity to the drug.

Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. As with all CNS-acting drugs, caution patients against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Though physical and psychological dependence have rarely been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage; withdrawal symptoms (including convulsions), following discontinuation of the drug and similar to those seen with barbiturates, have been reported. Use of any drug in pregnancy, lactation, or in women of childbearing age requires that its potential benefits be weighed against its possible hazards.

Precautions: In the elderly and debilitated, and in children over six, limit to smallest effective dosage (initially 10 mg or less per day) to preclude ataxia or oversedation, increasing gradually as needed and tolerated. Not recommended in children under six. Though generally not recommended, if combination therapy with other psychotropics seems indicated, carefully consider individual pharmacologic effects, particularly in use of potentiating drugs such as MAO inhibitors and phenothiazines. Observe usual precautions

organic basis and that reduction of excessive anxiety and emotional overreaction would be medically beneficial.

The benefits of antianxiety therapy

Antianxiety medication, when used to complement counseling and reassurance, should be both effective and comparatively free from undesirable side effects. More than 13 years of extensive clinical experience has demonstrated that Librium (chlordiazepoxide HCl) fulfills these requirements with a high degree of consistency. Because of its wide margin of safety, Librium may generally be administered for extended periods, at the physician's discretion, without diminution of effect or need for increase in dosage. (See summary of prescribing information.) If cardiovascular drugs are necessary, Librium is used concomitantly whenever anxiety is a clinically significant factor. (See Precautions.) Librium should be discontinued when anxiety has been reduced to appropriate levels.

For relief of excessive anxiety adjunctive

Librium® 10 mg
(chlordiazepoxide HCl)

1 or 2 capsules t.i.d./q.i.d.

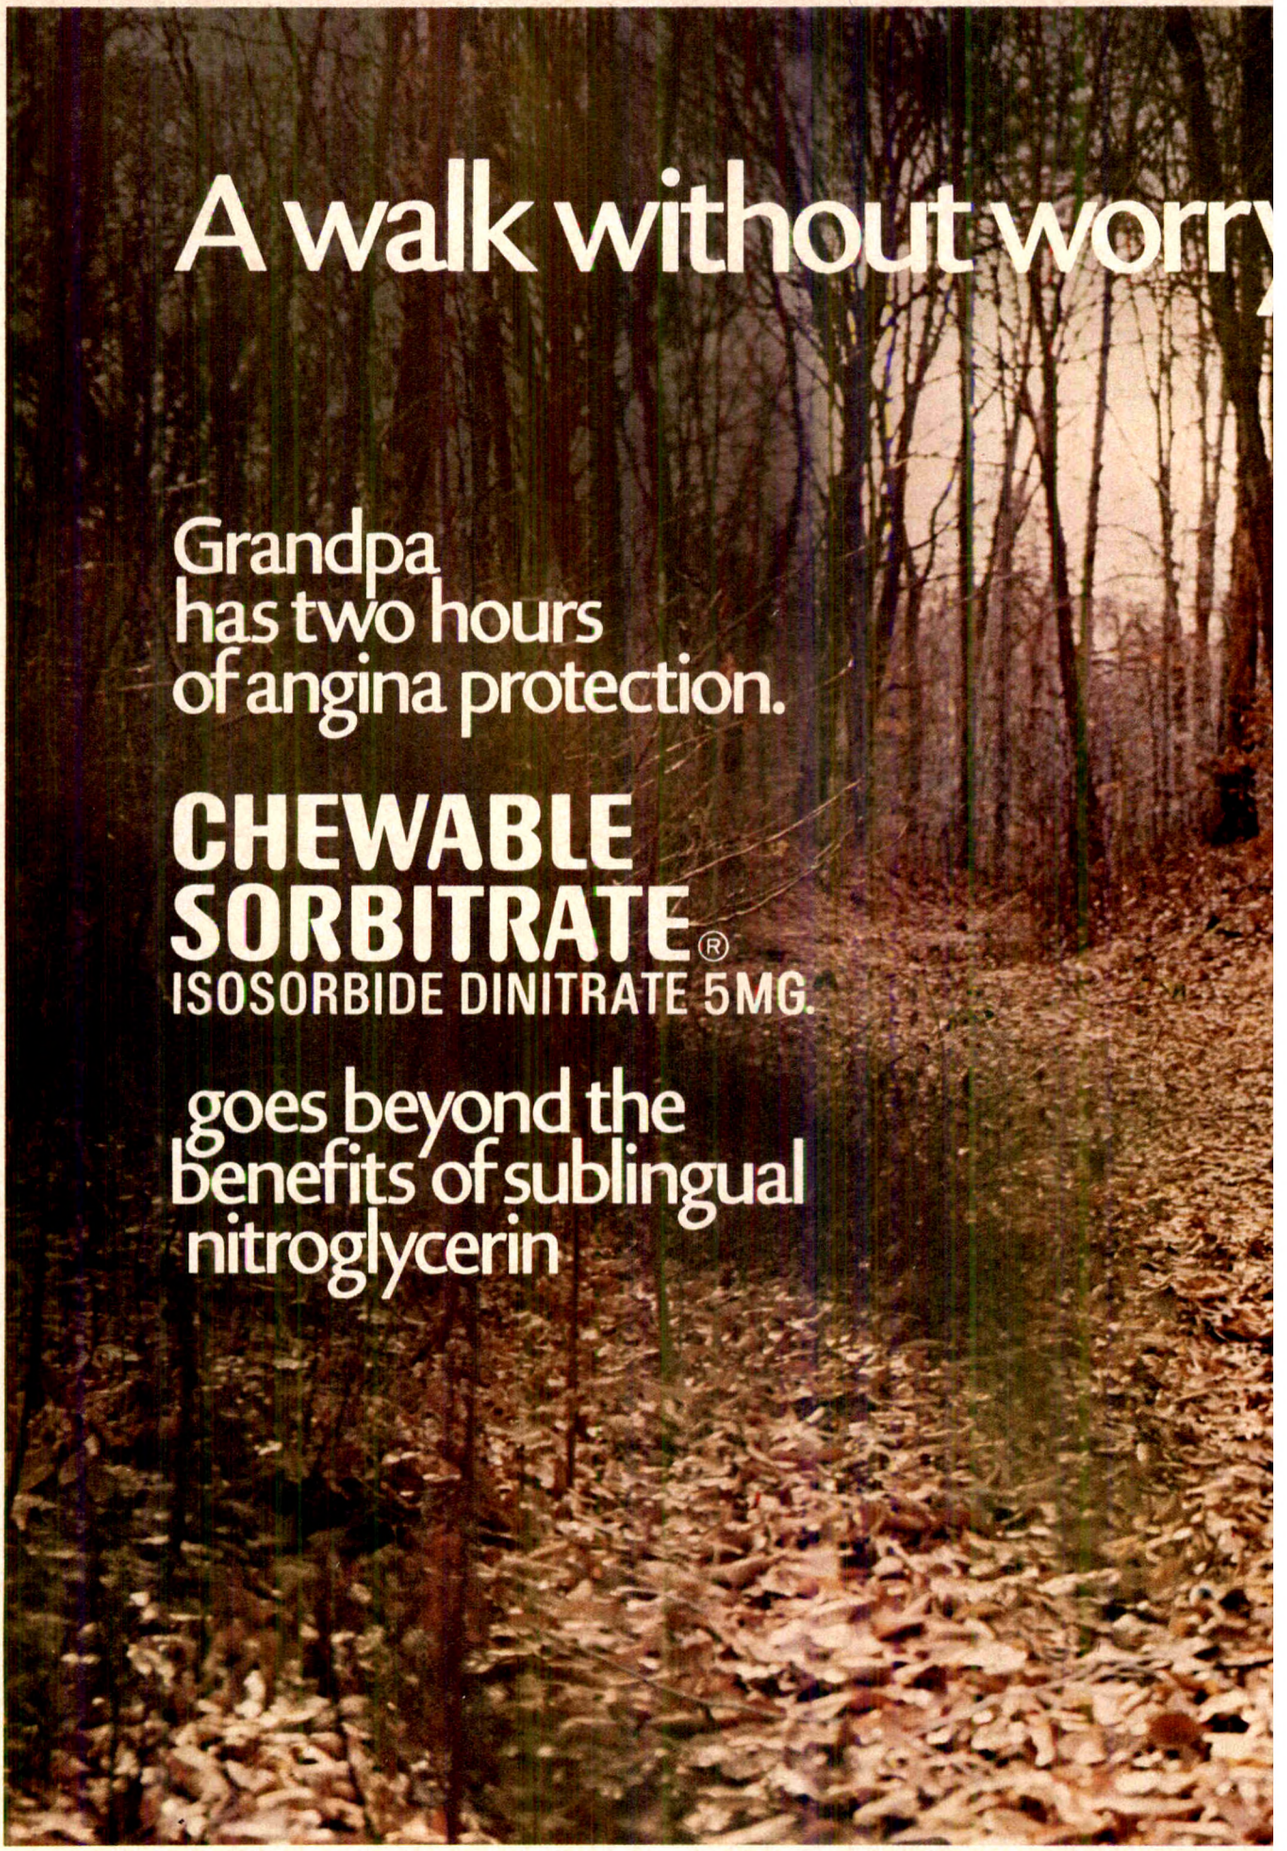
ROCHE
Roche Laboratories
Division of Hoffmann-La Roche Inc.
Nutley, N.J. 07110

---

in presence of impaired renal or hepatic function. Paradoxical reactions (*e.g.*, excitement, stimulation and acute rage) have been reported in psychiatric patients and hyperactive aggressive children. Employ usual precautions in treatment of anxiety states with evidence of impending depression; suicidal tendencies may be present and protective measures necessary. Variable effects on blood coagulation have been reported very rarely in patients receiving the drug and oral anticoagulants; causal relationship has not been established clinically.

Adverse Reactions: Drowsiness, ataxia and confusion may occur, especially in the elderly and debilitated. These are reversible in most instances by proper dosage adjustment, but are also occasionally observed at the lower dosage ranges. In a few instances syncope has been reported. Also encountered are isolated instances of skin eruptions, edema, minor menstrual irregularities, nausea and constipation, extrapyramidal symptoms, increased and decreased libido—all infrequent and generally controlled with dosage reduction; changes in EEG patterns (low-voltage fast activity) may appear during and after treatment; blood dyscrasias (including agranulocytosis), jaundice and hepatic dysfunction have been reported occasionally, making periodic blood counts and liver function tests advisable during protracted therapy.

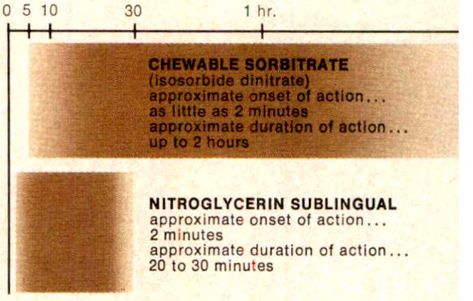
Supplied: Librium® Capsules containing 5 mg, 10 mg or 25 mg chlordiazepoxide HCl. Libritabs® Tablets containing 5 mg, 10 mg or 25 mg chlordiazepoxide.



A walk without worry
Grandpa
has two hours
of angina protection.
CHEWABLE
SORBITRATE®
ISOSORBIDE DINITRATE 5MG.
goes beyond the
benefits of sublingual
nitroglycerin

For up to two hours of protection, your angina patier needs *more* than sublingual nitroglycerin. And Chewable Sorbitrate provides more.

☐ Acts almost as fast as nitroglycerin...lasts about 4 times as long.



☐ More stable in air than sublingual nitroglycerin: it can be stored or carried wit no significant loss of potency

☐ And when indicated: Sorbitr (isosorbide dinitrate) Sublingual 5 mg. and 2.5 mg.

SUMMARY OF PRESCRIBING INFORMATION

Mode of action: The mechanism of action of SORBITRATE bide dinitrate) is unknown, although the basic pharmacolog is to relax smooth muscle. Isosorbide dinitrate reduces in and severity the incidence of angina pectoris attacks, w comitant reduction in nitroglycerin intake.

Indications: Sublingual and Chewable: For the prevention a ment of angina pectoris.

Oral: For the relief of angina pectoris. It is not intended the acute anginal episode. SORBITRATE WITH PHENOB is indicated for patients in whom the angina pectoris is acc by anxiety or its related symptoms.

Contraindications: A history of sensitivity to the drug.

Warnings: Data supporting the use of nitrates during the e of the acute phase of myocardial infarction are insufficient lish safety. Phenobarbital may be habit forming.

Precautions: Should be used with caution in patients w glaucoma. Tolerance and cross tolerance to other nitrates m

Adverse Reactions: Headache which may be severe and p Lowering the dose and using analgesics will help control t aches which usually diminish or disappear as therapy is c

Adverse reactions seen occasionally: Cutaneous vasodila flushing; transient dizziness and weakness as well as other cerebral ischemia associated with postural hypotension; i marked sensitivity to the hypotensive effects of nitrates wh vere responses can occur even with the usual therapeutic do hol may enhance this effect); drug rash and/or exfoliative d

This drug can act as a physiological antagonist to norepi acetylcholine, histamine and other agents.

Dosage and Administration: Route: Sublingual, oral and tablets.

Individual Dose: To minimize hypotensive responses, w occasionally be severe with chewable doses as low as 5 smallest effective dose should be employed. Chewable ta generally given in doses of 5 mg. Sublingually or orally, 5 t is the range commonly used although doses of up to 30 frequently been employed.

Dosage Schedule: Smallest effective dose necessary for vention and treatment of pain of an anginal attack. S SORBITRATE may be taken p.r.n. or at 4 to 6 hour interv SORBITRATE may be taken 3 to 4 times daily. CHI SORBITRATE may be taken for prompt relief of anginal pa times daily. Although the onset and duration of effect of nitrates may vary, following are the generally reported r these values for SORBITRATE:

Onset of Effect: Sublingual and Chewable: 2 to 5 minut 15 to 30 minutes.

Duration of Effect: Sublingual and Chewable: 1 to 2 hou Estimated to be 4 to 6 hours.

It is recommended that the oral dosage be taken on a stomach.

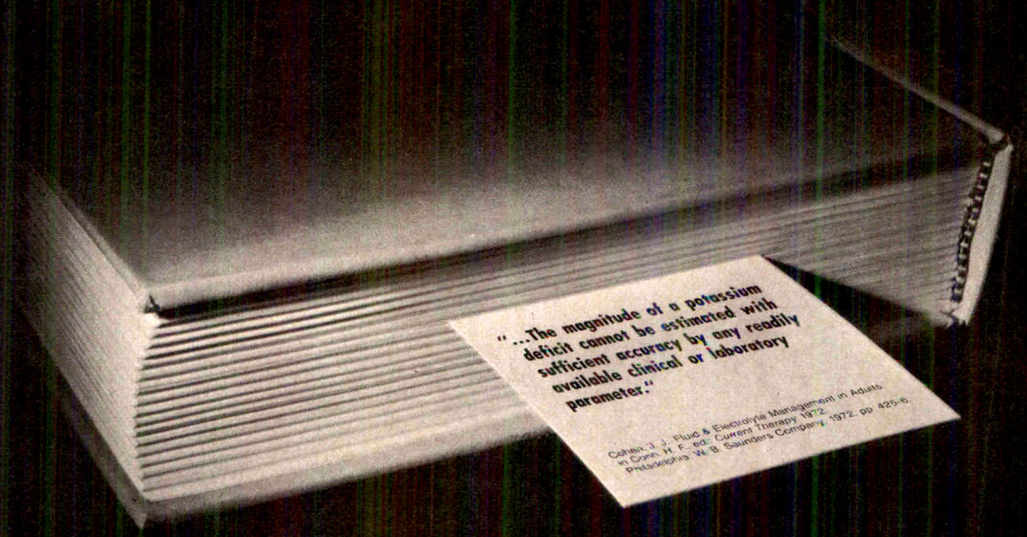
Help prevent this common thiazide and furosemide problem:

HIDDEN HYPOKALEMIA



Prescribe good-tasting

K^+LORVESS®

effervescent tablets

Each tablet contains 20 mEq. each of potassium and chloride supplied by potassium chloride 1.125 g., potassium bicarbonate 0.5 g., l-lysine hydrochloride 0.913 g.

1:1 ratio K^+ and Cl^- in solution

SIMPLE TO TAKE—Tablets dissolve in 3-4 oz. cold water

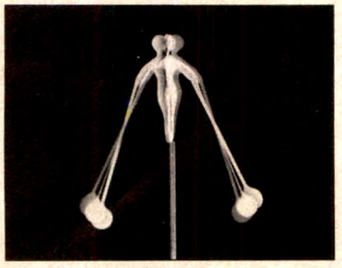
SPARKLING TASTE APPEAL—Fruitlike flavor

PATIENT ACCEPTANCE—Reduces chance of G.I. irritation. No added calories.

UNIT DOSE CONVENIENCE—Tablets individually foil-wrapped

KLORVESS offers what you and the patient like

Dorsey
LABORATORIES
Division of Sandoz-Wander, Inc.
Lincoln, Nebraska 68501



KLORVESS®
Effervescent Tablets

Description: Each dry effervescent tablet contains 20 mEq. each of potassium and chloride supplied by potassium chloride 1.125 g., potassium bicarbonate 0.5 g., l-lysine hydrochloride 0.913 g. Solution of the tablet in water provides the potassium and chloride available for oral ingestion as potassium chloride, potassium bicarbonate, potassium citrate, and l-lysine hydrochloride.

Indications: For prevention or correction of potassium depletion and hypokalemic alkalosis. Especially useful when thiazide diuretics or corticosteroids cause excessive excretory potassium losses.

Contraindications: Severe renal impairment with oliguria or azotemia, untreated Addison's disease, adynamia episodica hereditaria, acute dehydration, heat cramps, and hyperkalemia from any cause.

Precautions: In response to a rise in the concentration of body potassium, renal excretion of the ion is increased. With normal kidney function, it is difficult, therefore, to produce potassium intoxication by oral administration. However, potassium supplements must be administered with caution, since the amount of the deficiency or daily dosage is not accurately known. Frequent checks of the clinical status of the patient, and periodic ECG and/or serum potassium levels should be made. High serum concentrations of potassium ion may cause death through cardiac depression, arrhythmias or arrest. This drug should be used with caution in the presence of cardiac disease. Potassium supplements should be given cautiously to digitalized patients. To minimize the possibility of gastrointestinal irritation associated with the oral ingestion of concentrated potassium salt preparations, patients should be carefully directed to dissolve each tablet completely in the stated amount of water.

Adverse Reactions: Vomiting, diarrhea, nausea and abdominal discomfort may occur with the use of potassium salts. The symptoms and signs of potassium intoxication include paresthesias of the extremities, flaccid paralysis, listlessness, mental confusion, weakness and heaviness of the legs, fall in blood pressure, cardiac arrhythmias and heart block. Hyperkalemia may exhibit the following electrocardiographic abnormalities: disappearance of the P wave, widening and slurring of QRS complex, changes of the S-T segment, and tall, peaked T waves.

Dosage and Administration: Adults: 1 tablet (20 mEq. each of potassium and chloride) completely dissolved in 3 to 4 ounces of cold water 2 to 4 times daily depending upon the requirements of the patient. The approximate minimum adult daily requirement of potassium is 40 mEq. Deviations from this recommendation may be indicated, since no average total daily dose can be defined but must be governed by close observation for clinical effects.
NOTE: Klorvess should be taken with meals.

Overdosage: Potassium intoxication may result from overdosage of potassium or from therapeutic dosage in conditions stated under "Contraindications." Hyperkalemia, when detected, must be treated immediately because lethal levels can be reached in a few hours.

How Supplied: Klorvess Tablets (white, round) in boxes of 60 (2 Rx units of 30, NDC 43-100-87). Each tablet is individually foil wrapped.

NEWS FROM THE AMERICAN HEART ASSOCIATION

Today's best reason to consider our monitoring systems: tomorrow's needs.

When it comes to monitoring equipment decisions, perhaps it's not enough to learn that General Electric has been around for some time. More important than stability is the assurance that GE will continue as the innovator in monitoring systems, and make these concepts readily available to present users.

The specifics:

Today, GE offers a broad spectrum of monitoring configurations to serve in ICU/CCU, and surgery.

In addition, a mobile system can be wheeled to any care area to alleviate patient loads in outpatient or emergency units. And GE Telemetry can monitor and transmit ECG data from ambulatory patients —enabling you to evaluate heart activity during the still-crucial period prior to patient release.

Tomorrow, General Electric's new Patient Data System, a third generation monitoring concept, will put more kinds of patient data at your fingertips. Computer integration can provide the recall of patient parameters from the previous 1, 4, 8 or 24 hours; the generation of complex derived parameters relating to the cardiovascular and respiratory system; and more sophisticated alarm schemes to indicate proper intervention based on data you've programmed-in.

Yet PDS can provide derived patient information without a computer. Bedside and nurse station displays present dynamic waveforms, derived parameters, alarm limits, physiological alarms, trend graphs, and multiparameter plots of patient data. Computer integration, but not dependency. It's the unique reason PDS is designed to meet both immediate, basic monitoring requirements and also extremely sophisticated long-term needs.

Today's monitoring systems.
With the prerogative of upgrading
to tomorrow's when you desire.
More incentive to see your GE
representative about upcoming
monitoring requirements now.

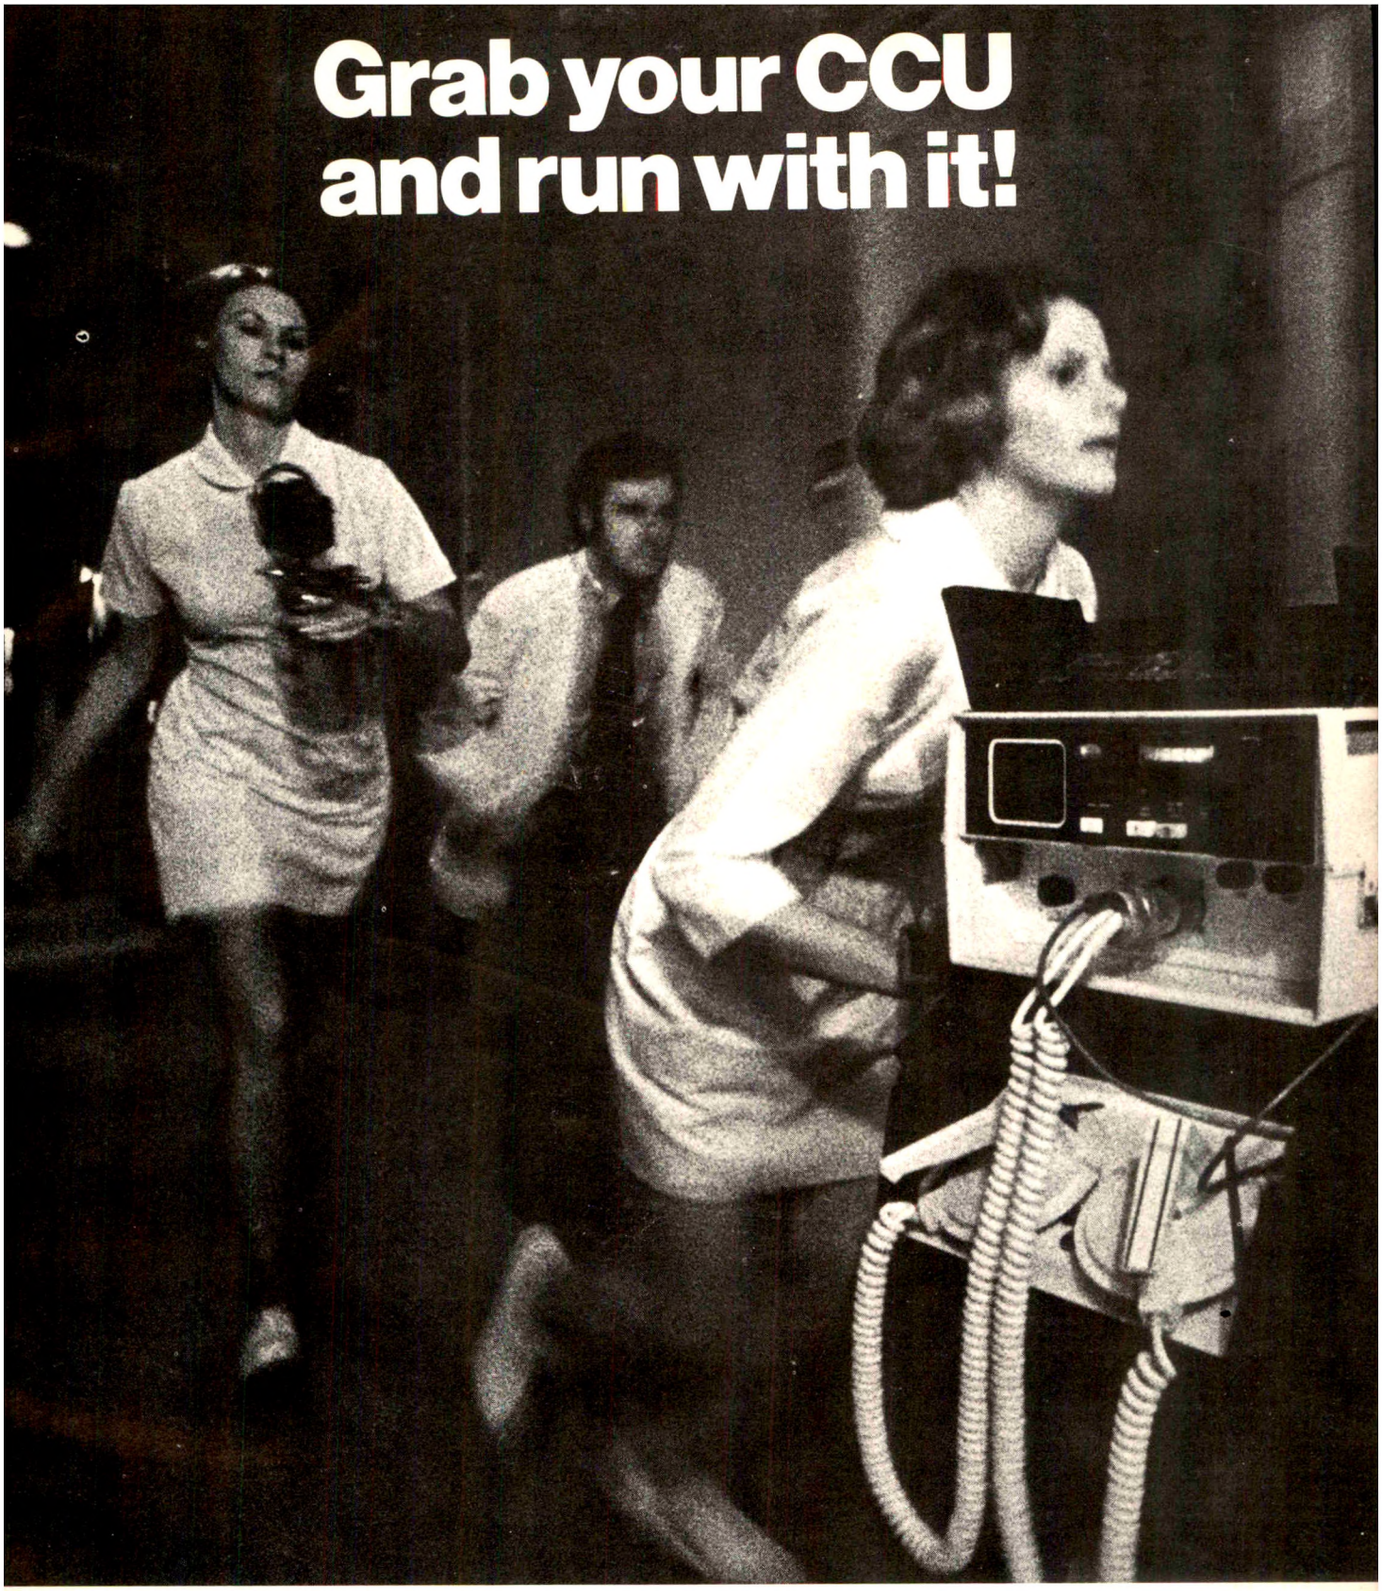
Grab your CCU and run with it!



It would be ideal if you could confine all cardiac arrest cases to the Coronary Care Unit . . . where they could be treated immediately. The trouble is, they can and do happen anywhere in the hospital.

One solution is a crash cart for every floor . . . manned by a special team trained to respond instantly to cardiac emergencies on their floor, and outfitted with the necessary emergency equipment, including a LIFEPAK portable, defibrillator/cardioscope from Physio-Control.

LIFEPAKS offer a wide range of features, from Quik-Look® (instantaneous ECG trace through the defibrillator paddles), to optional built-in recorders, to modulators for transmitting ECG signals by radio or telephone. Many of LIFEPAK's features were industry "firsts" developed by Physio-Control, the world's leading manufacturer of defibrillators.

For complete details, write for our new full-color-illustrated, 24-page brochure: Physio-Control Corporation, 11811 Willows Road, Redmond, Wash. 98052. Phone (206) 883-1181.
Cable: Physio-Red. Telex: 32-0166.

Physio-Control

"The drug of choice for oral replacement of potassium is potassium chloride solution."

AMA Drug Evaluations 1971, First Edition, Chicago, American Medical Association, p. 121.

Kay Ciel® Elixir is potassium chloride... tastes good too!

COMPOSITION: Each 15 cc. (one tablespoonful) contains potassium chloride 1.5 Gm., supplying 20 mEq. of elemental potassium, in a cherry-flavored, palatable base, alcohol 4%. Contains no sugar.
INDICATIONS: Treatment of potassium deficiency occurring especially during thiazide diuretic or corticosteroid therapy, digitalis intoxication, low dietary intake of potassium or as a result of excessive vomiting and diarrhea.
CONTRAINDICATIONS: Impaired renal function, untreated Addison's Disease, dehydration, heat cramps, and hyperkalemia.
PRECAUTIONS: Potassium chloride should be administered with caution and adjusted to the requirements of the individual patient, since the amount of deficiency and corresponding daily dose is often not known. Excessive or even therapeutic dosages may result in potassium intoxication. Patients should be frequently checked and periodic ECG and/or plasma potassium levels made. High plasma concentrations of potassium ion may cause cardiac depression, arrhythmias or arrest. Use with caution in patients with cardiac disease. In hypokalemic states, attention should be directed toward the correction of the frequently associated hypochloremic alkalosis.
SIDE EFFECTS: Vomiting, nausea, abdominal discomfort and diarrhea may occur. Symptoms and signs of potassium intoxication include listlessness, mental confusion, paresthesia of the extremities, weakness of the legs, flaccid paralysis, fall in blood pressure, cardiac arrhythmias, and heart block. When hyperkalemia exists, it should be promptly treated with the discontinuance of potassium administration or other steps to lower serum levels if indicated, since sudden shift in plasma levels may induce potentially dangerous cardiac arrhythmias.
DOSAGE AND ADMINISTRATION: Adults, one tablespoonful (15 cc.) diluted in one glass of water, twice daily after the morning and evening meal. Larger doses may be indicated according to the individual patient's requirements but should be administered under close supervision due to the possibility of potassium intoxication. Patients should be cautioned to follow directions explicitly in regard to dilution of Kay Ciel Elixir to prevent gastrointestinal injury.
HOW SUPPLIED: One pint and one gallon bottles.

Cooper Laboratories, Inc., Wayne, N.J. 07470/Ste. Therese, P.Q., Canada

The American Journal of CARDIOLOGY®

OFFICIAL JOURNAL OF THE AMERICAN COLLEGE OF CARDIOLOGY

Prevention of Arrhythmias After Myocardial Infarction

Electrophysiologic Properties of Antiarrhythmic Agents

Contents on Page A9

A YORKE MEDICAL JOURNAL

UNIVERSITY COLLEGE OF MEDICINE LIBRARY

The patient with cardiac arrhythmia may need medication most when he's least likely to take it...

while he's sleeping.

Quinaglute® Dura-Tabs® (quinidine gluconate) "a pharmacologic pacemaker":

- produces sustained serum quinidine levels, thus providing a convenient 8 or 12 hour dosage schedule
- usually insures uninterrupted therapeutic quinidine gluconate levels during sleep
- avoids peaks and valleys in plasma levels during which time the arrhythmias may recur
- maintains normal sinus rhythm following conversion by other techniques
- well tolerated to enhance patient cooperation—few G.I. disturbances

Contraindications: Quinaglute Dura-Tabs are contraindicated in patients with partial A-V or complete heart block, or intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening; in patients manifesting idiosyncrasy or sensitivity to quinidine (e.g. febrile reactions, skin eruptions, thrombocytopenia, etc.), in patients with renal disease resulting in significant azotemia, or those developing cardiotoxic effects such as conduction defects; ventricular premature beats, ventricular tachycardia or flutter while on the drug. It may be contraindicated in certain patients who have marked cardiac enlargement, particularly with congestive failure, poor renal function, and especially renal tubular acidosis.

Precautions: The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate should be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered; especially during the first weeks of therapy.

Signs of idiosyncrasy include febrile reactions, skin eruptions, thrombocytopenic purpura, and respiratory embarrassment. Extreme caution should be exercised in using the drug in patients with severe heart disease and congestive heart failure, with digitalis intoxication, or renal insufficiency. It should be administered cautiously, if at all, to senile patients. Hospitalization for close clinical observations, electrocardiographic monitoring, and possibly plasma quinidine levels, is indicated when large doses are used, or with patients who present an increased risk.

As with all quinidine preparations, the titrating of the exact quinidine dosage will vary with each individual patient. With the dosage regimen of 2 tablets every 8 hours, higher blood levels than necessary for maintenance of normal sinus rhythm could be reached, whereas with 1 tablet every 12 hours, the blood levels may be too low to maintain normal sinus rhythm.

As with other quinidine products, Quinaglute Dura-Tabs should not be used during pregnancy.

Adverse Reactions: The patient should be advised to report immediately to the physician any symptoms of cinchonism (including tinnitus, decreased auditory acuity, vertigo, blurred vision, color perception disturbances, photophobia, diplopia, night blindness, scotomata, reduced visual fields, mydriasis and respiratory distress).

Where such symptoms develop, or if evidence of hypotension appears, the drug should be discontinued. Gastrointestinal disturbances have only rarely been reported. If they occur, they may be minimized by administering the drug with food. If they persist, dosage should be decreased.

Dosage: For the prevention of premature atrial, nodal or ventricular contractions, the dose usually ranges from 1 to 2 tablets every 8 or 12 hours.

Before prescribing or administering, please refer to QUINAGLUTE full product information.

Cooper Laboratories, Inc.
Wayne, New Jersey 07470

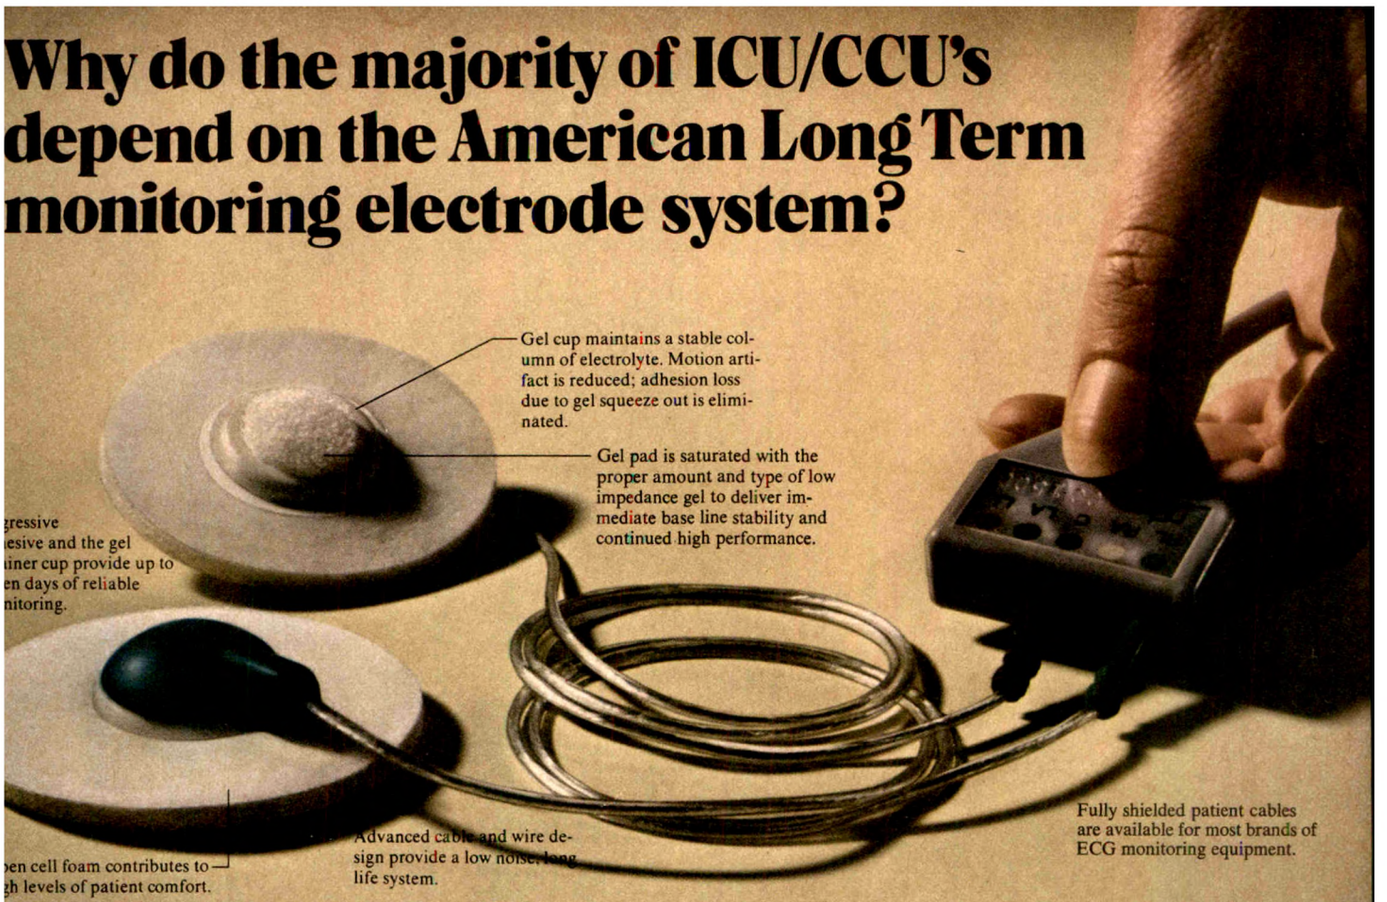
Why do the majority of ICU/CCU's depend on the American Long Term monitoring electrode system?



This is the system that has established new standards for high performance in long term ECG monitoring.

Designed for single patient use, the self-adhering silver/silver chloride electrode is pregelled with the correct amount of proper electrolyte. Adhesion loss and electrolyte evaporation are virtually eliminated by the gel retaining cup. The results: Immediate base line stability and better long term performance than any other electrode—reusable or disposable—is capable of delivering.

Open cell foam complements the electrode's mild gel formulation and low profile to enhance patient comfort. When used as directed, American's Long Term Electrode provides from five to seven days of continuous, accurate monitoring . . . with no discomfort to the patient.

This advanced electrode, used with the appropriate American leadwire and cable, is fully compatible with your present ECG equipment.

A clinical trial will show you why the American Long Term Electrode system is the overwhelming choice of ICU/CCU's throughout the country.

Please contact your American Hospital Supply or NDM representative and ask for:

- A demonstration of the system's benefits.
- A no obligation clinical trial. American will supply electrodes, leadwires and cables to adapt to your present monitoring equipment during the trial period.
- A total inservice for your staff.
- Information about our nationwide technical support program.

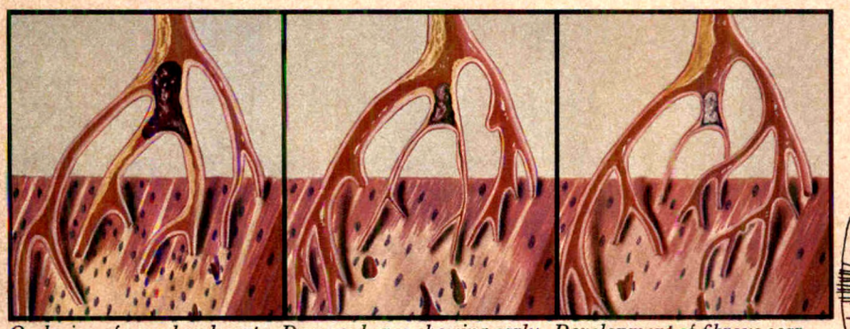
As the infarct heals,



Occlusion of vessel and acute infarct of the myocardium.

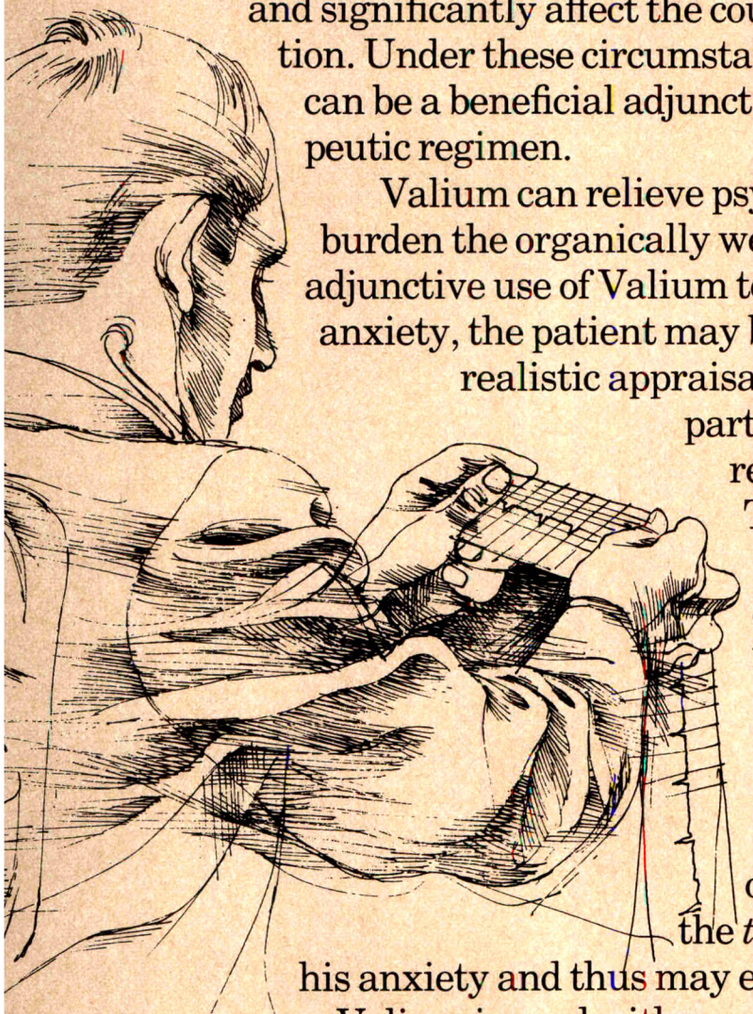
Damaged area showing early collateral vessel formation.

Development of fibrous scar and healing of infarcted area.

will psychic tension affect the patient's rehabilitation?

ROCHE

After the MI patient's acute episode has been successfully managed, a program of rehabilitation is begun. At times the overly tense cardiac patient may present a special problem. Although you continue to encourage a positive outlook through counseling and enlistment of support from the patient's family, psychic tension may remain, and significantly affect the course of rehabilitation. Under these circumstances, Valium (diazepam) can be a beneficial adjunct to the patient's therapeutic regimen.



Valium can relieve psychic tension that may burden the organically weak heart. As a result of adjunctive use of Valium to relieve unwarranted anxiety, the patient may be able to arrive at a more realistic appraisal of his situation and participate more fully with his rehabilitation program.

Therapy should normally be continued until the patient's anxiety has been reduced to tolerable levels.

Since the cardiac patient may be particularly prone to tension and anxiety at bedtime, the addition of an *h.s.* dose of Valium to the *t.i.d.* schedule can relieve his anxiety and thus may encourage sleep.

Valium is used with most classes of primary medications such as cardiac glycosides, diuretics, vasodilators, anticholinergics and antacids. The most commonly reported side effects have been drowsiness, fatigue and ataxia. Patients taking Valium should be cautioned against driving or operating dangerous machinery.

Valium®(diazepam)
2-mg, 5-mg, 10-mg tablets

when you consider it essential to keep the heart patient calm

Please turn page for a summary of product information.

When you consider it essential to keep the heart patient calm

- Valium (diazepam) can relieve psychic tension and anxiety that may burden the organically weak heart and interfere with the patient's course of rehabilitation.
- Valium works promptly in most patients. Significant improvement is usually noted during the first few days of therapy, although some patients may require more time to respond.
- Adjustments in dosage can alter clinical response. With appropriate titration, a regimen can be tailored to the patient's individual needs.
- Valium has a wide margin of safety in the usual oral dosage range and generally does not significantly affect respiration or pulse.

Valium® (diazepam) 2-mg, 5-mg, 10-mg tablets

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Tension and anxiety states, somatic complaints which are concomitants of emotional factors; psychoneurotic states manifested by tension, anxiety, apprehension, fatigue, depressive symptoms or agitation; symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology, spasticity caused by upper motor neuron disorders, athetosis, stiff-man syndrome, convulsive disorders (not for sole therapy).

Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.

Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms (similar to those with barbiturates and alcohol) have occurred following abrupt discontinuance (convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence. In pregnancy, lactation or women of childbearing age, weigh potential benefit against possible hazard.

Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.

Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.

Dosage: Individualize for maximum beneficial effect. *Adults:* Tension, anxiety and psychoneurotic states, 2 to 10 mg b.i.d. to q.i.d.; alcoholism, 10 mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. to q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).

Supplied: Valium® (diazepam) Tablets, 2 mg, 5 mg and 10 mg; bottles of 100 and 500. All strengths also available in Tel-E-Dose® packages of 1000.

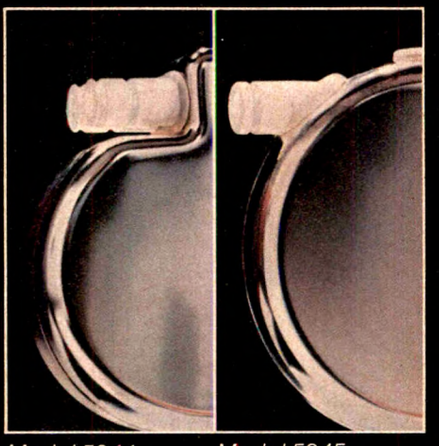
pacemakers conserve it.

The concept of Energy Conservation is based on one simple fact: lessen the drain on a power source and you extend its life.

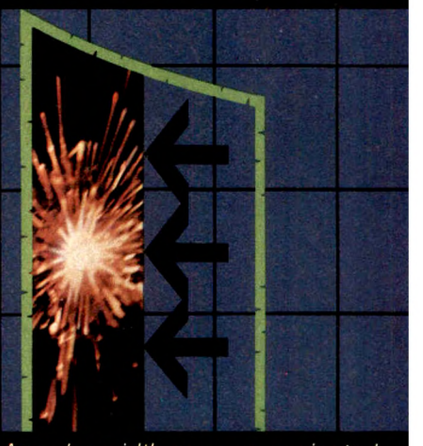
In the new Medtronic pacemakers, pulse width has been reduced to reduce the energy expenditure per pulse.

Less energy expended means longer projected life. It's that simple.



Model 5944— Bipolar Demand Pulse Generator

Model 5945— Unipolar Demand Pulse Generator



As pulse width narrows, projected life of the pulse generator is extended

Another significant improvemen combines the idea of energy compensation with a redundant cell depletion indicator. It works this way: when depletion of the first cell occurs the new Medtronic pulse generators show a decrease in rate similar to most other pulse generators. But, the also automatically increase pulse width when depletion occurs. This

The Four Horsemen of Stroke...

PAVABID®
(papaverine HCl, 150 mg.) Plateau CAPS®

Pavabid® Plateau CAPS® (Papaverine HCl, 150 mg.)—Each capsule contains papaverine hydrochloride, 150 mg. in a special base for prolonged therapeutic effect. *Indications:* ischemia associated with arterial spasm and myocardial ischemia complicated by arrhythmias. *Dosage:* One capsule every 12 hours. In difficult cases, administration may be increased to one capsule every 8 hours, or two capsules every 12 hours. *Precaution:* Use with caution in patients with glaucoma. Hepatic hypersensitivity has been reported with gastrointestinal symptoms, jaundice, eosinophilia and altered liver function tests. Discontinue medication if these occur. *Side effects:* Infrequently reported side effects of papaverine include nausea, abdominal distress, anorexia, constipation, malaise, drowsiness, vertigo, sweating and headache, diarrhea and skin rash.

583 Bundle Branch Block. Demonstration of the Incomplete Nature of Some "Complete" Bundle Branch and Fascicular Blocks by the Extrastimulus Technique

DELON WU, PABLO DENES, RAMESH DHINGRA and KENNETH M. ROSEN

These electrophysiologic studies using the atrial extrastimulus technique in three patients demonstrate that partial bundle branch block depends on a discordance of conduction time and refractory period. The bundle or fascicle with depressed conduction has a shorter refractory period than the more normally conducting bundle or fascicle. The data suggest that incomplete blocks can occur in the three fascicles and may predispose to development of trifascicular block with a normal H–V interval and to aberrant conduction during supraventricular tachyarrhythmias.

590 Concealed Bypasses of the Atrioventricular Node in Patients with Paroxysmal Supraventricular Tachycardia Revealed by Intracardiac Stimulation and Verapamil

ROWORTH A. J. SPURRELL, DENNIS M. KRIKLER and EDGAR SOWTON

Acting predominantly on antegrade and retrograde conduction in the atrioventricular node, verapamil (10 mg) given intravenously terminated paroxysmal supraventricular tachycardia in all 13 patients. The minimal effect of this drug on retrograde conduction and the minimal increase in retrograde conduction during ventricular pacing in five of the patients suggested the presence of an A–V nodal bypass not apparent from the surface electrocardiogram.

596 Electrophysiologic Properties of Procainamide in Man

MARK E. JOSEPHSON, ANTHONY R. CARACTA, MICHAEL A. RICCIUTTI, SUN H. LAU and ANTHONY N. DAMATO

Procainamide given to 16 patients with sinus rhythm minimally prolonged atrioventricular (A–V) conduction in 11 subjects and significantly prolonged His-Purkinje conduction time in 15. The effective refractory period of the A–V node decreased in eight of nine patients. The relative refractory period of the His-Purkinje system was prolonged in 10 of 11 patients.

604 Arrhythmias After Cardiac Transplantation

JOHN S. SCHROEDER, DAVID K. BERKE, ANTHONY F. GRAHAM, ALAN K. RIDER and DONALD C. HARRISON

Atrial arrhythmias were noted in 72 percent and ventricular premature contractions in 57 percent of 45 cardiac allograft recipients. Two patients had ventricular fibrillation. Antiarrhythmic agents, cardioversion or treatment of the underlying rejection process controlled these cardiac irregularities. These interesting observations indicate autonomic innervation of the heart is neither a prerequisite for the development of cardiac arrhythmias nor a requirement for a successful response to antiarrhythmic therapy.

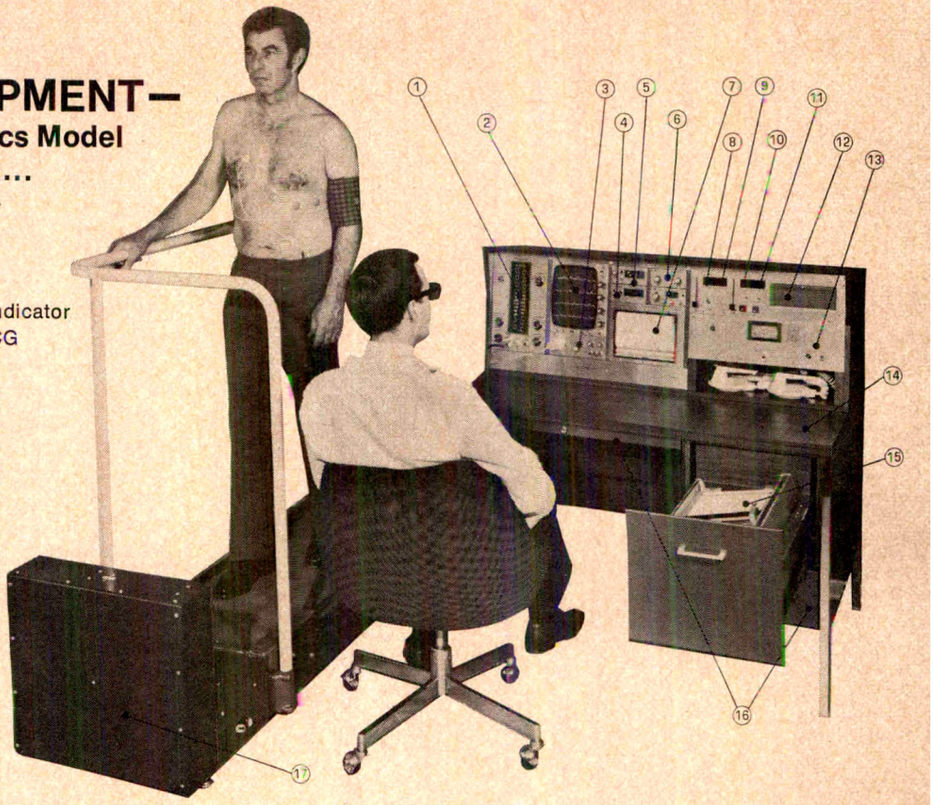
TWO GOOD REASONS WHY AVIONICS IS THE LEADER IN EXERCISE STRESS TESTING!

1. BETTER EQUIPMENT—

introducing the new Avionics Model 3600 ExerStress™ Console...

1. Automatic Blood Pressure Monitor
2. Four-Channel Memory Scope
3. Standard 12-lead Capability
4. Accurate Heart Rate Meter
5. ST-Segment Computer With PVC Indicator
6. Automatic Timer For Activating ECG Write-out
7. Three-Channel ECG Writer
8. Digital Display of Treadmill Speed
9. Digital Display of Treadmill Grade
10. Digital Elapsed Time Clock
11. Digital Display of Stage of Test
12. Automatic Programmer For Controlling Treadmill
13. DC Defibrillator
14. Work Area
15. XY Charter of ST-Segment, Heart Rate, and Time
16. Storage Areas
17. Treadmills: Finest Quality Available



2. BETTER SERVICE— full service and maintenance contracts available...

Compare the quality and performance of our system with all others. We'll bring the entire system, including the treadmill, to your hospital, clinic, or office and conduct an actual stress test under your control. You can prove the superior performance and diagnostic quality of our system to your own satisfaction.

Ask any competitor to bring and demonstrate his complete system to you, including treadmill exercising. If he refuses, that should tell you something! If you want the best, we've got it and we're ready to bring it to you.

For action, just use the coupon below.

608 Criteria for Electrocardiographic Differentiation of Right Ventricular Hypertrophy from True Posterior Myocardial Infarction

P. MANOHAR KINI and HUBERT V. PIPBERGER

A Q/R ratio greater than 0.25 in lead Y led to the recognition of 51 percent of cases of posterior wall myocardial infarction and proved the most useful criterion in this study to differentiate true posterior wall myocardial infarction from right ventricular hypertrophy. With seven measurements obtained in multivariate analysis 78 percent of cases of posterior myocardial infarction and 79 percent of cases of right ventricular hypertrophy were correctly classified.

614 Comparative Prevalence of the Fourth Heart Sound in Hypertensive and Matched Normal Persons

MICHAEL SWISTAK, HARRY MUSHLIN and DAVID H. SPODICK

This blind, randomized phonocardiographic study of 50 normal and 50 age- and sex-matched hypertensive subjects showed a high and equal prevalence rate of S_4 in middle-aged persons as in older persons. Quantitative studies are indicated to determine when this sound can be considered a presystolic gallop.

EXPERIMENTAL STUDIES

617 Sinus Nodal Reentry. Effect of Quinidine

KARLEN L. PAULAY, GERALD M. WEISFOGEL and ANTHONY N. DAMATO

Sinus nodal reentry experimentally produced in 19 dogs was abolished by therapeutic blood levels of quinidine which increased atrial refractoriness and slowed atrial conduction in 15 dogs and also induced conduction delay and block along the reentrant pathway in 6 of the animals. Such delay and block may be another mechanism for abolishing sinus nodal reentry.

623 Functional Anatomy of the Canine Left Bundle Branch

RALPH LAZZARA, BILLY K. YEH and PHILIP SAMET

Anatomic and electrophysiologic data obtained in vitro before and after lesions were placed in the proximal left bundle branch of the heart in 11 dogs suggest that this branch is best represented as a fan-shaped network of interwoven fibers whose diverging border fibers are specialized for rapid, distant transport. The clinical implications with reference to the bifascicular representation of the human left bundle branch are discussed.

633 Electrophysiologic Antagonism of Quinidine and Bretylium Tosylate

IRANY M. DE AZEVEDO, YOSHIO WATANABE and LEONARD S. DREIFUS

Administration of quinidine and bretylium tosylate in isolated perfused rabbit hearts demonstrated contrasting electrophysiologic effects of these agents on atrioventricular conduction and the duration of action potential and the refractory period in ventricular fibers. The results suggest that use of bretylium to control arrhythmias may require withdrawal of other antiarrhythmic agents.

639 Effects of Intraperitoneal Administration of Propranolol on the Mouse Heart. Histochemical and Electron Microscopic Observations

EDGAR F. ALLIN, JANICE M. MILLER, GEORGE G. ROWE and JAMES A. WILL

Ultrastructural and histochemical studies showed no acceptable evidence that propranolol caused myocardial damage in 3 week old Swiss white mice, negating earlier reported evidence that propranolol produces cardiac lesions.

Beat after beat...day after day

CARDIOQUIN tablets

(quinidine polygalacturonate)

To convert...to MAINTAIN normal sinus rhythm

After conversion of cardiac arrhythmias—whether with CARDIOQUIN Tablets or some other current method—only low b.i.d. or t.i.d. dosage of this unique polygalacturonate salt of quinidine is required in most cases to maintain normal sinus rhythm.

Well-tolerated, CARDIOQUIN Tablets are particularly suited for maintenance therapy, since the polygalacturonic acid serves as a buffering moiety. It protects the mucosa of the stomach and permits dependable absorption of the quinidine.*

*Aviado, D. M., *Krantz and Carr's Pharmacologic Principles of Medical Practice*, ed. 8, Baltimore, Williams and Wilkins Co., 1972, p. 456.

BRIEF SUMMARY—INDICATIONS: CARDIOQUIN Tablets (quinidine polygalacturonate) are indicated in the treatment of: premature atrial and ventricular contractions; paroxysmal atrial tachycardia; paroxysmal AV junctional rhythm; atrial flutter; paroxysmal atrial fibrillation; established atrial fibrillation when therapy is appropriate; paroxysmal ventricular tachycardia when not associated with complete heartblock; maintenance therapy after electrical conversion of atrial fibrillation and/or flutter. CONTRAINDICATIONS: Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine. WARNING: In the treatment of atrial flutter reversion to sinus rhythm may be preceded by a progressive reduction in the degree of AV block to a 1:1 ratio and resulting extremely rapid ventricular rate. COMPOSITION: Each CARDIOQUIN Tablet (quinidine polygalacturonate 275 mg.) is equivalent in quinidine content to 3 grains quinidine sulfate. DOSAGE AND ADMINISTRATION: Dosage must be adjusted to individual needs, both for conversion and maintenance. An initial dose of 1 to 3 tablets may be used to terminate arrhythmias, and may be repeated in 3-4 hours. If normal sinus rhythm is not restored after 3 or 4 equal doses, the dose may be increased by ½ to 1 tablet (137.5 to 275 mg.) and administered three to four times before any further dosage increase. For maintenance, one tablet may be used two to three times a day; generally one tablet morning and night will be adequate. SUPPLIED: Uncoated, scored tablets in bottles of 50.

METHODS

643 Computerized System for Noninvasive Techniques. I. Its Value for Systolic Time Intervals

SAMUEL ZONERAICH, OLGA ZONERAICH and JOHN RODENRYS

Use of a total computerized system described in this article for the study of noninvasive techniques can more rapidly and accurately calculate many variables and lead to better evaluation of left ventricular function.

650 Quantification of Serum Creatine Phosphokinase Isoenzyme Activity

ROBERT ROBERTS, PHILIP D. HENRY, SAKE A. G. J. WITTEEVEEN and BURTON E. SOBEL

This new procedure to determine quantitatively activity of individual creatine phosphokinase (CPK) isoenzymes in a serum sample with or without increased total CPK activity appears particularly useful in assessing myocardial infarction. Serum MB CPK activity averaged 0.002 IU/ml in 27 normal persons, 0.064 IU/ml in 30 subjects with myocardial infarction and was not increased in 23 patients after intramuscular injection or abdominal surgery.

REPORTS ON THERAPY

655 Prophylactic Quinidine for the Prevention of Arrhythmias After Acute Myocardial Infarction

DAVID T. JONES, WILLIAM J. KOSTUK and RAMSAY W. GUNTON

This reappraisal of the value of prophylactic orally administered quinidine in 103 patients with uncomplicated myocardial infarction of less than 24 hours' duration shows that over the observation period of 72 hours ventricular arrhythmias occurred in 45 percent of the 58 patients receiving placebo and in 16 percent of those receiving quinidine. Ventricular tachycardia occurred in 12 of 58 patients receiving placebo and in only 1 of 45 quinidine-treated patients. There was no difference in mortality in either group during the 72 hour study or during the entire period of hospitalization.

661 Comprehensive Treatment Plan for the Prevention of Primary Ventricular Fibrillation in Acute Myocardial Infarction

MILFORD G. WYMAN and LUCILLE HAMMERSMITH

Prophylactic administration of lidocaine or procainamide, or both, according to a carefully prescribed plan upon a patient's admission to the emergency room and coronary care unit of a community hospital lowered the prevalence rate of primary ventricular fibrillation from 6.5 percent of 139 cases to 0.3 percent and no deaths in 1,026 cases.

PEDIATRIC CARDIOLOGY

668 Ostium Secundum Atrial Septal Defect Associated with Balloon Mitral Valve in Children

BENJAMIN E. VICTORICA, LARRY P. ELLIOTT and IRA H. GESSNER

These studies in eight patients indicate a balloon mitral valve should be suspected in all children with an ostium secundum atrial septal defect and particularly those with unusual electrovectorcardiographic features or suggestive auscultatory findings such as a midsystolic click or a late systolic murmur of mitral insufficiency. Left ventriculograms in every patient with an atrial septal defect are recommended to determine the status of the mitral valve.

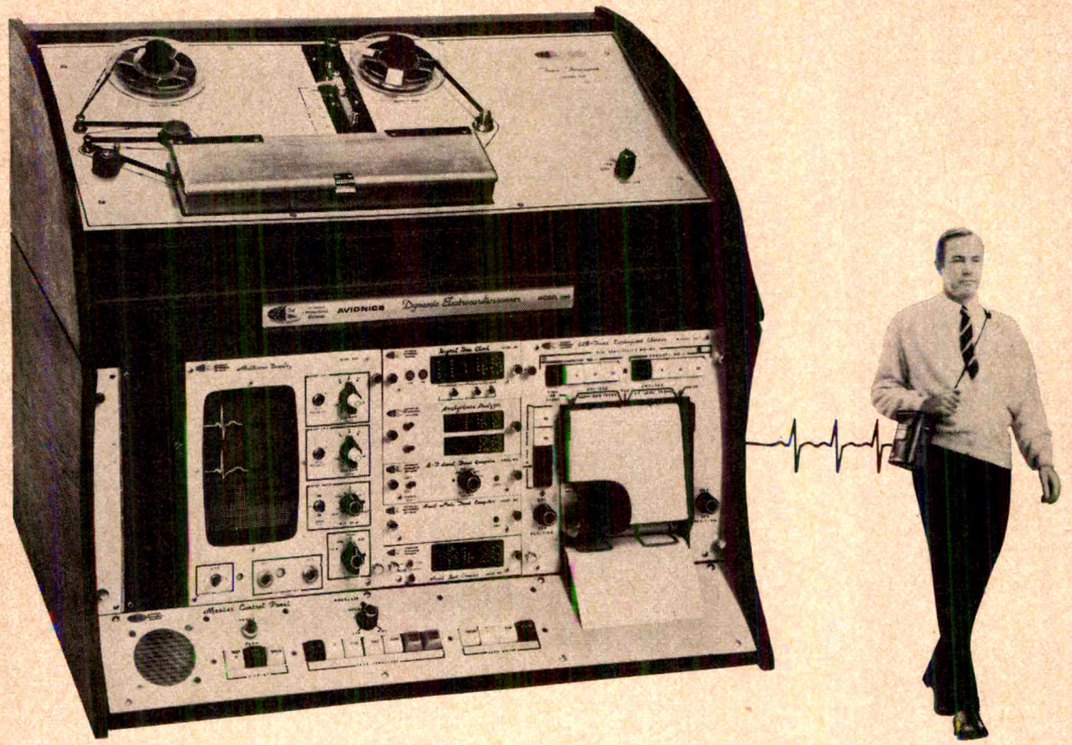
THE NEW 660 A DRAMATIC LEAP FORWARD IN DYNAMIC ELECTROCARDIOGRAPHY!



Model 660 Features:

- 2-channel playback of Holter recordings
- 2-channel paper writer
- 120:1 playback ratio (24-hour recording scanned in 12 minutes)
- Trend recording of S-T segment and heart rate
- Digital display and chart recording of ventricular and supraventricular ectopic beats
- Total heart beat counter
- Digital display clock
- Automatic time print-out on ECG write-out
- Adjustable delay loop for tape deck
- Solid state, modular design

Now available to every physician . . . an advanced ECG system for post MI follow-up, pacemaker evaluation, evaluation of drug administration, and detecting the causes of such fleeting symptoms as phantom chest pains and dizziness.

Model 425 Holter Monitor
Provides a 2-channel, 24-hour ECG recording of ambulatory patients.

Model 660 Electrocardioscanner®
Performs a 12-minute scan of the 24-hour, 2-channel tape recording and provides standard ECG documentation of abnormalities and quantification of arrhythmia and ischemic data.

AVIONICS

☐ Please send me the literature. I would like to know more about Holter monitoring and the Avionics Dynamic Electrocardiographic Systems.

☐ Send the literature, and schedule me for a visiting demonstration. I am definitely interested in acquiring this kind of equipment.

674 Cyanosis in Patients with Atrial Septal Defect Due to Systemic Venous Drainage into the Left Atrium

MAXWELL S. MAILLIS, TSUNG O. CHENG, JERRY F. MEYER, I. SYLVIA CRAWLEY and JOSEPH LINDSAY, Jr.

Three patients with atrial septal defect had cyanosis and significant left to right shunting due to systemic venoarterial shunting into the left atrium. Since cyanosis is not a contraindication to surgical closure of the septal defect in such patients, diagnostic cardiac catheterization studies should be performed to detect this less well recognized mechanism.

PROGRESS REPORTS

679 Patency of Aortocoronary Vein Grafts and Serum Triglycerides. Three Year Follow-Up Study

CLAUDE ALLARD, CLAUDE GOULET, CLAUDE M. GRONDIN, JACQUES LESPERANCE and MARTIAL BOURASSA

This 3 year study demonstrates an increased risk of occlusion or stenosis of aortocoronary vein grafts in patients with hypertriglyceridemia. Serum cholesterol levels did not affect the fate of these grafts.

CASE REPORTS

681 Chordae Tendineae Rupture Complicating the Systolic Click-Late Systolic Murmur Syndrome

DORIS GOODMAN, DEMETRIOS KIMBIRIS and JOSEPH W. LINHART

Acute mitral insufficiency occurring after spontaneous rupture of mitral chordae tendineae belies the commonly accepted benignity of the systolic click-late systolic murmur syndrome. This complication in a 52 year old woman necessitated the insertion of a mitral valve prosthesis and led to her death from hypotension, bradycardia and bleeding several days after operation.

685 Diastolic Blood Flow Into the Pulmonary Artery in Carcinoid Heart Disease

PAUL M. WOLFSON, LOTFY L. BASTA, RICHARD P. SNODGRASS and J. MICHAEL KIOSCHOS

Diastolic blood flow into the pulmonary artery is attributed to the combined effects of increased right atrial pressure, decreased right ventricular compliance and normal pulmonary arterial pressure in this 45 year old patient with carcinoid heart disease.

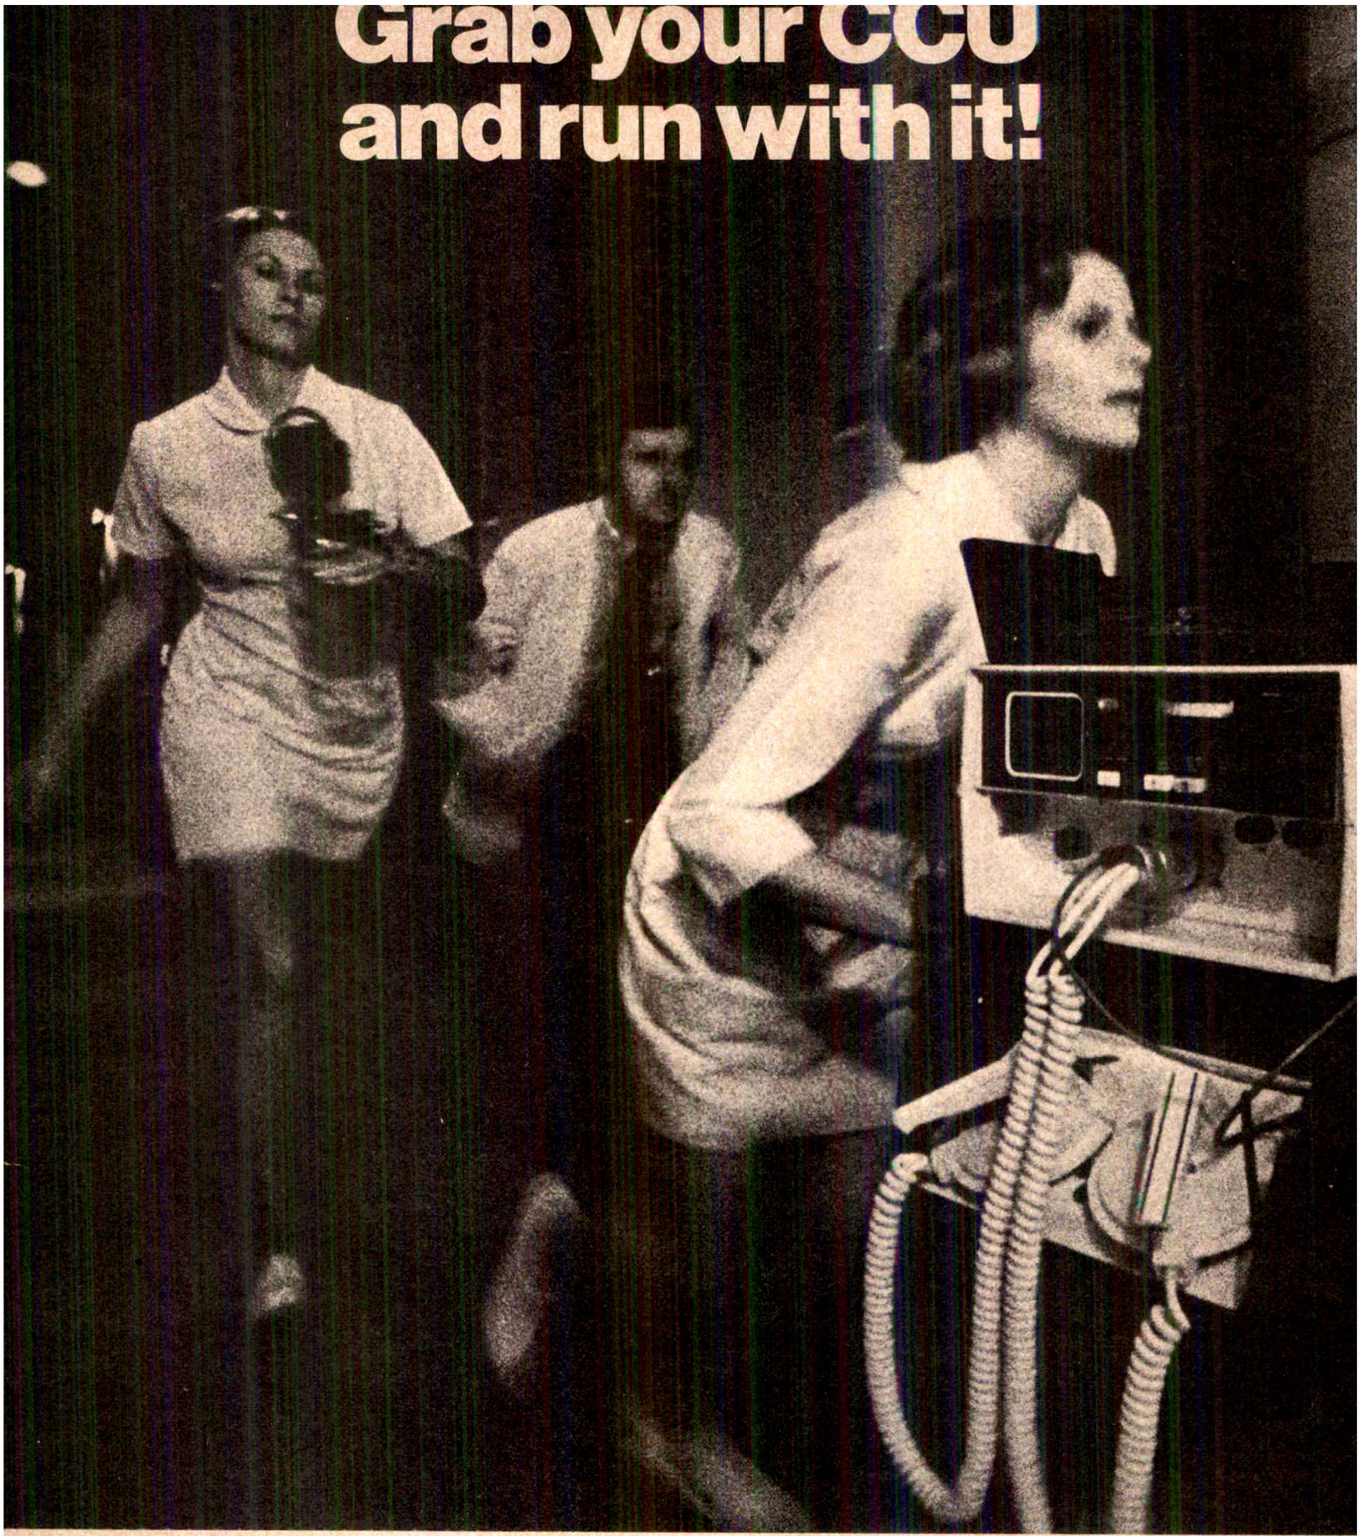
Grab your CCU and run with it!



It would be ideal if you could confine all cardiac arrest cases to the Coronary Care Unit . . . where they could be treated immediately. The trouble is, they can and do happen anywhere in the hospital.

One solution is a crash cart for every floor . . . manned by a special team trained to respond instantly to cardiac emergencies on their floor, and outfitted with the necessary emergency equipment, including a LIFEPAK portable, defibrillator/cardioscope from Physio-Control.

LIFEPAKS offer a wide range of features, from Quik-Look® (instantaneous ECG trace through the defibrillator paddles), to optional built-in recorders, to modulators for transmitting ECG signals by radio or telephone. Many of LIFEPAK's features were industry "firsts" developed by Physio-Control, the world's leading manufacturer of defibrillators.

For complete details, write for our new full-color-illustrated, 24-page brochure: Physio-Control Corporation, 11811 Willows Road, Redmond, Wash. 98052. Phone (206) 883-1181. Cable: Physio-Red. Telex: 32-0166.

Large Hospital Chooses Single Manufacturer For Its Patient Monitoring Equipment

One of the nation's comprehensive patient monitoring facilities is located in a 620-bed northern Ohio hospital. Here, 53 beds are electronically monitored for heart attack victims, the critically ill, and trauma patients. All monitoring equipment is General Electric, with the exception of 16 beds installed several years earlier.

Cardiac Care

In the cardiac care unit, GE monitoring equipment includes an ECG amplifier, heart rate module, and single channel display at each of 16 beds. The central nurse station is equipped with remote heart rate and arrhythmia monitors for each of these beds. In addition the nurse station also has four 4-trace nonfade displays with a 12-second memory and ECG "freeze" mode, three AHA automatic graph recorders, and a portable graph recorder for use at bedside.

According to the CCU division manager, "The nonfade displays with built-in alarms have been a big help. We can freeze any of the 16 patient's baselines, look at any particular complex, hold it indefinitely, and write out the information at any given time afterwards. The nonfade feature lets us hold information for more extensive study while maintaining a complete record."

Post-cardiac care

The 25-bed post-cardiac care unit serves ambulatory patients requiring only intermediate care, following their transfer from the CCU. This unit is equipped with GE telemetry systems. Patients are free to move about within the area while small transmitters, attached to their chests, transmit ECG data to the unit's nurse station.

At this station, up to four ECG transmissions are monitored on a single 4-trace nonfade display. Heart rate information is presented by four digital heart rate displays. The system has automatic visual and audible alarms to alert the staff if preset limits are exceeded. A single graph recorder serves four patients, and automatically switches to the appropriate channel in an alarm condition. An additional portable, battery-powered telemetry system is available for use at bedside, or to monitor a fifth patient.

Intensive care

At each bedside in the 12-bed intensive care unit there is an ECG amplifier, heart rate module, single-trace display, and digital temperature readout. Four mobile carts provide bedside monitoring of venous and arterial blood pressures; blood pressures for an 8-bed section can be remotely displayed at the central nurse station.

The central station in ICU features three 4-trace, nonfade displays, remote digital heart rate monitors, and three automatic graphs. ICU division manager states that the large work load required "an easy-to-use, highly-accurate monitoring system." Another consideration, he adds, "was the likelihood of an eventual move to a more convenient location. The modular design of the GE equipment will make that a relatively simple job.

GENERAL ELECTRIC

The burn unit and hemodialysis units, located adjacent to the ICU, are equipped with identical emergency carts consisting of an ECG amplifier, heart rate monitor, single-channel scope, graph, recorder, and DC defibrillator.

Emergency department

The hospital's emergency department is furnished with two mobile telemetry monitoring systems, comprising a telemetry receiver, heart rate monitor, graph recorder, and a 2-trace nonfade display with 12-second memory.

The division manager of the emergency department says, "On an average, we are using the telemetry system approximately 10 times during each 24-hour period. Each patient monitored is on the system for about two hours." He adds, "We routinely monitor all patients admitted who exhibit any indication of possible heart problems, therefore, increasing our capability of providing anticipatory care."

All telemetry information is duplicated at the central nurse station, eliminating any need to keep medical personnel in constant attendance at bedside. The station is equipped with a 4-trace, nonfade display. The display is operated in the "cascade" mode, thus 12 seconds of ECG data for each of two patients is always on view.

Why GE Equipment?

The hospital's CCU division manager, who coordinated monitoring equipment acquisition explains:

"We knew we wanted to buy all the equipment from a single manufacturer. With only one manufacturer's equipment throughout the house, training problems are simplified. And because we were changing from one system to another, the quality of in-service education offered was important," he adds.

"Our GE representative spent an extensive amount of time in the hospital developing a program to instruct nurses in the application of the equipment. We've had two sessions of in-service education of four days each, involving about 150 hospital personnel, with future programs planned," he says.

"We also considered maintenance of the equipment. When you have as many patients monitored as we do, time is very important.

"The GE service technicians give us service at a moment's notice. If a problem does occur, the modular design permits repairs to be performed quickly.

"We believe the nursing staff must feel very confident with a monitoring system, and they do feel confident with GE's. The equipment has few controls to adjust, and doesn't require extensive set-up procedures by the nurses."

Total Involvement from Beginning to Present

The planning staff of a 518-bed medical center, located in the far northwestern corner of the country, reports that total and early involvement of the manufacturer was of immeasurable help in getting its coronary care area designed, equipped and functioning on schedule.

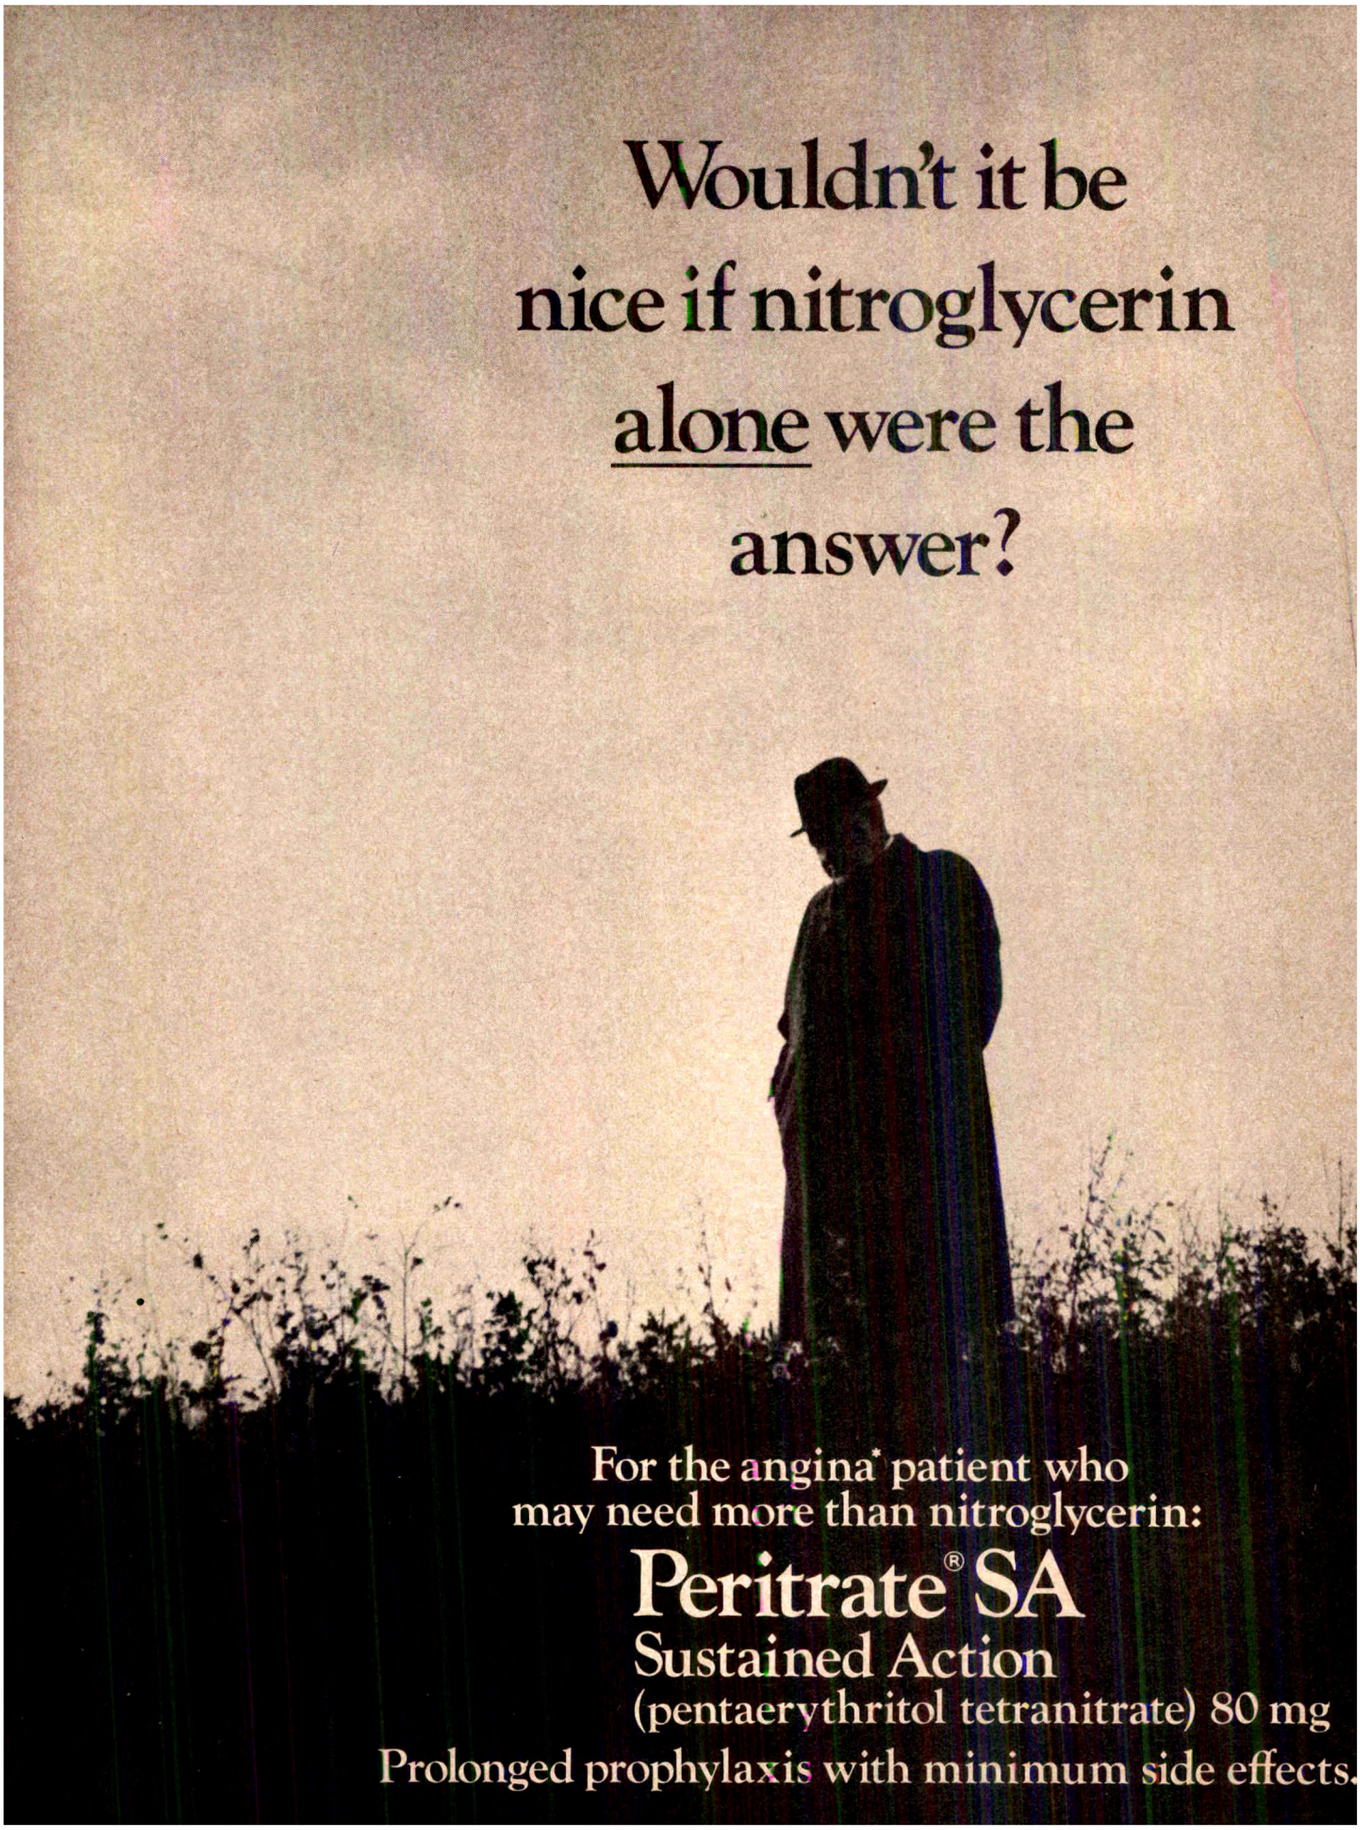
The department called for 10 monitored beds of acute coronary care, and 6 beds of monitored telemetry in intermediate coronary care, with capabilities of expanding to 20 beds. Intensive care was to include 4 monitored beds, with expansion capabilities to 12 beds.

The nurse station comprised 4-trace, nonfade displays and automatic graphs. Each room was equipped with an ECG amplifier, master heart rate and 2-trace nonfade display. General Electric patient monitoring was specified throughout.

Manufacturer participation, through GE's Northwest District, began soon after the building decision was made. Under the supervision of this District, GE architectural, electrical and biomedical engineers were involved in the actual installation of the equipment.

As part of the service contract, a GE Medical Systems serviceman is assigned to the center on a full time basis, servicing the coronary care area and the 30-room radiology department.

General Electric
Medical Systems
Milwaukee, Toronto,
Liege, Madrid



Wouldn't it be
nice if nitroglycerin
alone were the
answer?
For the angina* patient who
may need more than nitroglycerin:
Peritrate® SA
Sustained Action
(pentaerythritol tetranitrate) 80 mg
Prolonged prophylaxis with minimum side effects.

Peritrate® SA

Sustained Action
(pentaerythritol tetranitrate) 80 mg

CAUTION: Federal law prohibits dispensing without prescription.

Each tablet of Peritrate SA Sustained Action contains: pentaerythritol tetranitrate 80 mg (20 mg in immediate release layer and 60 mg in sustained release base). Peritrate® (pentaerythritol tetranitrate) is a nitric acid ester of a tetrahydric alcohol (pentaerythritol).

Indications: Based on a review of this drug by the National Academy of Sciences–National Research Council and/or other information, FDA has classified the indications as follows:

"Possibly" effective: Peritrate (pentaerythritol tetranitrate), is indicated for the relief of angina pectoris (pain associated with coronary artery disease). It is not intended to abort the acute anginal episode but it is widely regarded as useful in the prophylactic treatment of angina pectoris.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg is contraindicated in patients who have a history of sensitivity to the drug.

Warning: Data supporting the use of Peritrate (pentaerythritol tetranitrate) during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents.

Precautions: Should be used with caution in patients who have glaucoma. Tolerance to this drug, and cross-tolerance to other nitrites and nitrates may occur.

Adverse Reactions: Side effects reported to date have been predominantly related to rash (which requires discontinuation of medication) and headache and gastrointestinal distress, which are usually mild and transient with continuation of medication. In some cases severe persistent headaches may occur.

In addition, the following adverse reactions to nitrates such as pentaerythritol tetranitrate have been reported in the literature:

(a) Cutaneous vasodilatation with flushing.
(b) Transient episodes of dizziness and weakness, as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop.
(c) An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur, even with the usual therapeutic doses. Alcohol may enhance this effect.

Dosage: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg (b.i.d. on an empty stomach), 1 tablet immediately on arising and 1 tablet 12 hours later.

Supplied: Peritrate SA Sustained Action (pentaerythritol tetranitrate) 80 mg, double layer, biconvex, dark green/light green tablets in bottles of 100 and 1000.

Additional Dosage Forms: Peritrate 20 mg–light green, scored tablets; Peritrate 10 mg–light green, unscored tablets. Bottles of 100 and 1000. Full information is available on request.

Div. Warner-Lambert Company
Morris Plains, N.J. 07950

PE-GP-41

Problem: The patient who plays doctor.

You prescribe a low-sodium diet, but after a spell of dreary meals it's the patient who prescribes better things for himself—better for his taste buds, but worse for his health.

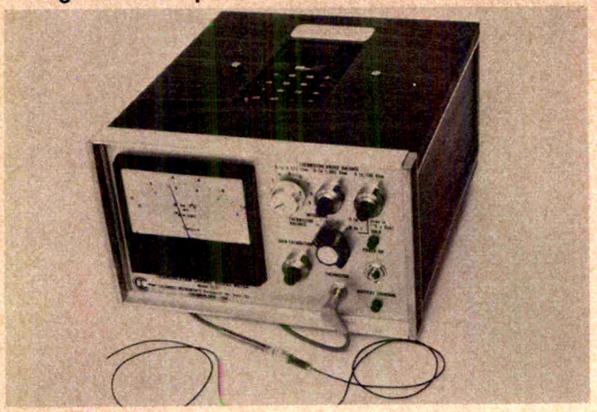
Amateur malpractice.

To avert this obvious subversion of your orders, we suggest that you recommend Adolph's Salt Substitute. Non-clinical evidence indicates that patients like the taste of Adolph's better: it's the best-seller, nationwide. What's more, Adolph's can be used in cooking just like ordinary salt. It's a source of supplemental potassium, too.

We'll be glad to send you samples—free, of course. Write to: Jeannette Frank, c/o Adolph's Ltd., Box 828, Dept. SM, Burbank, California 91503.

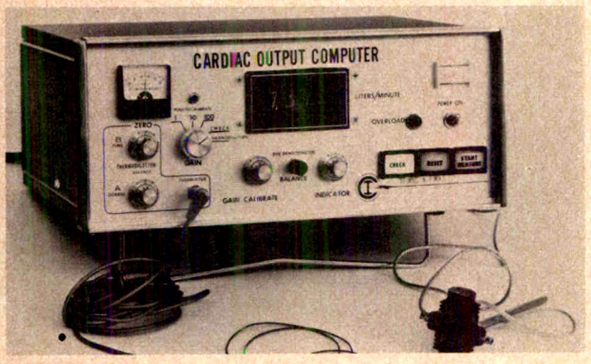
THERMODILUTION

Using room temperature indicator!



THERMODILUTION CARDIAC OUTPUT METER AND INTEGRATOR

- An intermediate instrument between the simple bridge and full scale computer.
- Battery operated—no shock hazards. Rechargeable.
- Will work with any thermistor catheter on the market; including Swan-Ganz balloon flow-directed catheter.
- Equipped with a recorder output.
- Provides information on the area under the dilution curve. (Extrapolates the dilution curve!)
- Price: $1,540.00



THERMO AND DYE DILUTION CARDIAC OUTPUT COMPUTER

- Equipped with Thermodilution and/or Dye Dilution Densitometer
- Easy calibration, automatic zeroing.
- Remote control by foot switch.
- Digital readout in L/min.
- Recorder outputs.

Hygroton®
(chlorthalidone USP)

BRIEF SUMMARY

Indications: Hypertension, adjunctive therapy in edema. **Contraindications:** Anuria, hypersensitivity to chlorthalidone; routine use of diuretics in an otherwise healthy pregnant woman with or without mild edema is contraindicated and possibly hazardous. **Warnings:** Should be used with caution in severe renal disease, impaired hepatic function or progressive liver disease. May be additive or potentiative of the action of other antihypertensive drugs. Sensitivity reactions may occur in patients with a history of allergy or bronchial asthma. Usage in women of childbearing age requires that the potential benefits of the drug be weighed against its possible hazards to the fetus. These hazards include fetal or neonatal jaundice, thrombocytopenia, and possibly other adverse reactions which have occurred in the adult. In nursing mothers, thiazides cross the placental barrier and appear in cord blood and breast milk. **Precautions:** Periodic determination of serum electrolytes to detect possible electrolyte imbalance should be performed at appropriate intervals. All patients receiving chlorthalidone should be observed for clinical signs of fluid or electrolyte imbalance; namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with chlorthalidone as with any other potent diuretic, especially with brisk diuresis, when severe cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis therapy may exaggerate metabolic effects of hypokalemia especially with reference to myocardial activity. Any chloride deficit is generally mild and usually does not require specific treatment except under extraordinary circumstances (as in liver disease or renal disease). Dilutional hyponatremia may occur in edematous patients in hot weather. Hyperuricemia may occur or gout precipitated in certain patients. Insulin requirements in diabetic patients may be increased, decreased, or unchanged and latent diabetes mellitus may become manifest. Chlorthalidone and related drugs may increase the responsiveness to tubocurarine. The antihypertensive effects of the drug may be enhanced in the postsympathectomy patient. Chlorthalidone and related drugs may decrease arterial responsiveness to norepinephrine. If progressive renal impairment becomes evident, as indicated by a rising nonprotein nitrogen or blood urea nitrogen, a careful reappraisal of therapy is necessary with consideration given to withholding or discontinuing diuretic therapy. Chlorthalidone and related drugs may decrease serum PBI levels without signs of thyroid disturbance. **Adverse Reactions:** Anorexia, gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic cholestatic jaundice), pancreatitis; dizziness, vertigo, paresthesias, headache, xanthopsia; leukopenia, agranulocytosis, thrombocytopenia, aplastic anemia; purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis) (cutaneous vasculitis), Lyell's syndrome (toxic epidermal necrolysis). Orthostatic hypotension may occur and may be aggravated by alcohol, barbiturates or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, impotence. Whenever adverse reactions are moderate or severe, chlorthalidone dosage should be reduced or therapy withdrawn. **Usual Dose:** One tablet daily. **How Supplied:** Tablets—100 mg. (white, scored) and 50 mg. (aqua) in bottles of 100 and 1000; single-dose blister packs, boxes of 500.

USV PHARMACEUTICAL CORP., Tuckahoe, N.Y. 10707

Suppose you had mild hypertension

Wouldn't you opt for medication that was simple to take and easy to live with?

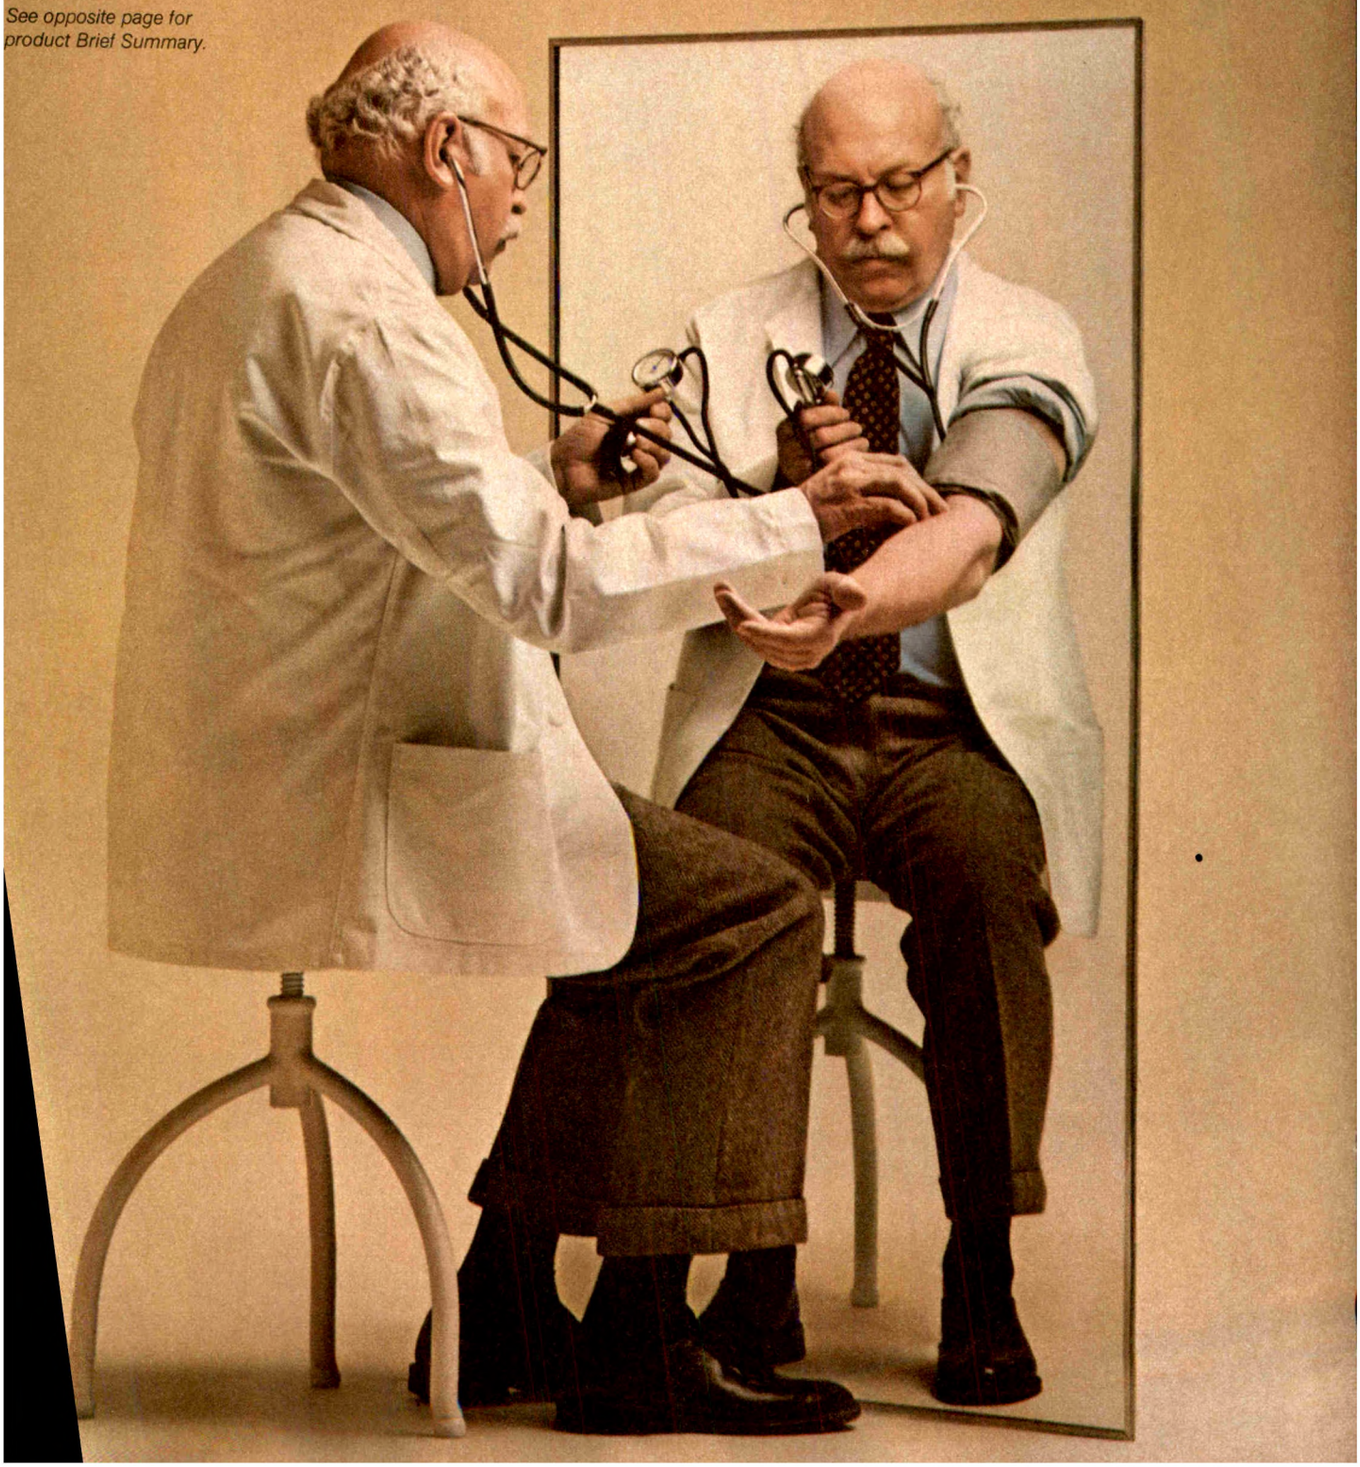
Hygroton, for example. As effective as comparable agents for lowering blood pressure and relieving edema. This unique nonthiazide antihypertensive/diuretic offers the significant advantage of smooth, long action with once-a-day dosage to help assure that it will be taken *exactly* as prescribed, for as long as necessary. While side effects can of course occur (see Brief Summary), they should not unduly disrupt the average patient's life.

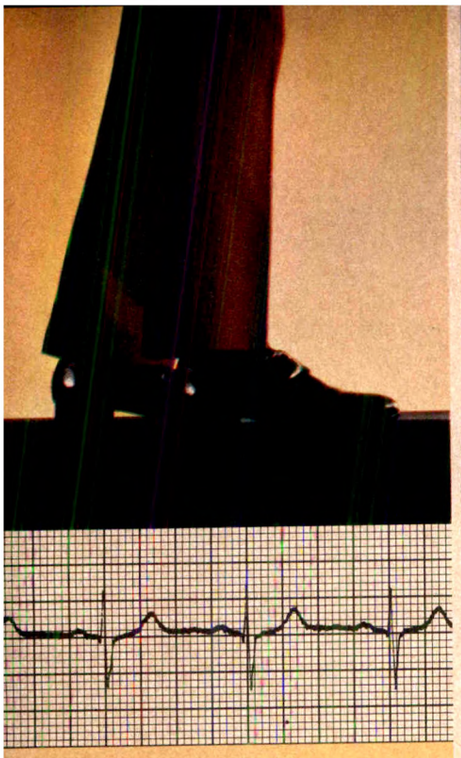
Hygroton. You'd appreciate it if you had hypertension. So will your patients.

the once-a-day antihypertensive/diuretic that helps your patients stay the long therapeutic course

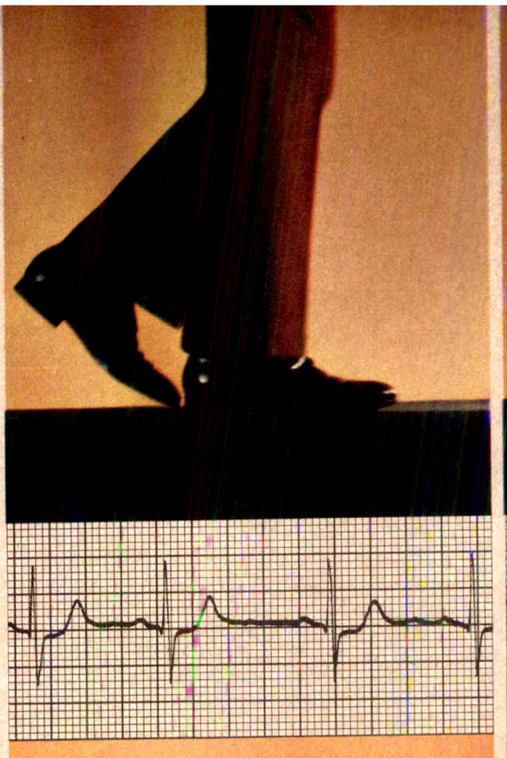
Hygroton®
(chlorthalidone USP)

See opposite page for product Brief Summary.

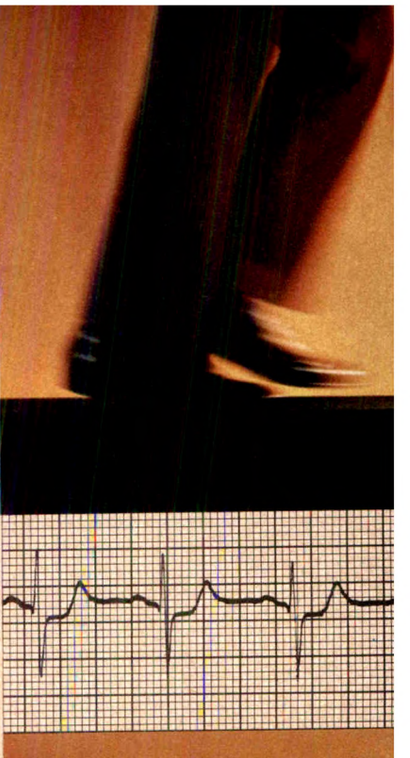




Standing, at rest, V-5, HR-74. American's Stress Test Electrode supplies immediate base line stability. Testing with a narrow, drift free base line can begin as soon as the self-adhering, silver/silver chloride electrodes have been applied to the patient and connections made to your monitoring equipment.



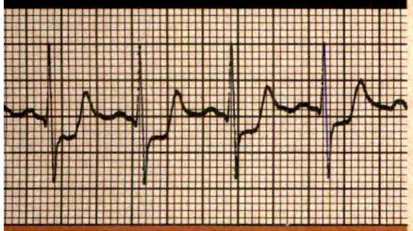
4th Minute at 2 mph, 0% Grade, V-5, HR-75. Base line stability is maintained because of the electrode's gel retaining cup and impregnated foam pad which is slightly oversize to assure positive, continuous pressure at the electrode-skin surface. The results: immediate onset and virtual elimination of base line instability and motion artifact.



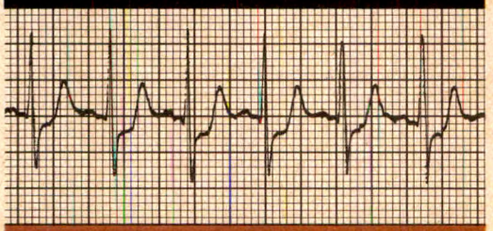
4th Minute at 3 mph (8th minute test), 0% Grade, V-5, HR-83. (T patient's ECG indicates 1 mm of depression.) Fully shielded cable and leadwire provide an effectiv barrier to the electrical interfere that might otherwise mask smal amounts of S-T depression.

Finally.

An electrode/cable system specifically designed for stress testing.

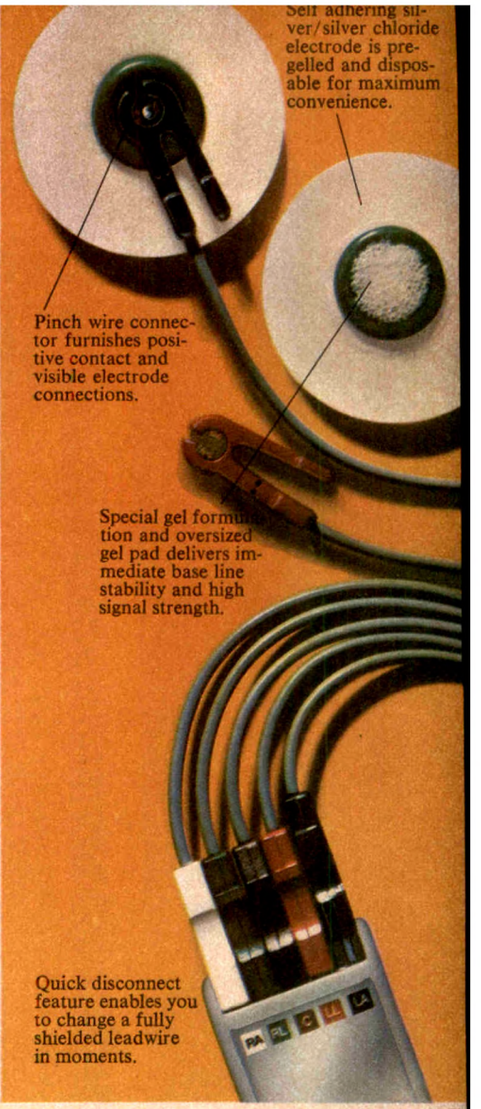


Minute at 3 mph (12th minute
est), 5% Grade, V-5, HR-117.
T depression increases to 2.5 mm.)
n at high work loads, the Ameri-
Stress Test Electrode and fully
elded cable system delivers a stable
e line and noise-free signal.



4th Minute at 3 mph (16th minute of test), 7.5% Grade, V-5, HR-135. (S-T depression drops to 2.0 mm.)
Long test procedures* seldom affect the electrode's contact with a patient's skin; trace quality remains high, even with patients who perspire heavily.

* Because of this electrode's special gel formulation, application periods of longer than four hours are not recommended.



Compare the stress test electrocardiograms you have been getting with those reproduced above.* There's a reason for the unusually high quality of the ECG traces shown: The patient was being monitored with American's new Stress Test Electrode and fully shielded cable system.

If you've been diagnosing from stress test electrocardiograms that display wide or unstable base lines, severe motion artifact or possible hidden S-T depression, please contact us. We think we can help.

Examples shown were produced under clinical conditions during an actual stress test procedure using the American Stress Test Electrode system.

We invite you to try the only electrode/cable system designed to match the "no compromise" nature of exercise stress testing. The fully shielded patient cable is adaptable to your present monitoring equipment, regardless of its make.

Please contact your American Hospital Supply or NDM representative and ask for:

- A complete demonstration of this system's benefits.
- A no obligation clinical trial. American will supply electrodes, fully shielded cables and fully shielded, quick disconnect leadwires adaptable to your present monitoring equipment during the trial period.
- A total inservice for your staff.
- Information about our nationwide technical support program.

ndm® Manufactured in U.S.A. by NDM Corporation, Dayton, Ohio 45439

The art of antianginal therapy

For centuries, treating the heart's ills has been the subtlest of arts. Even today, evaluating a drug for chronic angina pectoris involves the art of medicine as well as its science.

Persantine — over a decade of use

During more than a decade of clinical experience, compounding both science and art, Persantine has often been found useful in the long-term management of chronic angina pectoris.* It may:

eliminate or reduce the frequency of anginal attacks

improve exercise tolerance

reduce nitroglycerin requirements

Persantine — give enough — long enough

The recommended dosage: 50 mg. t.i.d. at least one hour before meals. *Give enough, long enough* — several weeks or longer of continuous therapy may be needed to see response.

Persantine®

Tablets of 25 mg.

dipyridamole

the non-nitrate
coronary vasodilator

*INDICATIONS–Based on a review of this drug by the National Academy of Science-National Research Council and/or other information, FDA has classified the indication as follows:

"Possibly" effective: For long-term therapy of chronic angina pectoris. Prolonged therapy may reduce the frequency or eliminate anginal episodes, improve exercise tolerance, and reduce nitroglycerin requirements. The drug is not intended to abort the acute anginal attack.

Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS–No specific contraindications are known.

PRECAUTIONS–Since excessive doses can produce peripheral vasodilation, the drug should be used cautiously in patients with hypotension.

ADVERSE REACTIONS–Adverse reactions are minimal and transient at recommended dosages. Instances of headache, dizziness, nausea, flushing, weakness or syncope, mild gastrointestinal distress and skin rash have been noted during therapy. Rare cases of what appeared to be an aggravation of angina pectoris have been reported, usually at the initiation of therapy. On those uncommon occasions when adverse reactions have been persistent or intolerable, withdrawal of medication has been followed promptly by cessation of undesirable symptoms.

DOSAGE AND ADMINISTRATION–The recommended dosage is 50 mg. (2 tablets) three times a day, taken at least one hour before meals. In some cases higher doses may be necessary but a significantly increased incidence of side effects is associated with increased dosage. Clinical response may not be evident before the second or third month of continuous therapy.

For complete details, please see the full prescribing information.

Taoist Eye-Heart Pathway
Representation of inner man as conceived by Taoism. Note the connecting line running from the eye to the heart. The eye-heart pathway may well allude to the Taoist principles of the right path delineated by Confucian philosophy—the path of virtuous conduct.

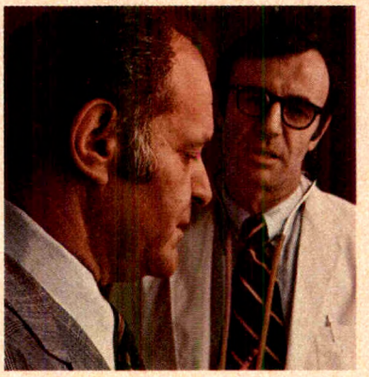
Why add Librium® (chlordiazepoxide HCl) to your cardiovascular regimen?

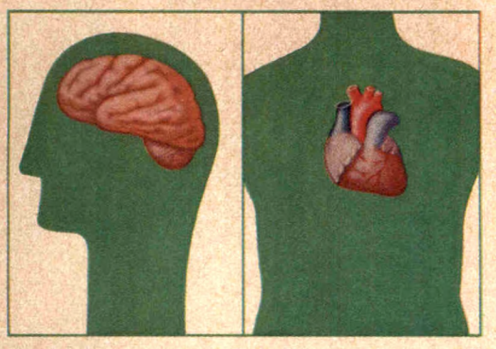


Excessive anxiety in susceptible patients can set in motion a chain of responses which add to the heart's work and thereby increase the possibility of cardiovascular complications. Furthermore, intense anxiety may interfere with effective medical management since some patients, in an attempt to deny their illness, may resist acceptance of necessary medication, dietary restrictions and other therapeutic directives. When counseling and reassurance alone are inadequate to relieve undue anxiety, adjunctive Librium (chlordiazepoxide HCl) may be beneficial.

"Specific" for anxiety reduction... wide margin of safety

Librium is used as an adjunct to primary cardiovascular medications, since it acts directly on the central nervous system, reducing excessive anxiety and emotional tension. In so doing, Librium indirectly affects cardiovascular function.

Librium has a high degree of antianxiety effectiveness with a wide margin of safety. In proper dosage, Librium usually helps calm the overanxious patient without unduly interfering with mental acuity or general performance. In the elderly and debilitated, the initial dosage is 5 mg *b.i.d.* or less to preclude ataxia or oversedation, in-



creasing gradually as needed and tolerated.

Librium is used concomitantly with certain specific medications of other classes of drugs, such as cardiac glycosides, diuretics, antihypertensive agents, vasodilators and anticoagulants. Although clinical studies have not established a cause and effect relationship, physicians should be aware that variable effects on blood coagulation have been reported very rarely in patients receiving oral anticoagulants and Librium. After anxiety has been reduced to tolerable levels, Librium therapy should be discontinued.

For relief of excessive anxiety
adjunctive

Librium® 10 mg
(chlordiazepoxide HCl)
1 or 2 capsules t.i.d./q.i.d.

ROCHE

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Relief of anxiety and tension occurring alone or accompanying various disease states.

Contraindications: Patients with known hypersensitivity to the drug.

Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. As with all CNS-acting drugs, caution patients against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Though physical and psychological dependence have rarely been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage; withdrawal symptoms (including convulsions), following discontinuation of the drug and similar to those seen with barbiturates, have been reported. Use of any drug in pregnancy, lactation, or in women of childbearing age requires that its potential benefits be weighed against its possible hazards.

Precautions: In the elderly and debilitated, and in children over six, limit to smallest effective dosage (initially 10 mg or less per day) to preclude ataxia or oversedation, increasing gradually as needed and tolerated. Not recommended in children under six. Though generally not recommended, if combination therapy with other psychotropics seems indicated, carefully consider individual pharmacologic effects, particularly in use of potentiating drugs such as MAO inhibitors and phenothiazines. Observe usual precautions in presence of impaired renal or hepatic function. Paradoxical reactions (*e.g.*, excitement, stimulation and acute rage) have been reported in psychiatric patients and hyperactive aggressive children. Employ usual precautions in treatment of anxiety states with evidence of impending depression; suicidal tendencies may be present and protective measures necessary. Variable effects on blood coagulation have been reported very rarely in patients receiving the drug and oral anticoagulants; causal relationship has not been established clinically.

Adverse Reactions: Drowsiness, ataxia and confusion may occur, especially in the elderly and debilitated. These are reversible in most instances by proper dosage adjustment, but are also occasionally observed at the lower dosage ranges. In a few instances syncope has been reported. Also encountered are isolated instances of skin eruptions, edema, minor menstrual irregularities, nausea and constipation, extrapyramidal symptoms, increased and decreased libido—all infrequent and generally controlled with dosage reduction; changes in EEG patterns (low-voltage fast activity) may appear during and after treatment; blood dyscrasias (including agranulocytosis), jaundice and hepatic dysfunction have been reported occasionally, making periodic blood counts and liver function tests advisable during protracted therapy.

Supplied: Librium® Capsules containing 5 mg, 10 mg or 25 mg chlordiazepoxide HCl. Libritabs® Tablets containing 5 mg, 10 mg or 25 mg chlordiazepoxide.

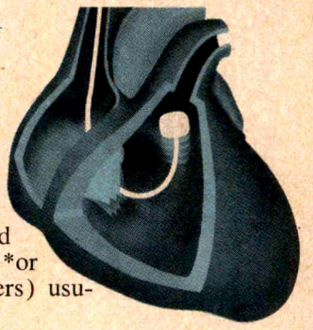
Balloon-Tipped Catheters



Swift access to the pulmonary artery* at bedside.

The *Swan-Ganz* Flow-Directed Catheter product line encompasses an expanding series of cardiac catheters which are directed by force of blood flow on the balloon into the pulmonary artery (*or into the right ventricle, in the case of the Bipolar Pacing Catheters) usually in one minute or less.

These catheters can provide valuable hemodynamic information to the cardiologist at bedside without requiring removal of the critically ill patient from bed to a fluoroscopy facility. Specific models are available to the pediatric cardiologist for diagnostic use in infants and children.

First with the concept, the *Swan-Ganz* catheters maintain preeminence through constant adaptation and refinement of the flow-directed principle to meet a diversity of diagnostic and therapeutic challenges. Present applications range from the ICU/CCU to the operating room and post-surgical recovery unit, anesthesiology department, pediatric section, pulmonary department, burn unit, and cardiac catheterization laboratory. Future applications of the flow-directed principle are the subject of continuing research at Edwards Laboratories.

Please write to the Vice President, Marketing, Edwards Laboratories, for *Swan-Ganz* Flow-Directed Catheter data, reprints of journal articles, and personal answers to any questions you may have. If you prefer, an Edwards Laboratories technical representative will be glad to call on you at your convenience.

- to abort or terminate acute anginal attacks
- to reduce the frequency and severity of anginal episodes often caused by unavoidable everyday stress

ISORDIL® SUBLINGUAL

(ISOSORBIDE DINITRATE)

SUBLINGUAL TABLETS: 2.5 mg. and 5 mg.

***Indications:** Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indication as follows:
"Probably" effective: When taken by the sublingual route, Isordil Sublingual is indicated for the treatment of acute anginal attacks and for prophylaxis in situations likely to provoke such attacks.
Final classification of the less-than-effective indications requires further investigation.

Contraindication: Idiosyncrasy to this drug.

Warnings: Data supporting the use of nitrites during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

Precautions: Tolerance to this drug and cross-tolerance to other nitrites and nitrates may occur.

Adverse Reactions: Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents. An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

Consult direction circular before prescribing.

May we send you reprints, detailed information and/or professional samples?

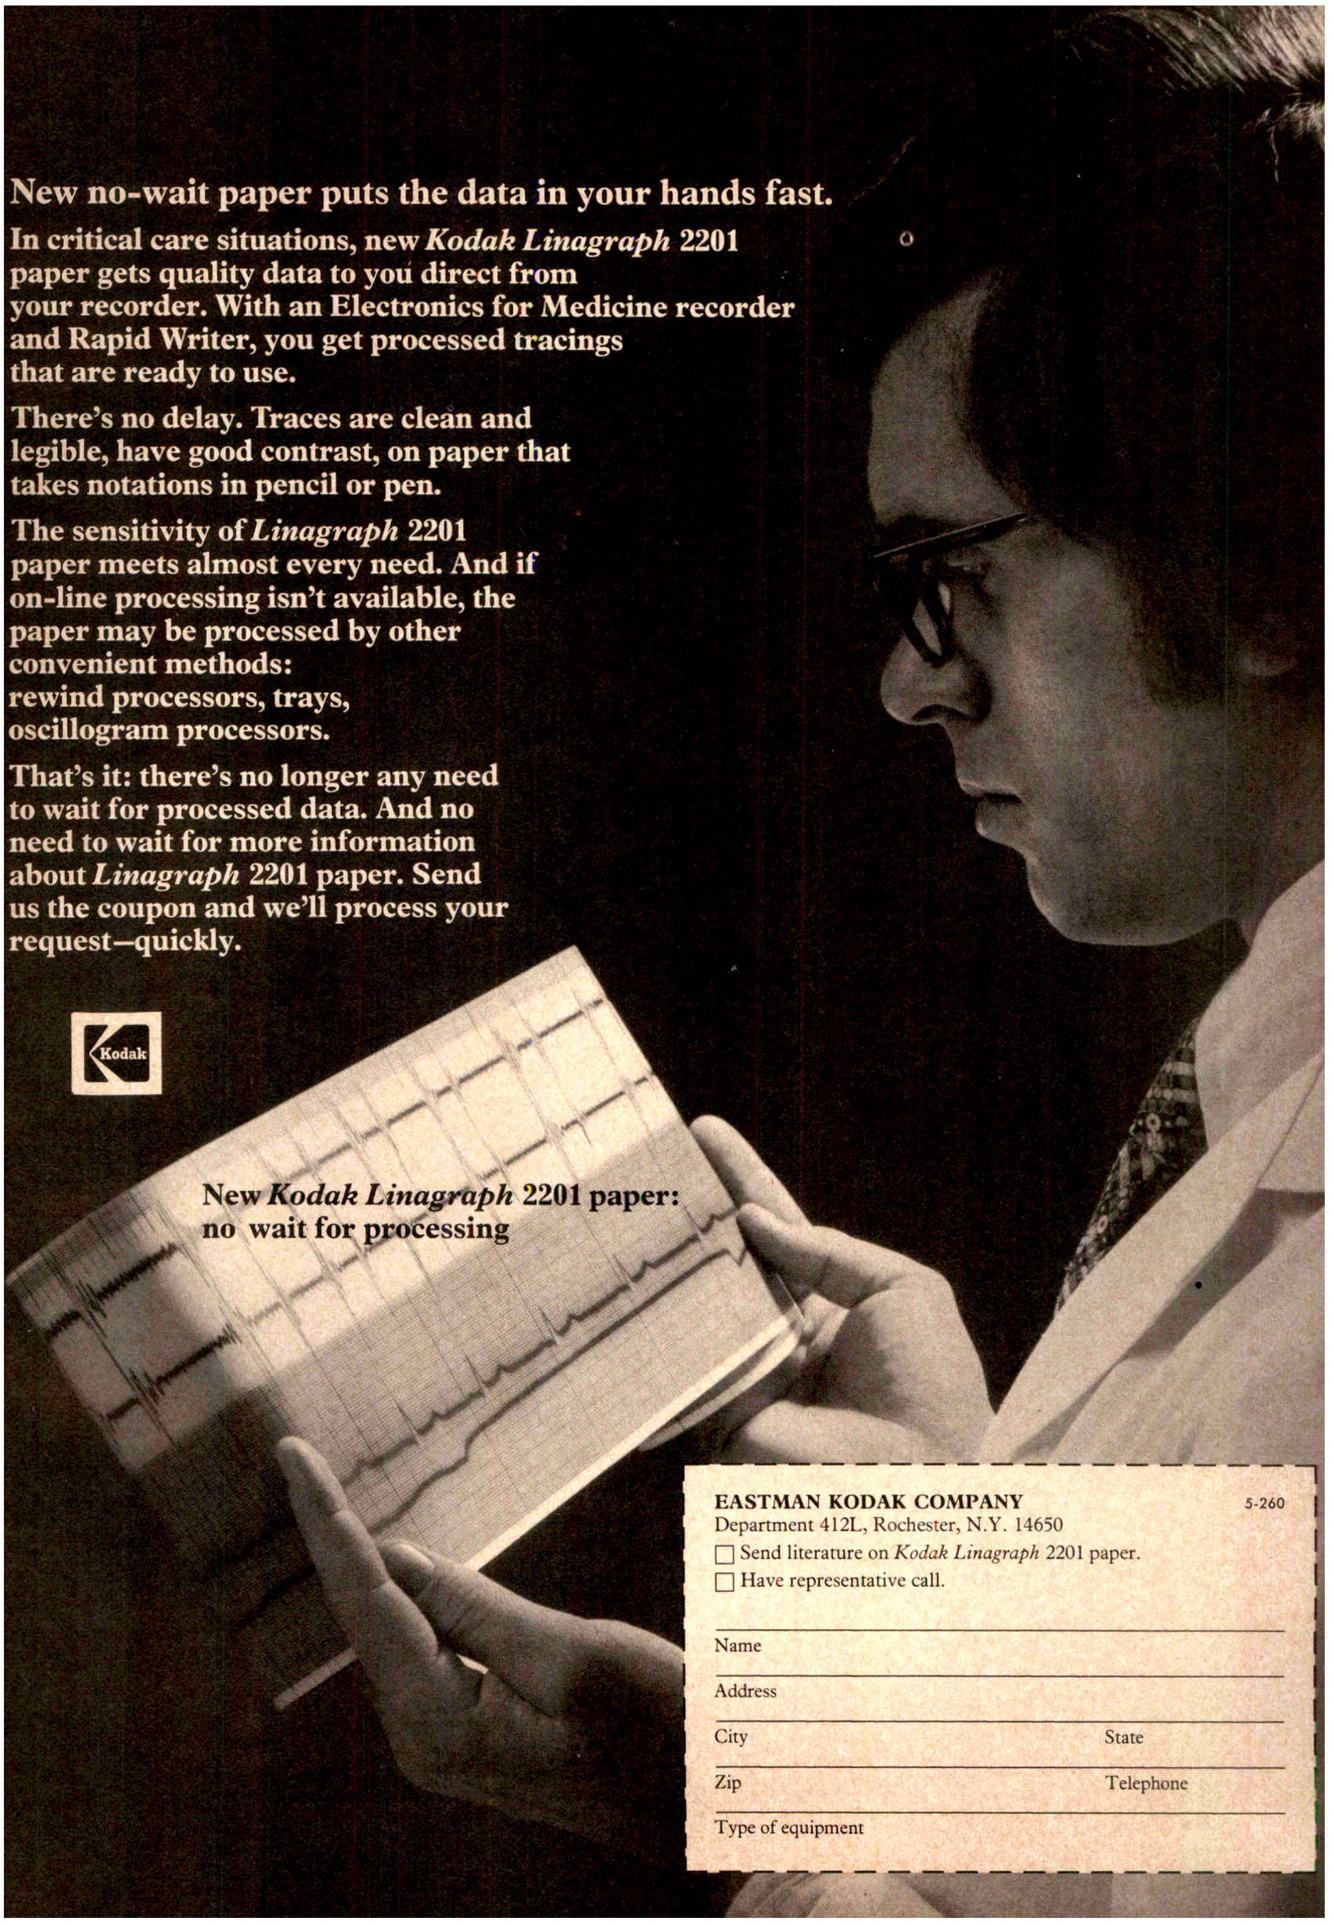
DEDICATED TO IMPROVING THE QUALITY OF LIFE, THROUGH MEDICINE

Adapted from: Kasparian H, Najmi M, Likoff W: * Laboratory Evaluation of Coronary Artery Disease. Scientific Exhibit, AMA Convention, Chicago, Ill, June 1966.



New no-wait paper puts the data in your hands fast.

In critical care situations, new *Kodak Linagraph* 2201 paper gets quality data to you direct from your recorder. With an Electronics for Medicine recorder and Rapid Writer, you get processed tracings that are ready to use.

There's no delay. Traces are clean and legible, have good contrast, on paper that takes notations in pencil or pen.

The sensitivity of *Linagraph* 2201 paper meets almost every need. And if on-line processing isn't available, the paper may be processed by other convenient methods: rewind processors, trays, oscillogram processors.

That's it: there's no longer any need to wait for processed data. And no need to wait for more information about *Linagraph* 2201 paper. Send us the coupon and we'll process your request—quickly.

Type of equipment

Lifeguard 1500 portable defibrillator saves you headache while saving patient's lives.

When you need a quick reaction lifesaving tool for ECG monitoring and defibrillation, you need the Lifeguard LG 1500 from Gould, the portable, battery operated defibrillator with built-in cardioscope and synchronizer for cardioversion.

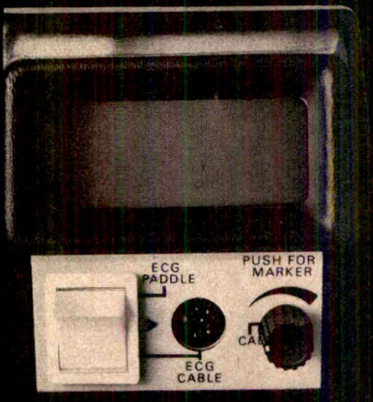
Easy to use.

Everything about the LG 1500 is designed for fast, effective action. For "quick look" or emergency monitoring, you can

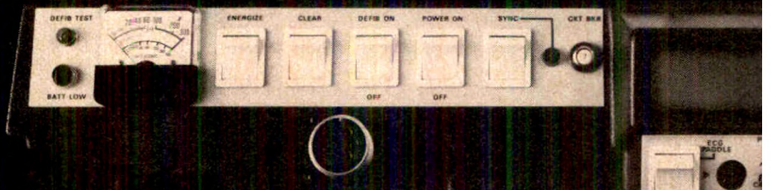
obtain the ECG signal through the paddle electrodes. Standard ECG electrodes and cables, which are stored in pockets built into the lid, may also be used.

The built-in monitoring cardioscope produces clear, readable ECG traces even in bright ambient light conditions.

The panel controls and indicators are logically located and arranged for people in a hurry. All switches are positive

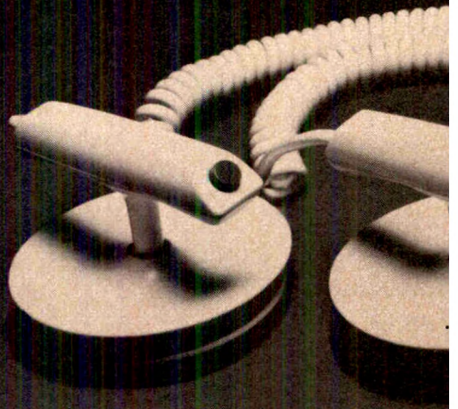


action and clearly labeled. A large, illuminated meter shows the energy level in both delivered and stored energy units. If the operator selects an energy level higher than desired, he can



simply lower it to the proper level by pressing a clear button. This also saves battery energy.

Paddles have handles lik pistol grips so the operator get a firm grip when removi paddles from their holders a pressing them against a pat chest. To give precise cont discharge timing, there is a pushbutton on each handle.



The LG 1500 is easy to carry. It's a trim, 25 pounds. Just a little larger than an attache case. The case is thin and the handle is balanced, so you can carry it naturally and easily, without straining your arm or banging it into your leg.

Outstanding safety features.

Take the paddles, for example. They have dual insulating rings

path between the handles and the electrodes. The bottom ring insulation prevents contact with the electrode and contact gel. The top ring, which is larger in diameter, is contoured so even if the operator's hand or fingers slip, they won't touch the electrodes.

The discharge control device—unique all-electronic Plasatron—eliminates circuit "ringing" due to contact bounce, which could cause deadly refibrillation. It also assures a virtually pure Lown waveform.

All high voltage circuits are isolated and the front panel controls and case are non-conductive. For maximum patient safety, the ECG input circuits are also isolated to minimize leakage to less than 10 microamps.

Chances of a premature discharge are minimized because of the location of the pushbuttons they have to be pressed simultaneously.

Superior performance and reliability.

The hermetically sealed, all-electronic Plasatron device is unexcelled for reliability. It has no moving parts and no contacts to pit, corrode, bounce or weld shut. Life expectancy is more than 100,000 operations, many times greater than electro-mechanical devices.

For maximum effectiveness, the LG 1500 provides infinitely selectable delivered energy levels from 10 to 320 watt-seconds, with up to 90 maximum-energy discharges from a fully charged battery.

An output connector permits graphic recording of ECG. It also provides an FM signal for transmitting ECG by radio or telephone.

What's more, the LG 1500 is rugged and durable. It will take rough handling, bumps and jars in stride.

Simple to service.

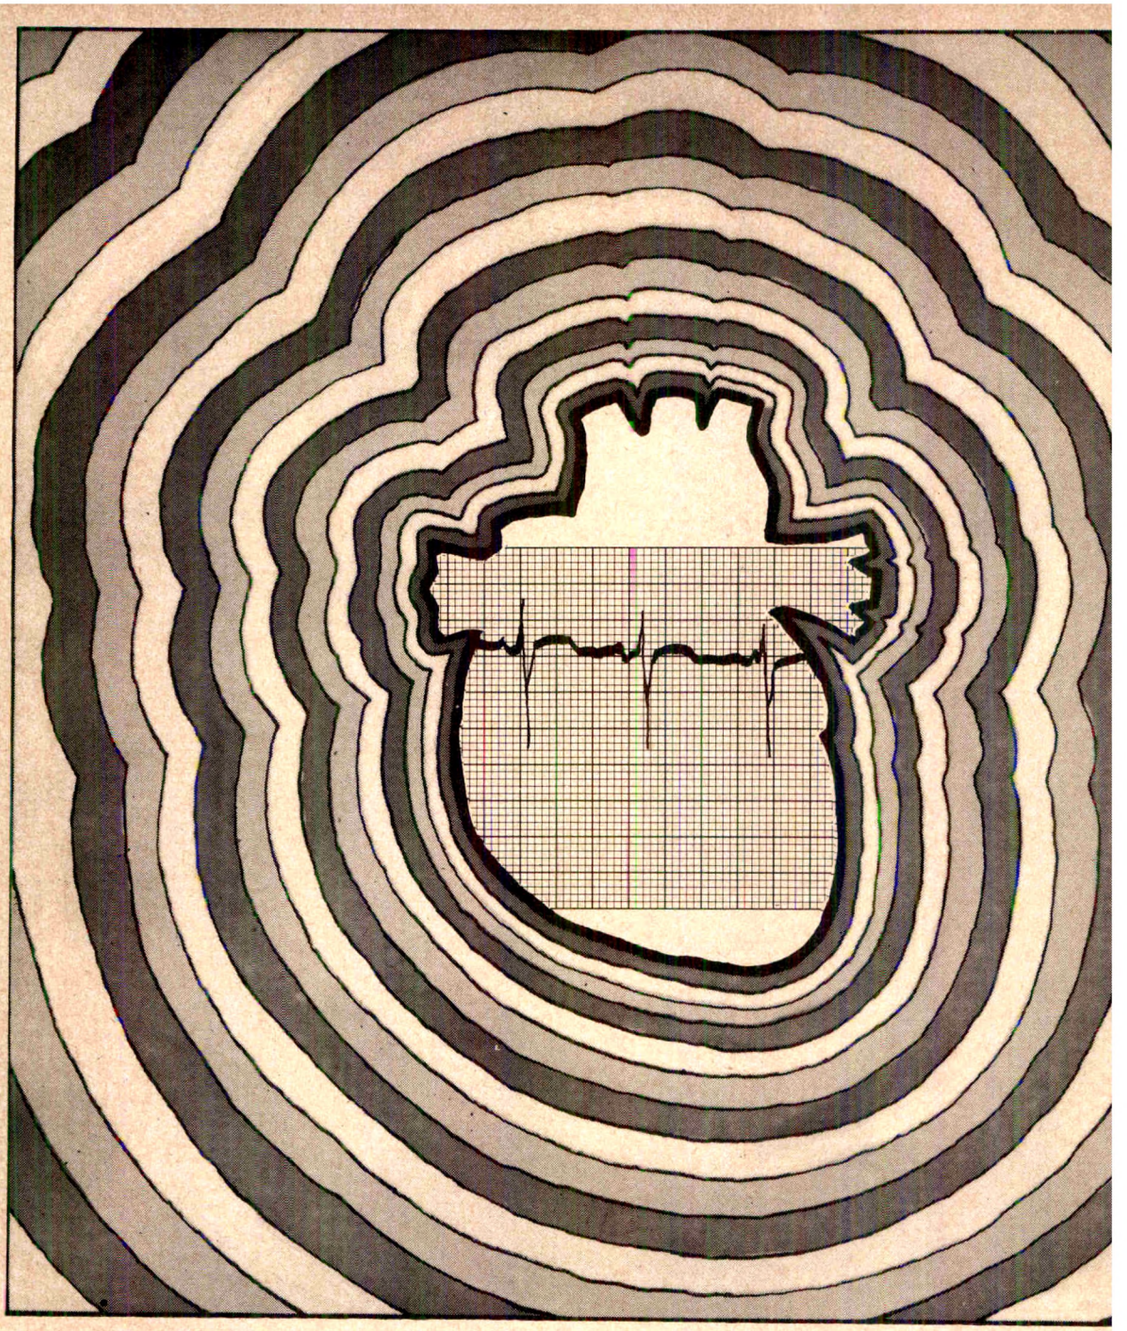
All the critical circuit components for the LG 1500 are on plug-in p.c. boards for quick, easy replacement.

A true value.

When you consider all you get with the LG 1500, you'll probably be pleasantly surprised at its low cost. For complete details and specifications, write today for our new, free brochure.

Write: Gould Inc., Medical Systems, 384 Santa Trinita Avenue, Sunnyvale, California 94086 or Kouterveldstraat Z/N, B 1920 Diegem, Belgium.

GOULD



the heart of your electrocardiogra diagnosis is made of paper

Accurate interpretation of analytical data presented by your electrocardiograph and subsequent proper diagnosis is manifested by the chart paper.

If there's a chance the chart paper is lacking in quality or accuracy, an inaccurate recording may well be the result.

Why take the chance. Specify the paper and produced expressly for the manufa your instrument. The cost of total simply isn't worth the few pennies substi save.

Thrombo embolism

The Silent Threat

"Thrombotic phenomena now occupy first place as a complicating factor, if not the cause, of mortality as determined in all autopsy series in the United States today. Thrombotic disease has become an increasingly important cause of disability and death as infectious diseases have responded to chemotherapy and as public health measures have become increasingly effective."

Contributing to the seriousness of the problem is the fact that "At present there is no satisfactory technique for the recognition in man of the incipient or active thrombotic state."[1] There are, however, a number of factors which are known to predispose to thrombus formation and potentially fatal embolism. Recognition of these factors, plus the application of adequate prophylactic and therapeutic measures, could contribute significantly toward decreasing the morbidity and mortality caused by 'the silent threat.'

The population at risk

Although such modern techniques as isotopic lung scanning, the radioactive fibrinogen uptake test, and the Doppler ultrasound flow detector show promise of permitting early detection of thrombus formation, it is generally agreed that these methods are not completely accurate as diagnostic tools, nor are they practical for large-scale patient screening. As a result, most physicians rely on the presence of known predisposing factors as a means of identifying patients who are especially prone to venous thrombosis and pulmonary emboli.

The high risk groups

As one authority has noted, these high risk "...groups include severely injured patients, particularly those over age 50 who have fractures of the pelvis, hip, or lower extremities; those undergoing elective cup arthroplasty or pelvic surgery; those immobilized or completely bedridden; those with a previous history of venous thrombosis or pulmonary embolism; those with severe obesity or congestive heart failure, or any combination of the above categories."[2]

Myocardial infarction: a special high risk category

Patients with acute myocardial infarction comprise another high risk group, especially if they have "...large transmural infarctions, previous infarction or angina, severe hypotension or shock, congestive heart failure, chronic atrial fibrillation, or past history of venous thrombosis or embolism."[2]

Therapy to lessen the risk

In patients with conditions known to predispose them to thrombosis and potentially fatal pulmonary embolism—the high risk groups—the use of anticoagulant therapy can be of significant benefit. As one investigator recently remarked: "If [the physician] believes that the risk of embolism is high he should use the only proved form of prevention, anticoagulation."[3]

With special regard to pulmonary embolism, it has been noted that "...a pulmonary infarct proves the existence of intravenous thrombosis and should be considered as a warning of possible further emboli. It is generally accepted that diagnosis of pulmonary infarction justifies the immediate application of anticoagulant therapy. Heparin is usually used initially, then oral anticoagulants (most commonly warfarin). The length of such therapy is often arbitrary, averaging four to six weeks, but depends on the extent and chronicity of the venous disease, whenever these can be determined."[4]

Myocardial infarction: a special case for longer term therapy

Following acute myocardial infarction patients are especially prone to such thromboembolic complications as mural and venous thrombosis and pulmonary and systemic emboli. The increased risk is due to reduced cardiac output, reduced arterial perfusion of the limbs, hypercoagulability (in the presence of cardiac ischemia), and venous pooling in the lower limbs—all of which may induce venous stasis leading to potentially fatal thrombus formation and embolization.

Because of the great risk of thromboembolic complications after myocardial infarction, anticoagulant therapy is widely recommended. As noted in a recent study, "...an excellent case can be made for the use of anticoagulants for the prevention of thromboembolic complications [following acute myocardial infarction]."[5]

With regard to duration of therapy, although there is no consensus, it is generally agreed that anticoagulants should be given for as long as observable benefits persist. In a study of 735 myocardial infarction patients treated with COUMADIN or another coumarin derivative: "Results indicate that anticoagulant therapy reduces the death rate significantly during the first three years after an acute myocardial infarction. However, survival rates converge after the third year, and by the fifth year there is no difference in survival of treated and untreated groups. Therapy appeared to be more effective in patients who had experienced more than one infarction. The incidence of recurrent infarction and congestive heart failure was less in the group treated with anticoagulants."[6]

Another investigator expressed his opinion on the duration of therapy by remarking that "...male patients on anticoagulants during the acute phase of myocardial infarction can logically be kept on them for 2 or 3 years when feasible. Such treatment can be recommended especially to men under age 55 and to men who have had a previous history of angina pectoris, myocardial infarction, or both, since they are the ones most likely to benefit."[2]

COUMADIN®
(crystalline sodium warfarin*)

*present as crystalline sodium warfarin isopropanol clathrate

Please refer to brief summary of prescribing information on last page of this advertisement.

COUMADIN (crystalline sodium warfarin) BRIEF SUMMARY

EFFECTIVENESS: Coumadin® (crystalline sodium warfarin) is indicated for the prophylaxis and treatment of venous thrombosis and its extension, the treatment of atrial fibrillation with embolization, the prophylaxis and treatment of pulmonary embolism, and as an adjunct in the treatment of coronary occlusion.

CONTRAINDICATIONS: Hemorrhagic blood dyscrasias. Recent or contemplated surgery of: (1) central nervous system; (2) eye; (3) traumatic surgery resulting in large open surfaces. **Bleeding tendencies associated with active ulceration or overt bleeding of:** (1) gastrointestinal, genitourinary or respiratory tracts; (2) cerebrovascular hemorrhage; (3) aneurysms—cerebral, dissecting aorta; (4) pericardial effusions; (5) subacute bacterial endocarditis. **Threatened abortion,** eclampsia and preeclampsia. **Inadequate laboratory facilities,** or lack of patient cooperation. **Miscellaneous:** polyarthritis, vitamin C deficiency, major regional block anesthesia.

WARNINGS: Administration of anticoagulants in the following conditions will be based upon clinical judgment in which the risk of hemorrhage due to anticoagulants is weighed against the risk of thrombosis or embolization in untreated cases. The following may be associated with increased risk of hemorrhage: **Pregnancy**—oral anticoagulants pass through the placental barrier, and the danger of hemorrhage to the fetus exists even to the point of fatal hemorrhage *in utero*, even in the accepted therapeutic range of maternal prothrombin level. Close observation and laboratory control are essential. **Lactation**—coumarins may pass into the milk of mothers and cause a prothrombinopenic state in the nursing infant. **Prolonged dietary deficiency** (cachexia, vitamin K). **Severe to moderate hepatic or renal insufficiency. Infectious diseases or disturbances of intestinal flora**—sprue, antibiotic therapy. **Severe trauma** of head, bones or muscles associated with extreme raw surfaces. **Surgery** resulting in large exposed raw surfaces. **Indwelling catheters. Spinal puncture. Severe to moderate hypertension. Miscellaneous:** polycythemia vera, vasculitis, severe diabetes, menometrorrhagia, allergic and anaphylactic disorders.

Abrupt cessation of anticoagulant therapy is not generally recommended; taper dose gradually over three to four weeks.

PRECAUTIONS: Periodic determination of prothrombin time is essential.

Numerous factors, alone or in combination, including travel, changes in diet, environment, physical state and medication may influence response of the patient to anticoagulants. It is generally good practice to monitor the patient's response with additional prothrombin time determinations whenever other medications are initiated, discontinued or taken haphazardly. The following factors are listed for your reference; however, other factors may also affect the prothrombin response.

The following factors, alone or in combination, may be responsible for increased prothrombin time response:

ENDOGENOUS FACTORS: Carcinoma; collagen disease; congestive heart failure; diarrhea; elevated temperature; hepatic disorders—infectious hepatitis, jaundice; poor nutritional state; vitamin K deficiency—steatorrhea.

EXOGENOUS FACTORS: Alcohol†; allopurinal; anabolic steroids; antibiotics; bromelains; chloral hydrate†; chlorpropamide; chymotrypsin; cinchophen; clofibrate; Coumadin® (crystalline sodium warfarin) overdosage; dextran; dextrothyroxine; diazoxide; dietary deficiencies; diuretics†; disulfiram; drugs affecting blood elements; ethacrynic acid; glucagon; hepatotoxic drugs; indomethacin; inhalation anesthetics; mefenamic acid; methylphenidate; monoamine oxidase inhibitors; nalidixic acid; oxyphenbutazone; phenylbutazone; phenyramidol; prolonged hot weather; prolonged narcotics; quinidine; quinine; salicylates (in excess of 1 Gm./day); sulfinpyrazone; sulfonamides, long acting; thyroid drugs; tolbutamide; triclofos sodium; unreliable prothrombin time determinations.

†Increased and decreased prothrombin time responses have been reported.

The following factors, alone or in combination, may be responsible for decreased prothrombin time response:

ENDOGENOUS FACTORS: Diabetes mellitus; edema; hereditary resistance to coumarin therapy; hyperlipemia; hypothyroidism.

EXOGENOUS FACTORS: Adrenocortical steroids; alcohol†; antacids; antihistamines; barbiturates; chloral hydrate†; chlordiazepoxide; cholestyramine; Coumadin® (crystalline sodium warfarin) underdosage; diet high in vitamin K (vegetables, fish, fish oil, onions); diuretics†; ethchlorvynol; glutethimide; griseofulvin; haloperidol; meprobamate; oral contraceptives; paraldehyde; primidone; rifampin; unreliable prothrombin time determinations; vitamin C.

†Increased and decreased prothrombin time responses have been reported.

A patient may be exposed to a combination of the above factors, some of which may increase and some decrease his sensitivity to Coumadin. Because the net effect on his prothrombin time response may be unpredictable under these circumstances, more frequent laboratory monitoring is advisable.

ADVERSE REACTIONS: Potential side effects of Coumadin® (crystalline sodium warfarin) include: 1. Minor or major hemorrhage from any tissue or organ—which is an extension of the physiologic activity of prothrombinopenia. Bleeding during anticoagulant therapy does not always correlate with prothrombin activity. (See TREATMENT FOR OVERDOSAGE.) Bleeding which occurs when the prothrombin time is within the therapeutic range warrants diagnostic investigation since it may unmask a previously unsuspected lesion, e.g. tumor, ulcer etc. 2. Side effects other than hemorrhage are infrequent and consist of alopecia, urticaria, dermatitis, fever, nausea, diarrhea, hypersensitivity reactions and an extremely rare reaction consisting of hemorrhagic infarction and necrosis of the skin.

TREATMENT FOR OVERDOSAGE: Excessive prothrombinopenia, with or without bleeding, is readily controlled by discontinuing Coumadin® (crystalline sodium warfarin), and if necessary, the oral or parenteral administration of vitamin K_1. The appearance of microscopic hematuria, melena, petechiae or oozing from nicks made while shaving are early manifestations of hypoprothrombinemia beyond a safe and satisfactory level.

In excessive prothrombinopenia with mild or no bleeding, omission of one or more doses of Coumadin® (crystalline sodium warfarin) may suffice; and if necessary, small doses of vitamin K_1 (Mephyton®*) orally, 2.5 mg., will usually correct the problem.

If minor bleeding persists, or progresses to frank bleeding, vitamin K_1 (AquaMephyton®*) in doses of 10 to 25 mg. may be given parenterally. (Please note recommendations accompanying vitamin K preparations prior to use.) Fresh whole blood transfusions should be considered in cases of severe bleeding or prothrombinopenic states unresponsive to vitamin K_1.

Resumption of Coumadin® (crystalline sodium warfarin) administration reverses the effect of vitamin K_1, and a therapeutic hypoprothrombinemia level is readily obtained.

*Trademark, Merck Sharp & Dohme.

For complete prescribing information, including dosage and laboratory control, see package circular.

SUPPLIED: Tablets: Coumadin® (crystalline sodium warfarin) for oral use, single scored, imprinted numerically with potency as follows: 2 mg. lavender, 2½ mg. orange, 5 mg. peach, 7½ mg. yellow, 10 mg. white, 25 mg. red. In bottles of 100 and 1000. Also available in Hospital Unit-Dose blister package of 100. **Injection:** Available as single injection units of amorphous sodium warfarin lyophilized for intravenous or intramuscular use in a box of 6 units, 50 mg.: Unit consists of 1 vial, 50 mg.; sodium chloride, 10 mg.; thimerosal, 0.2 mg. accompanied by a 2 ml. ampul Sterile Water for Injection. 75 mg.: Unit consists of 1 vial, 75 mg.; sodium chloride, 15 mg.; thimerosal, 0.3 mg. accompanied by a 3 ml. ampul Sterile Water for Injection.

Sterile Water for Injection contains no antimicrobial or other substance, and it is not suitable for intravascular injection without first having been made approximately isotonic by the addition of a suitable solute. Use only for reconstitution of the lyophilized product.

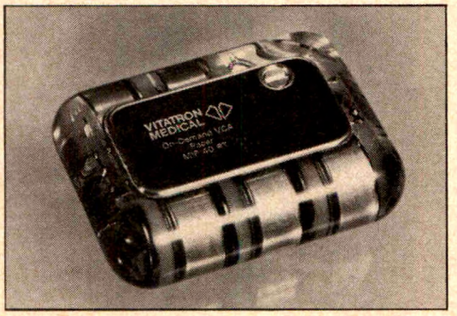
100% Pacemaker Analysability: Vitatron Medical



The present generation Vitatron Medical pacemakers are completely analysable during implantation.

The digital pacemaker analyzer MPA 1 allows post-operative determination of all important pacemaker parameters such as electrode impedance in ohms and stimulation threshold in mA.

A regular review of the data will determine the run down of a pacemaker's lifetime well in advance.

Use of Vitatron Medical VCA pacemakers eliminates the need for elective pacemaker replacement.

The Vitatron Medical analysis system enables a near 100 % utilization of the pacemaker lifetime, reducing replacement to an absolute minimum.

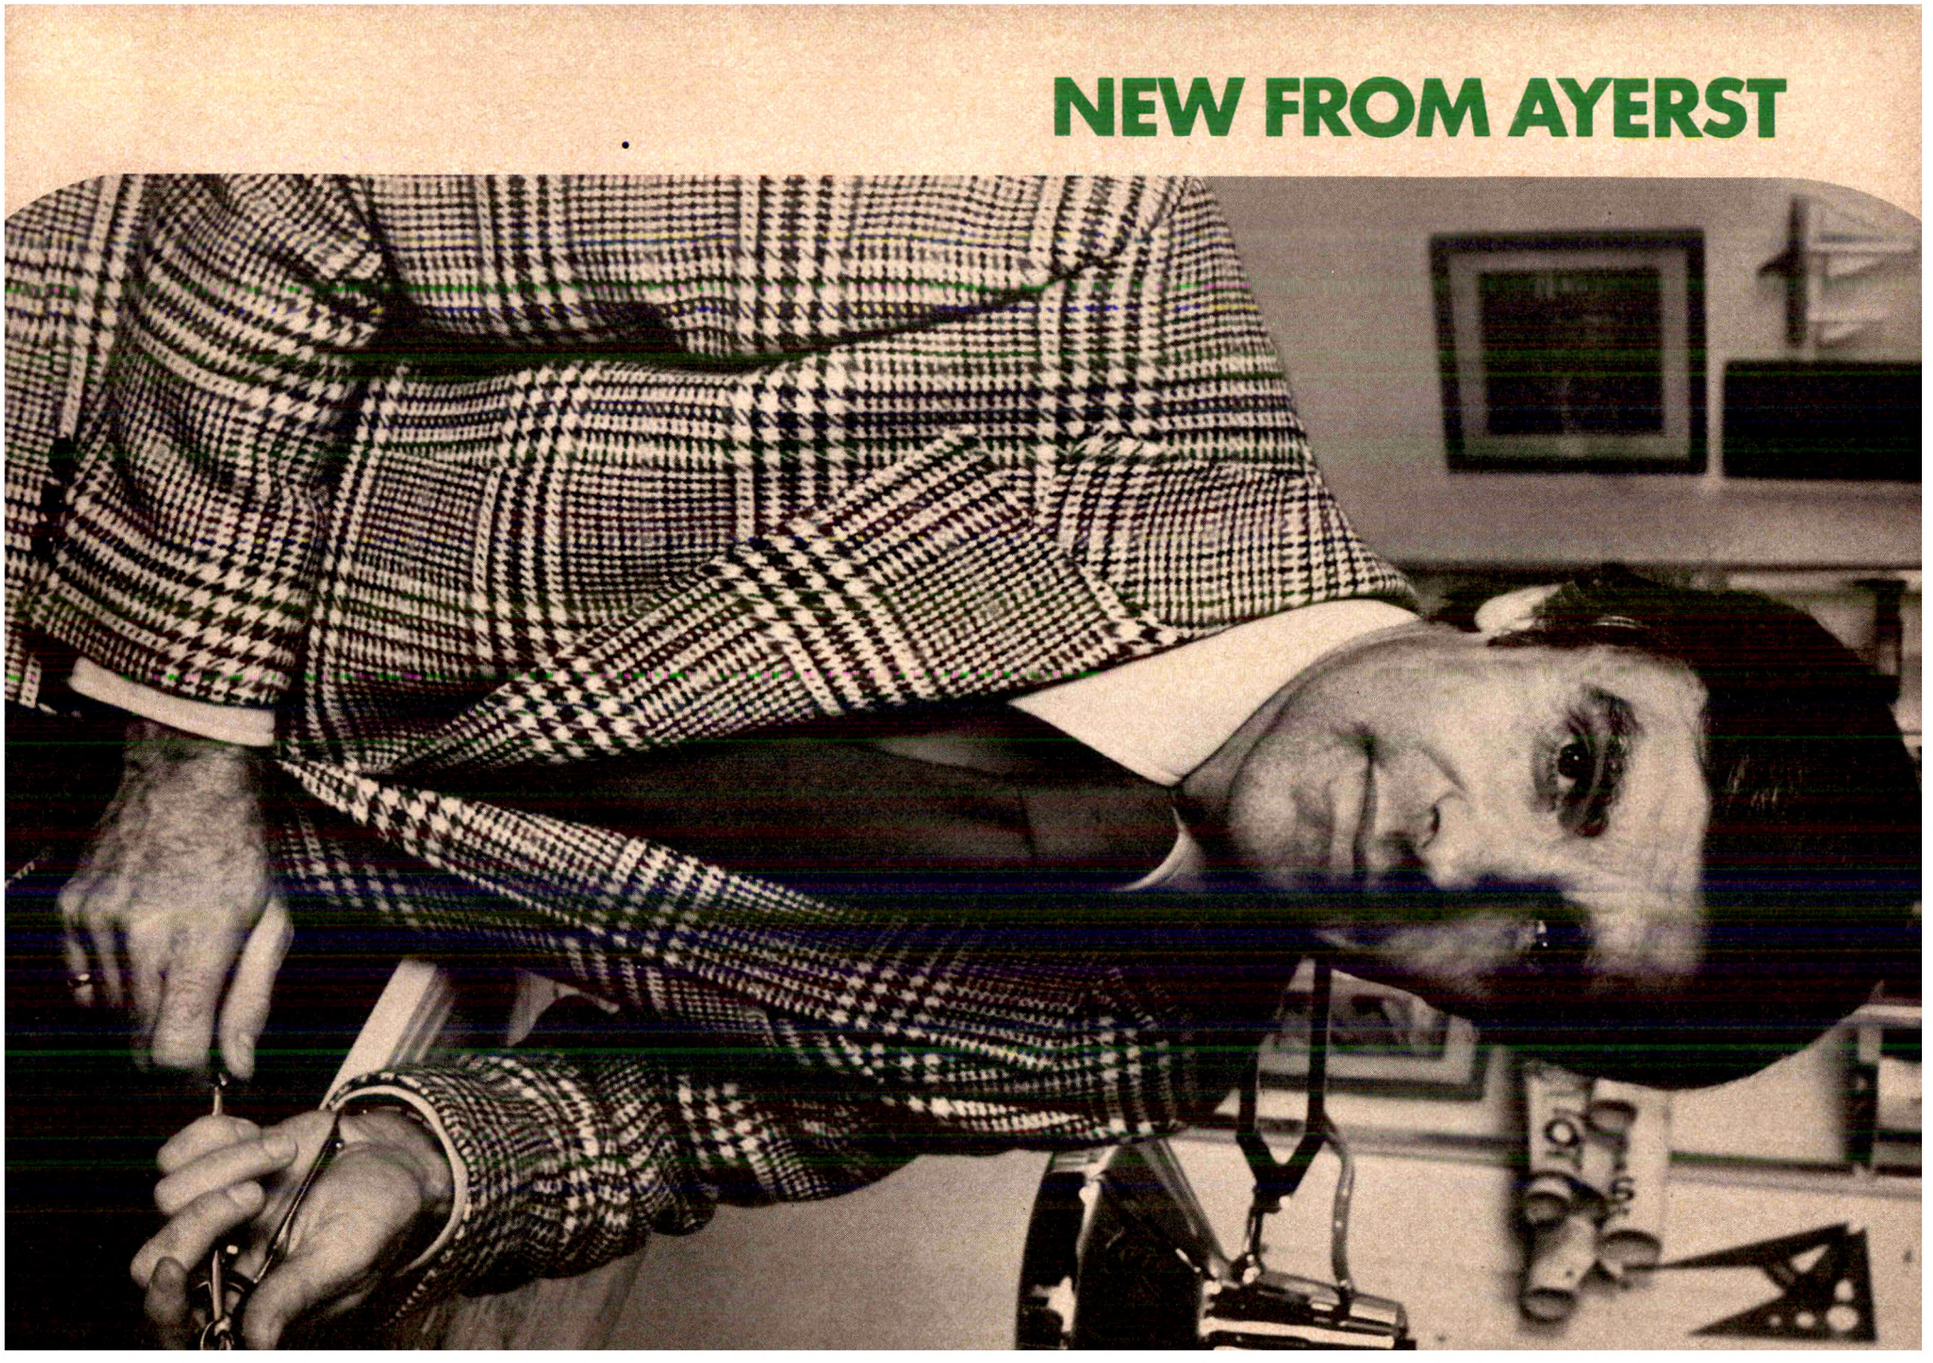
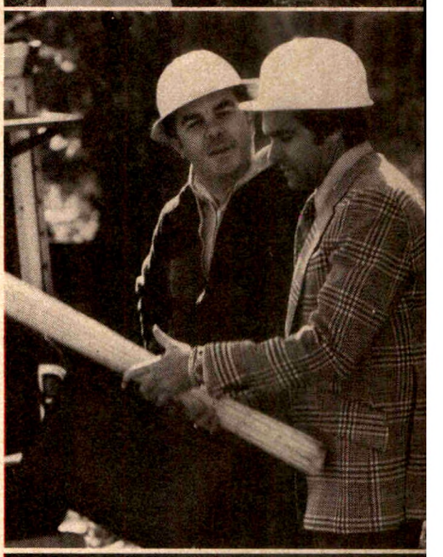
VITATRON MEDICAL

NEW FROM AYERST



the "healthy" hypertensive



It may be years before he experiences a single symptom of hypertension. But left untreated, even mild to moderate elevations of blood pressure may quietly strip years from an otherwise healthy and active life. Early control with DIUCARDIN may help forestall damage to healthy target organs.

DIUCARDIN provides approximately the same diuretic potency as hydrochlorothiazide at maximal therapeutic dosage. With DIUCARDIN, the onset of diuresis is gradual and may be maintained for twelve hours or more with a single dose.[1,2] The antihypertensive effect of DIUCARDIN is usually maintained in long term use. For many patients on DIUCARDIN, a convenient once-a-day dosage may suffice.

Based on efficacy *and* economy, DIUCARDIN provides a good beginning for many hypertensive patients. New DIUCARDIN 50 mg. Tablets. For mild to moderate hypertension and adjunctive therapy for many types of edema. Ayerst®

controlled early on

Diucardin® TABLETS

(hydroflumethiazide)

diuretic/antihypertensive

(See prescribing information on next page.)

NEW FROM AYERST

For the "healthy" hypertensive, early control with

Diucardin® TABLETS (hydroflumethiazide)

diuretic/antihypertensive

BRIEF SUMMARY

(For full prescribing information, see package circular.)

ACTIONS: The primary action of the thiazide diuretics is to produce diuresis by increasing the renal excretion of sodium and chloride. They inhibit the mechanism for tubular reabsorption of sodium and chloride by direct action on the distal segment. At maximal therapeutic dosage all thiazides are approximately equal in their diuretic potency.

The mechanism(s) of the antihypertensive action of the thiazides has not been elucidated.

INDICATIONS: Hypertension: DIUCARDIN alone may provide adequate control in mild or moderate hypertension. In severe hypertension or in cases of mild or moderate hypertension which do not respond adequately, DIUCARDIN may be used in conjunction with other antihypertensive agents.

DIUCARDIN alone or in conjunction with other antihypertensive agents is indicated for control of hypertension in pregnancy. (See WARNINGS)

Edema: DIUCARDIN is indicated as adjunctive therapy in edema associated with congestive heart failure, hepatic cirrhosis, and corticosteroid and estrogen therapy.

DIUCARDIN is indicated in severe edema during pregnancy. (See WARNINGS)

DIUCARDIN is indicated in the treatment of edema due to various forms of renal dysfunction, *e.g.* nephrotic syndrome, acute glomerulonephritis, and chronic renal failure.

CONTRAINDICATIONS: Anuria, oliguria. Hypersensitivity to DIUCARDIN or other sulfonamide derivatives.

The routine use of diuretics in an otherwise healthy pregnant woman with or without mild edema is contraindicated and possibly hazardous.

WARNINGS: Use with caution in severe renal disease since thiazides may precipitate azotemia. Effects due to accumulation of the drug may occur in patients with impaired renal function.

Use with caution in patients with impaired hepatic function or progressive liver disease since minor changes of fluid and electrolyte balance may precipitate hepatic coma.

Use with caution when hydroflumethiazide is administered in conjunction with other antihypertensive agents. Lowering of dosage of these agents is usually indicated. Thiazides potentiate ganglionic or peripheral adrenergic blocking drugs.

Sensitivity reactions may occur in patients with a history of allergy or bronchial asthma.

The possibility of exacerbation or activation of systemic lupus erythematosus has been reported.

Usage in Pregnancy and During Lactation: Thiazides cross the placental barrier and also appear in breast milk. Consequently, they may cause fetal or neonatal hyperbilirubinemia, thrombocytopenia, altered carbohydrate metabolism and other adverse reactions. Therefore, the potential benefits of thiazide administration in women of childbearing age must be weighed against the possible hazards to the fetus or child.

PRECAUTIONS: Tests should be made at appropriate intervals to detect possible electrolyte imbalance, *i.e.* hypokalemia, hyponatremia, and hypochloremic alkalosis. All patients taking thiazides should be observed for signs and symptoms of electrolyte or fluid imbalance, namely dryness of mouth, thirst, weakness, lethargy, drowsiness, restlessness, muscle pains or cramps, muscular fatigue, hypotension, oliguria, tachycardia, and gastrointestinal disturbances such as nausea and vomiting. Serum and urine electrolyte determinations are particularly important if the patient is vomiting excessively or receiving parenteral fluids.

If hypokalemia should develop, dietary potassium supplementation or the use of dilute potassium solutions should be tried. Small bowel lesions have been reported following the administration of enteric coated, concentrated preparations of potassium salts.

Dilutional hyponatremia may occur in edematous patients during hot weather. Water restriction rather than administration of salt is appropriate except in rare cases when hyponatremia is life-threatening. In actual salt depletion, appropriate replacement should be given.

Hypochloremia is generally mild and usually does not require specific treatment except under extraordinary circumstances, as in renal or liver disease.

The possibility of development of electrolyte or fluid imbalance is increased by brisk diuresis, severe liver disease, or concomitant administration of medications such as digitalis, ACTH, and corticosteroids.

Adequate oral intake of electrolytes should be maintained to minimize the possibility of electrolyte imbalance.

If a progressive increase in serum nitrogen occurs, a careful appraisal of the patient's condition should be made to determine whether diuretic therapy should be continued.

Because of the possibility of hypokalemia developing, patients taking digitalis should be followed carefully since a decrease in body potassium may necessitate lowering digitalis dosage.

Plasma uric acid levels may be increased and could, in susceptible patients, precipitate an attack of gout.

Thiazides alter carbohydrate metabolism. Patients who have diabetes mellitus or are suspected of being prediabetic should be followed closely since hyperglycemia and glycosuria may occur. Dosage adjustment of antidiabetic agents is frequently indicated.

Thiazides may decrease serum PBI without signs of thyroid disturbance.

Thiazides act to decrease the response of the peripheral arterial system to catecholamines and to enhance the effects of curare and its derivatives. Caution should be exercised in administering general anesthesia or curare derivatives to patients taking thiazides.

The antihypertensive effect of thiazides may be enhanced following sympathectomy.

ADVERSE REACTIONS: Gastrointestinal: anorexia, gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, acute pancreatitis. **Central Nervous System:** dizziness, vertigo, headache, paresthesias, xanthopsia, restlessness.

Hematologic: leukopenia, thrombocytopenia, agranulocytosis, aplastic anemia.

Allergic: purpura, photosensitivity, rash, urticaria, necrotizing angiitis, exfoliative dermatitis, glomerulonephritis, intrahepatic cholestatic hepatitis.

Cardiovascular: orthostatic hypotension (may be aggravated by alcohol, barbiturates, or narcotics).

Musculoskeletal: muscle cramps, weakness.

Clinical Laboratory Test Findings: electrolyte imbalance, elevation of serum nitrogen, elevation of plasma uric acid, hyperglycemia and glycosuria, decreased serum PBI levels.

DOSAGE AND ADMINISTRATION: Usual adult dosage: 50-100 mg. per day.

The dosage regimen should be individualized to obtain the maximum effect at the lowest dosage level. Dosage regimens using 25 mg. DIUCARDIN (hydroflumethiazide) may be adequate in some cases. Dosage should not exceed 200 mg. per day.

HOW SUPPLIED: DIUCARDIN—No. 702—Each scored tablet contains 50 mg. hydroflumethiazide, in bottles of 100 and 1,000.

Make Life Easier For You And Your Pacer Patients

Now, with the advent of the ESB Medcor Pacer-Check* system, it is possible for your office to conduct regular, accurate recordings of heart pacer patient's ECG and pacer rates by telephone.

Both you and your patients benefit. Now, with no more than a phone call, you can have information which permits elective decisions on replacement rather than emergency or prophylactic replacements. (By using a regular patient checking program, maximum pacer life can be realized.) Your patient and you have flexibility and safety at the same time.

This two-component system operates simply, requiring minimal training to both your personnel and patients.

The Medic Unit, at left, is the central component and is usually located in the hospital or clinic. It receives ECG and pacer rate input via unaltered telephones from the Patient Unit which is usually located in the patient's home. ECG data, produced on a standard paper chart, indicates the relationship between the QRS complex and pacer artifact to ascertain pacer capture. Pacer rate is shown continuously by illuminated numbers on the front panel. This is the first system available to physicians that records ECG and simultaneously displays pacer rate.

The Patient Unit is lightweight and battery powered. It is capable of transmitting from any telephone to your office. Transmissions have been successfully made from such great distances as Tokyo to New York. To operate, the patient places the telephone headset in the receiving cradle and then slips the two expandable bracelets over his forearms. Transmission begins immediately.

The Pacer-Check* system, approved for reimbursement by Medicare, has proven itself a useful and self-supporting method of maintaining a desirable pacer program.

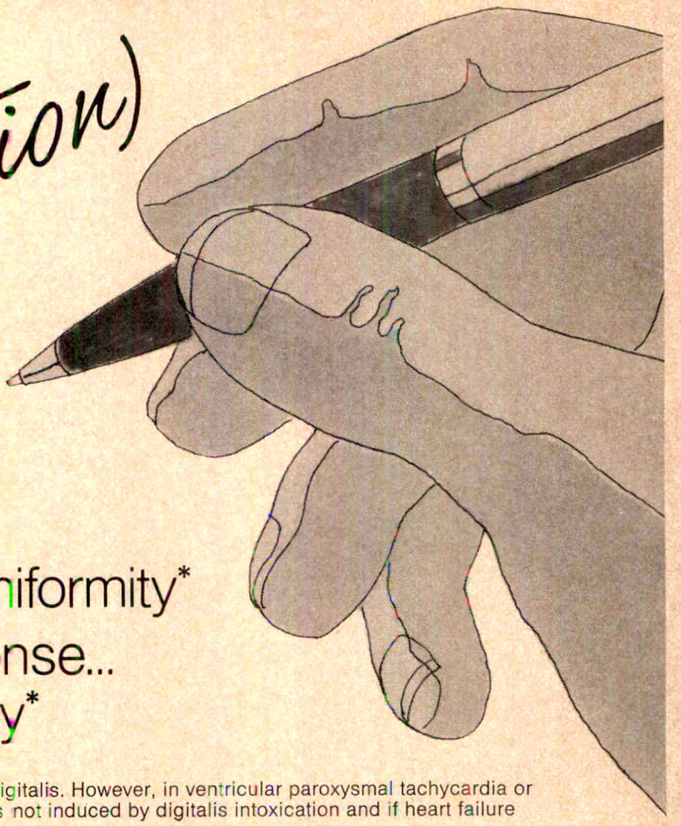
If the unique qualities of the Pacer-Check* system interest you, contact ESB Medcor, Inc., Dept. 373, 5920 Rodman St., Hollywood, Florida 33023. Toll free call: (800) 327-9780, Ext. 373.

ESB Medcor™

Lanoxin

[digoxin]

(no substitution)



write it

precision quality control...

- assured tablet content uniformity*

predictable patient response...

- proven biologic availability*

Contraindications: There are no absolute contraindications to digitalis. However, in ventricular paroxysmal tachycardia or ventricular fibrillation, it should be used *only* in refractory cases not induced by digitalis intoxication and if heart failure has developed.

Precautions: If the patient has been given digoxin during the previous week or any other less rapidly excreted drug of the digitalis group during the previous two weeks, the dose of Lanoxin brand Digoxin must be reduced accordingly. Because of impaired renal function and excretion in elderly patients, they frequently require lower than recommended doses.

Potassium loss in patients sensitizes the heart to digitalis intoxication even with recommended doses. The diuretic agents as well as electrolyte manipulations by the physician are major causes of potassium depletion in cardiac patients. Under these conditions, it may be necessary to reduce the usual dosages of Lanoxin brand Digoxin during digitalization and maintenance.

Digoxin is usually ineffective in cases of cardiac failure due to mechanical causes which are independent of myocardial diseases, e.g., cardiac tamponade, or to disorders not primarily of cardiac origin, as severe anemia. Despite a variable or poor response to digoxin in the presence of active rheumatic carditis, the development of cardiac failure is an indication for its use.

Effects of Overdosage and Treatment: The symptoms of overdosage with digoxin are quite similar to those occurring with other digitalis preparations. The most common toxic manifestations are anorexia, nausea, vomiting and various cardiac arrhythmias, including ventricular extrasystoles and paroxysmal supraventricular tachycardia or fibrillation with A-V block. In general, the gastrointestinal manifestations of toxicity with digoxin precede the cardiac arrhythmias occurring from overdosage. Furthermore, because of the rapid dissipation of digoxin, manifestations of toxicity are of short duration, usually lasting from a few hours to one or two days.

If necessary, potassium chloride may be administered as an intravenous infusion containing (adult dosage) 40 milliequivalents in 500 cc. of 5% dextrose in water, given over the course of 1 hour and repeated, if required, until a total of 120 milliequivalents have been given (1 mEq. KCl = 74.5 mg.). Electrocardiographic monitoring should be conducted and the infusion halted immediately upon the appearance of peaking of the T-waves. For children, the intravenous infusion dosage of potassium chloride would be 5 to 10 milliequivalents in 100 cc. of 5% dextrose in water given over the course of 1 hour, repeated if required, to a total of 15 to 30 milliequivalents. For more serious intoxication with abnormal cardiac rhythms, potassium chloride may be given orally in divided doses totalling 4 to 6 grams per day (adults) or 1 to 2 grams (children) provided renal failure is not present.

LANOXIN® digoxin TABLETS. **0.125 mg.** (yellow) in bottles of 100 and 1,000. **0.25 mg.** (white) scored, in bottles of 100, 500, 1,000 and 5,000; also Unit Dose Pack, strips of 10 tablets, 10 boxes of 100 tablets (1,000). **0.5 mg.** (green) scored, in bottles of 100 and 1,000.

Bundle Branch Block

Demonstration of the Incomplete Nature of Some "Complete" Bundle Branch and Fascicular Blocks by the Extrastimulus Technique

DELON WU, MD
PABLO DENES, MD
RAMESH DHINGRA, MD
KENNETH M. ROSEN, MD, FACC

Chicago, Illinois

The incomplete nature of some electrocardiographic "complete" bundle branch and fascicular blocks is demonstrated using the atrial extrastimulus technique. Patient 1, with a QRS pattern of "complete" left bundle branch block, manifested a QRS pattern of right bundle branch block at a shorter coupling interval, indicating that the left bundle could conduct. Patient 2, with a QRS pattern of right bundle branch block and "complete" left anterior hemiblock, manifested a pattern of left posterior hemiblock at a shorter coupling interval, indicating that the left anterior fascicle could conduct. Patient 3, with a normal QRS complex, showed left bundle branch block at shorter coupling intervals and then a pattern of right bundle branch block as the coupling interval was further decreased, indicating that functional left bundle branch block was incomplete. This demonstration of partial bundle branch block depends on a discordance of conduction time and refractory period, the bundle or fascicle with depressed conduction (incomplete block) having a shorter refractory period than the more normally conducting bundle or fascicle. This discordance may be related to the development of trifascicular block in patients with bifascicular block and a normal H–V interval. It is a predisposing factor in the complex patterns of aberrant conduction seen during supraventricular tachyarrhythmias with varying cycle lengths.

It has been suggested that a critical degree of slowing in a bundle branch or fascicle could produce the electrocardiographic pattern of "complete" bundle branch or fascicular block.[1–3] The incomplete nature of such complete block is not apparent on the surface electrocardiogram. In this study, we were able to demonstrate the incomplete nature of some complete bundle branch and fascicular blocks using the extrastimulus technique. This demonstration is dependent upon a discordance of conduction time and refractory period in portions of the His-Purkinje system in these patients, the bundle branch or fascicle with depressed conduction (incomplete block) having a shorter refractory period than the remaining more normally conducting portions.

This discordance of conduction time and refractory periods may also be related to the development of complete block in patients with bifascicular block and a normal H–V interval, and to the understanding of the complex patterns of aberrant conduction seen during supraventricular tachyarrhythmias with varying cycle lengths.

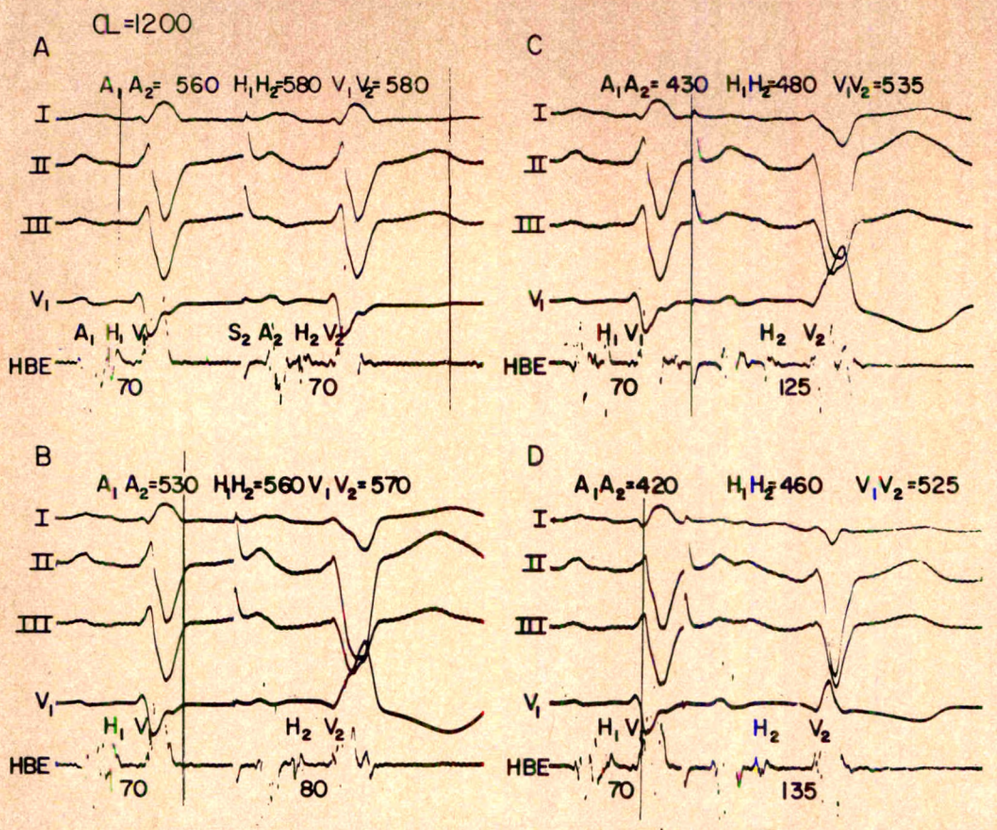

FIGURE 1. Case 1. Demonstration of the incomplete nature of "complete" left bundle branch block. Shown are electrocardiographic leads I, II, III and V_1 and a His bundle electrogram (HBE). A_1, H_1, V_1, S_2, A_2 and V_2 are labeled. A_1–A_2, H_1–H_2 and V_1–V_2 intervals are listed at the top of each panel. H_1–V_1 and H_2–V_2 intervals are listed at the bottom of each panel. Each panel shows the last of 10 sinus beats (cycle length [CL] 1,200 msec) and the extrastimulus and its responses at A_1–A_2 intervals of 560 msec **(A)**, 530 msec **(B)**, 430 msec **(C)** and 420 msec **(D)**. The coupled QRS complex has a pattern of left bundle branch block in **A** and a pattern of right bundle branch block in **B, C** and **D.** (See text for discussion.) Paper speed is 100 mm/sec and time lines are at 1 second intervals in this and all subsequent illustrations.

Methods

Electrophysiologic studies were performed in three patients in the supine, postabsorptive, nonsedated state. Informed consent was obtained from all patients. His bundle electrograms were recorded as previously described,[4] using a tripolar electrode catheter percutaneously introduced into a right femoral vein. A second quadripolar electrode catheter was percutaneously introduced into the left femoral vein and positioned in the high right atrium. The distal two electrodes of the quadripolar catheter were used for atrial pacing and the proximal two electrodes were used for recording the right atrial electrograms. Electrocardiographic leads I, II, III and V_1 and high right atrial and His bundle electrograms were recorded on a multichannel oscilloscopic photographic recorder (Electronics for Medicine DR-16) at paper speeds of 100 and 200 mm/sec. The electrical stimuli were provided by a digital programmable pulse generator (constructed by M. Bloom, Philadelphia, Pa.).

Conduction intervals were recorded during sinus rhythm. The atria were paced at a rate slightly higher than the sinus rate and then at increasing rates (in steps of 10 beats/min) until 1:1 conduction was lost and second degree atrioventricular (A–V) block was observed. Refractory periods were measured with the extrastimulus technique.[5] The test stimulus (S_2) was introduced after every 10th driven or spontaneous sinus beat (S_1). The S_1–S_2 interval was decreased in increments of 5 to 20 msec.

Definitions

A_1, H_1 and V_1 were, respectively, the atrial, His bundle and ventricular electrograms of driven or spontaneous sinus beats; A_2, H_2 and V_2 were the atrial, His bundle and ventricular responses to the test stimulus. A–H, H–V, H_1–H_2 and V_1–V_2 intervals were defined and measured as described by Wit et al.[5] The relative refractory period of the ventricular specialized conduction system was defined as the longest H_1–H_2 interval at which H_2 was conducted to the ventricle with lengthening of the H_2–V_2 interval relative to the H_1–V_1 interval of driven or spontaneous beats. The effective refractory period of the ventricular specialized conduction system was defined as the longest H_1–H_2 interval at which H_2 failed to propagate to the ventricles. The refractory period of a bundle branch or a fascicle was defined as the longest H_1–H_2 interval at which H_2 was conducted to the ventricles with the appropriate electrocardiographic QRS pattern of either bundle branch or fascicular block. This refractory period can reflect either a relative or an effective refractory period in the particular bundle or fascicle since the extrastimulus can provoke either incomplete or complete block.

Incomplete block in a fascicle or bundle refers to slow conduction in either structure. With a critical amount of delay, this incomplete block can produce the electrocardiographic manifestations of complete block. Thus, so-called complete block may or may not reflect total interruption of conduction in a bundle branch or fascicle. Functional bun-

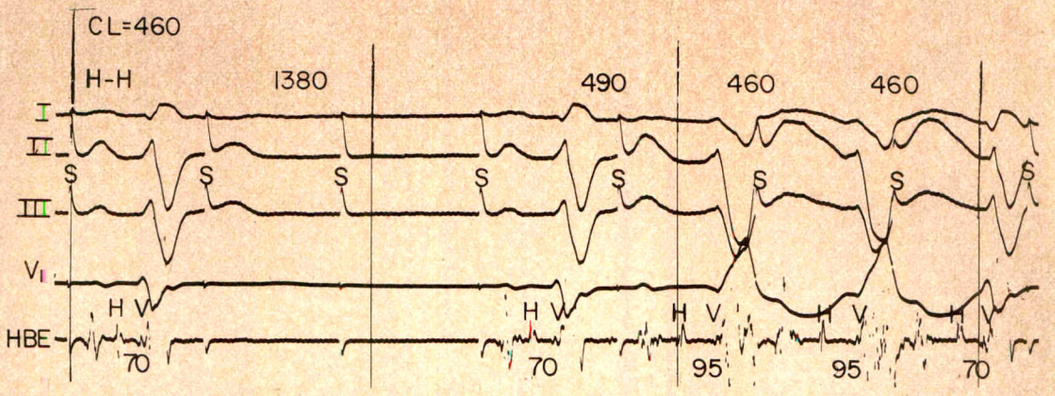

FIGURE 2. Case 1. Record showing a pattern of right bundle branch block after a long H–H interval. The atria were paced at a cycle length of 460 msec. H–H cycle lengths are listed on top and H–V intervals on bottom. The basic QRS configuration indicated left bundle branch block. The second and third beats after a long H–H interval (due to atrial noncapture) are conducted to the ventricles with a pattern of complete right bundle branch block and slight lengthening of the H–V interval from 70 to 95 msec.

dle branch block,[6] refers to the bundle branch block (aberrant conduction) produced by an extrastimulus. Again, this functional block could reflect either slowing or total interruption of conduction.

Results

Case 1

The patient was a 51 year old man with angina pectoris and congestive heart failure. The electrocardiogram showed first degree A–V block (P–R interval 210 msec), left atrial hypertrophy and complete left bundle branch block (QRS interval 170 msec, axis −60°). Electrophysiologic studies were performed during diagnostic cardiac catheterization. Recordings during sinus rhythm revealed a heart rate of 50 beats/min, an A–H interval of 95 msec and an H–V interval of 70 msec. Type I block proximal to the His bundle was noted at a paced heart rate of 170 beats/min. Premature test atrial stimuli were coupled to sinus rhythm (cycle length 1,200 msec) (Fig. 1). At initial coupling intervals, H_2 was conducted with a pattern of complete left bundle branch block (Fig. 1A). As the A_1–A_2 interval was decreased to 530 msec or less with a corresponding H_1–H_2 interval of 560 msec or less, H_2 was conducted to the ventricles with a pattern of right bundle branch block. The QRS axis was also shifted leftward to −120° and the H_2–V_2 interval was lengthened (80 to 125 msec) (Fig. 1, B and C). As the A_1–A_2 interval was decreased to 420 msec with a corresponding H_1–H_2 interval of 460 msec, H_2 was conducted to the ventricles with further prolongation of the H_2–V_2 interval (135 msec), and the QRS axis was shifted slightly rightward to −90°. The QRS configuration still indicated right bundle branch block but was narrower (Fig. 1D). Conduction was limited by an atrial effective refractory period of 370 msec. Figure 2 illustrates atrial pacing at a cycle length of 460 msec. Intermittent atrial noncapture was seen. After a long H–H interval due to noncapture, two consecutive beats were conducted to the ventricles with a pattern of right bundle branch block associated with lengthening of the H–V interval.

Comment: The results of this study indicate that the block in the left bundle branch with an electrocardiographic pattern of complete left bundle branch block was probably incomplete. This was shown by demonstration of right bundle branch block with coupled pacing, indicating that the left bundle branch could conduct. If the left bundle branch were totally blocked, superimposition of right bundle branch block with coupled pacing would produce complete block distal to the His bundle on the coupled beat. Left bundle branch block during sinus rhythm therefore reflected first degree left bundle branch block. H–V prolongation during sinus rhythm probably reflected lesser degrees of delay in the right bundle branch.

Despite a longer conduction time in the left bundle branch (incomplete left bundle branch block), the refractory period of the right bundle branch during sinus rhythm was longer than that of the left, demonstrating a discordance of conduction time and refractory period. The bundle branch with the longer conduction time (left) had a shorter refractory period than the bundle with faster conduction time (right). A pattern of right bundle branch block was also seen as the refractory period of the right bundle was lengthened after a long H–H interval due to atrial noncapture.[6,7] The shift in axis during early premature stimulation suggests an asynchronous conduction delay between the anterior and posterior fascicles. The narrowing of the QRS configuration during early premature stimulation also suggests that the functional block in the right bundle might have been incomplete.

Case 2

The patient, a 53 year old man, had angina pectoris, mild congestive heart failure and a history of previous myocardial infarction. The electrocardiogram revealed a sinus rate of 71 beats/min, a P–R interval of 160 msec, a QRS duration of 170 msec and a QRS axis of −80°. The QRS pattern was that of right bundle branch block with left anterior hemiblock and old anteroseptal myocardial infarction.

Electrophysiologic studies during sinus rhythm revealed an A–H of 89 msec and an H–V interval of 46 msec. Wenckebach phenomena above the His bundle occurred at a paced rate of 190/min. Atrial extrastimuli were coupled to spontaneous sinus rhythm (cycle length 848 msec) (Fig. 3). At an A_1–A_2 interval of 330 msec, H_2 was conducted to the ventricles with an H_1–H_2 interval of 420 msec without change in the QRS or H_2–V_2 interval (Fig. 3A). As the A_1–

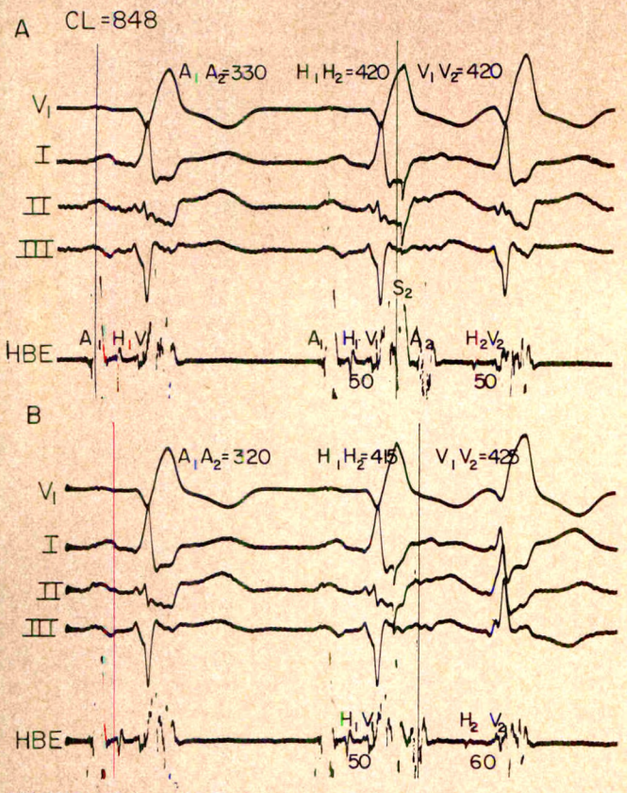

FIGURE 3. Case 2. Records showing the incomplete nature of complete left anterior hemiblock. In **A** and **B** the basic sinus cycle length is 848 msec, and the QRS pattern shows apparent complete right bundle branch block. The axis is −80°. The A_1–H_1 interval is 90 msec and the H_1–V_1 interval 50 msec. A sudden shift in the QRS axis from −80° to +120° (left posterior hemiblock) associated with lengthening of the H_2–V_2 interval from 50 to 60 msec occurs at H_1–H_2 intervals of 415 msec (third beat in **B**).

A_2 interval was decreased to 320 msec, the H_1–H_2 interval decreased to 415 msec with slight prolongation of the H_2–V_2 interval and a marked rightward shift in the QRS axis from −80° to +120° (left posterior hemiblock); the right bundle branch block pattern was unchanged (Fig. 3B). Similar results were observed in all H_1–H_2 intervals of less than 415 msec. The atrial effective refractory period of 220 msec limited A–V conduction. At a shorter driven cycle length of 610 msec, H_2 conducted to the ventricles without change in the QRS axis at all H_1–H_2 intervals (functional refractory period of the A–V node 390 msec).

Comment: In this patient, electrocardiograms showed complete right bundle branch block with complete left anterior hemiblock.[2] As the H_1–H_2 intervals were decreased to 415 msec or less, the pattern of left anterior hemiblock was replaced with a pattern of left posterior hemiblock. This change suggests that the left anterior hemiblock was incomplete since a pattern of left posterior hemiblock cannot be seen without conduction in the anterior fascicle. H_2–V_2 prolongation at close coupling intervals probably reflected slight delays in the anterior fascicle. A discordance of conduction time and refractory period is seen in this case also. The anterior fascicle had a longer conduction time but a shorter refractory period than the posterior fascicle during sinus rhythm. The refractory period of the posterior fascicle shortened with decreasing cycle length.[6,7] Right bundle branch block was probably total in this patient.

Case 3

The patient was a 68 year old man with a history of dizziness. Electrocardiograms revealed sinus bradycardia (rate 50/min) and a normal P–R interval, QRS duration and axis. Electrophysiologic studies during sinus rhythm revealed an A–H interval of 80 msec and an H–V interval of 40 msec. Wenckebach periods proximal to the His bundle were observed at a pacing heart rate of 180/min. Atrial extrastimuli were delivered at driving cycle lengths of 1,000, 640 and 480 msec.

With a cycle length of 1,000 msec, the A_1–H_1 interval was 95 msec and the H_1–V_1 interval 40 msec. At an A_1–A_2 interval of 500 msec, the H_1–H_2 interval was 530 msec, and H_2 was conducted to the ventricles with an H_2–V_2 interval of 40 msec and a normal QRS configuration. At an A_1–A_2 interval of 485 msec with a corresponding H_1–H_2 interval of 510 msec, H_2 was conducted with a pattern of left bundle branch block with a QRS duration of 125 msec; the H_2–V_2 interval remained unchanged. Similar results occurred at A_1–A_2 intervals of 485 to 440 msec with corresponding H_1–H_2 intervals of 510 to 495 msec. With A_1–A_2 intervals of 420 msec or less and corresponding H_1–H_2 intervals of 475 msec or less, H_2 was propagated to the ventricles with a QRS pattern of right bundle branch block and marked prolongation of the H_2–V_2 interval. The atrial effective refractory period of 350 msec limited A–V conduction. The rela-

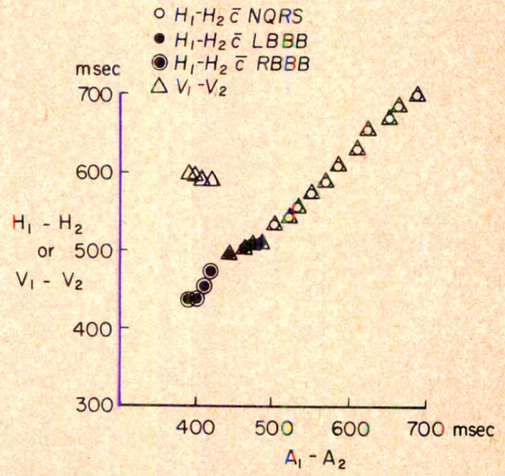

FIGURE 4. Case 3. Atrioventricular conduction curve showing development of functional left and then right bundle branch block and the relation of H_1–H_2, V_1–V_2 intervals to A_1–A_2 intervals. The driving cycle length was 1,000 msec. A_1–A_2 intervals are on the abscissa, V_1–V_2 intervals **(triangles)** and H_1–H_2 intervals **(circles)** are on the ordinate. The **open circles** indicate the H_1–H_2 intervals at which H_2 was conducted to ventricles with a normal QRS complex (NQRS); the **solid circles** indicate the H_1–H_2 intervals at which H_2 was conducted to the ventricles with a QRS pattern of left bundle branch block (LBBB); the **solid circles with a halo** indicate the H_1–H_2 intervals at which H_2 was conducted to the ventricles with a QRS pattern of right bundle branch block (RBBB). The V_1–V_2 intervals are suddenly lengthened at H_1–H_2 intervals of 475 msec or less when the QRS pattern shifts from left to right bundle branch block. (See text for discussion.)

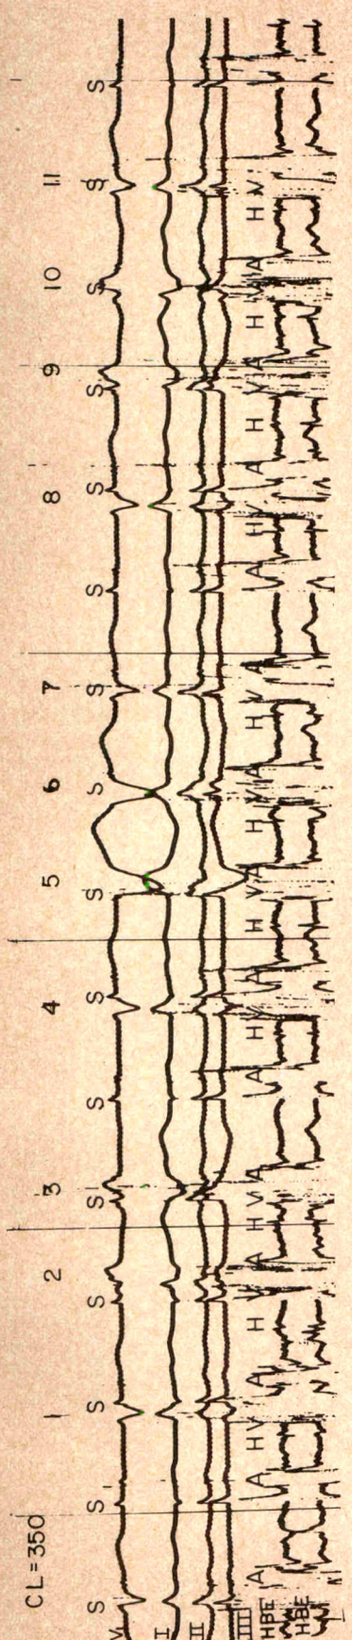

FIGURE 5. Case 3. Record showing rhythmic repetitive ventricular aberrations of both left and right bundle branch block patterns. The atria were paced at a constant interval of 350 msec; 5:4 and 4:3 Wenckebach sequences proximal to the His bundle are seen. The A–H, H–V and H–H intervals of each beat are labeled on the bottom. Beats 1, 4 and 8 are the first conducted beats with normal QRS configurations; beats 2, 5 and 9 are the second and beats 3, 6 and 10 the third conducted beats propagated with ventricular aberrations; beats 7 and 11 are the fourth conducted beats propagated to the ventricle normally. Beats 2, 3, 9 and 10 showed a pattern of right bundle branch block; beats 5 and 6 showed a pattern of left bundle branch block. (See text for discussion.)

tions are graphically demonstrated in Figure 4. The H_1–H_2 interval of 510 msec is the refractory period of the left bundle branch, and the H_1–H_2 interval of 475 msec is the refractory period of the right bundle branch. Left bundle branch block was partial as demonstrated by development of right bundle branch block with a prolonged H_2–V_2 interval (jump in the V_1–V_2 curve).

When the heart was driven at a cycle length of 640 msec, left bundle branch block occurred at an A_1–A_2 interval of 380 msec or less, and right bundle branch block was not noted. When the heart was driven at a cycle length of 480 msec, functional bundle branch block was no longer observed.

Figure 5 is a record obtained at an atrial paced rate of 180/min. Both 5:4 and 4:3 Wenckebach periods above the His bundle were noted. QRS complexes 1, 4 and 8 are the first, 2, 5 and 9 the second, 3, 6 and 10 the third and 7 and 11 the fourth conducted beats in the consecutive Wenckebach sequences. The first beat of each sequence and the fourth beat of the second and the third sequences were conducted normally (QRS complexes 1, 4, 7, 8 and 11). The second and the third conducted beats of each sequence were propagated with aberrant conduction of either left or right bundle branch block pattern associated with lengthening of the H–V intervals (QRS complexes 2, 3, 5, 6, 9 and 10). The H–V interval of the second conducted beats was always longer than that of the third conducted beat in each sequence. For those beats showing left bundle branch block aberrancy, the QRS duration of the second conducted beats was greater than that of the third conducted beats (complexes 5 and 6). For those beats showing right bundle branch block aberrancy, the QRS duration of the third conducted beats was slightly greater than that of the second conducted beats (complexes 2 and 3 and complexes 9 and 10). Aberrancy of a right bundle branch block pattern occurred more frequently than that of a left bundle branch block pattern.

Comment: The refractory period of the left bundle branch was longer than that of the right bundle at a cycle length of 1,000 msec. Functional block in the left bundle resulted in the electrocardiographic pattern of complete left bundle branch block although the block was incomplete, as demonstrated by development of functional right bundle branch block at a shorter H_1–H_2 interval. This demonstrates another type of discordance of conduction time and refractory period. Although the refractory period of the right bundle branch was shorter than that of the left, delays in the right bundle branch were greater once this refractory period was achieved.

The refractory periods of both the left and right bundles are rate-dependent: As cycle lengths shorten, refractory periods decrease.[6,7] This explains the lack of functional block at the shortest cycle length. The repetitive rhythmic ventricular aberration observed in Figure 5 can be explained by the differential effect of the cycle length upon refractory periods of the left and right bundle branches and by the effect of repetitive concealed conduction.[6,7] After long H–H intervals produced by blocked P waves during the A–V nodal Wenckebach sequences, the impulse encountered increased refractoriness in both bundle branches. The degree of delay in each bundle determined the type of aberrancy: If the delay was greater in the left bundle, a pattern of left bundle branch block re-

sulted; if the delay was greater in the right bundle, a pattern of right bundle branch block occurred. In both cases, the H–V interval was prolonged, reflecting delays in the bundle branch with less slowing. The ventricular aberration and shorter H–V interval in the third conducted beats in the Wenckebach sequence was the result of both the effect of cycle length and retrograde concealed conduction: Repetitive retrograde concealed conduction maintained the bundle branch block, and decreasing cycle length allowed the H–V interval to shorten.[6] The greater QRS duration observed in the third conducted beats (QRS complexes 3 and 10) showing right bundle branch block aberrancy can be explained by the asynchronous recovery in both bundle branches. The more frequent aberrancy of a right bundle branch block pattern after a Wenckebach block and the longer refractory period of the left bundle at the cycle lengths studied suggest that the refractory period of the right bundle was more sensitive to abrupt changes in cycle length. Greater delays in the right bundle branch system once the refractory period of this system was reached could also explain the predominance of right bundle branch aberrant conduction.

Discussion

From his analysis of electrocardiograms, Lepeschkin[1] proposed several possible combinations of incomplete block in both bundle branches. He stated that slowing of conduction in both bundle branches would produce P–R prolongation. If one bundle were delayed more than the other, the QRS configuration would reveal bundle branch block in the side showing greater delay. He also suggested that combinations of first and second degree block in both bundle branches could produce an electrocardiographic pattern of alternating bundle branch block.

Recently in a study of left bundle branch block with normal axis, Cannom et al.[8] demonstrated a leftward shift in axis with premature atrial stimulation. They suggested that in this condition, antegrade conduction was still present in the anterior fascicle and that the leftward shift in axis reflected additional conduction delays in the left anterior division. As an alternative explanation for their findings, one could postulate predivisional complete left bundle branch block. If this were the case, the impulse would have to travel from the right bundle across the ventricular septum and then spread through the peripheral Purkinje muscle network of the left ventricle. A premature impulse could encounter peripheral delays in the anterior left ventricle distal to the block with a resultant leftward shift in axis.

Our data suggest that incomplete blocks can occur in the three fascicles, thus confirming previous speculations. The measurement of refractory period by the atrial extrastimulus technique provides a means of demonstrating these incomplete blocks in patients with apparent complete bundle or fascicular block. By demonstrating that block in the opposite fascicle or bundle branch replaces the preexisting block, one can show that the blocked bundle branch or fascicle is capable of conduction.

This demonstration depends upon the presence of a discordance of conduction velocity and refractory period in the ventricular specialized conduction system: The faster conducting bundle branch or fascicle must have a longer refractory period than the incompletely blocked bundle branch or fascicle. In Patient 1 the refractory period was shorter in the incompletely blocked left bundle branch than in the right bundle branch. In Patient 2 the refractory period was shorter in the incompletely blocked anterior fascicle than in the posterior fascicle. In Patient 3, the refractory period of the left bundle branch was longer, but conduction delays were greater in the right bundle once its refractory period was achieved with an extrastimulus. Thus, a bundle or a fascicle with a longer conduction time does not necessarily have a longer refractory period. In a patient with incomplete bundle branch block, when the blocked bundle branch has a long refractory period (relative to that of the normal bundle branch), the extrastimulus technique will not demonstrate the partial block.

Bifascicular block and normal H–V interval: The demonstrated discordance of conduction velocity and refractory periods in portions of the His-Purkinje system may partially explain the recent finding of development of block distal to the His bundle in patients with bifascicular block and a normal H–V interval.[9] Although in these cases the normal H–V interval suggests a normal conduction time in the remaining functioning fascicle, it is possible that the refractory period in this fascicle is prolonged (or may become prolonged), thus predisposing to the development of complete trifascicular block. This discordance may also partially explain why complete trifascicular block may not develop in some patients with bifascicular block and a prolonged H–V interval. In these cases, although conduction velocity is depressed in the remaining functioning fascicle, the refractory period and the response of refractory period to change in cycle length of this fascicle might be normal, thus preventing development of block.

Ventricular conduction defects in arrhythmias: The existence of incomplete blocks masquerading as complete and the discordance of refractory period and conduction velocity in portions of the His-Purkinje system predispose to very complex sequences of ventricular activation, as demonstrated during Wenckebach periods in Case 3. In patients with atrial fibrillation or atrial flutter with varying block and cycle lengths that change from cycle to cycle, the potential exists for development of seemingly inexplicable changes in QRS configuration. One could easily misinterpret an electrocardiogram showing bilateral functional bundle branch block (aberrant conduction in both the left and right bundle branch systems) as a manifestation of bilateral bundle disease or multifocal premature ventricular beating. The difficulty in achieving a correct electrocardiographic diagnosis is further compounded by the

occurrence of repetitive concealed conduction maintaining a particular pattern of aberration, and by the differential responses of bundle branch refractory periods to change in cycle length. Knowledge of some of these potential difficulties should improve electrocardiographic diagnosis.

In conclusion, our study has demonstrated the following: (1) Incomplete block in a bundle branch or fascicle can produce an electrocardiographic pattern of complete fascicular or bundle branch block. (2) This incomplete block may be demonstrable with the extrastimulus technique. (3) Discordance of conduction velocity and refractory period may occur in portions of the His-Purkinje system, a bundle or fascicle with incomplete block having a shorter refractory period than a more normally conducting bundle branch or fascicle. (4) Delays in the fascicle or bundle branch with a shorter refractory period may be greater than delays in the portions of the His-Purkinje system with a longer refractory period, once the former refractory period is achieved. (5) The discordance of conduction time and refractory periods described in patients with partial bundle branch block may predispose to complex sequences of ventricular activation, particularly in supraventricular tachyarrhythmias with changing cycle length.

Concealed Bypasses of the Atrioventricular Node in Patients with Paroxysmal Supraventricular Tachycardia Revealed by Intracardiac Electrical Stimulation and Verapamil

ROWORTH A. J. SPURRELL, BSc
DENNIS M. KRIKLER, MD, FACC*
EDGAR SOWTON, MD, FACC

London, England

Thirteen patients with paroxysmal supraventricular tachycardia were studied with use of His bundle electrograms and programmed intracardiac stimulation. No patient had evidence of either the Wolff-Parkinson-White or Lown-Ganong-Levine syndrome. During ventricular pacing at a rate of 90 to 180 beats/min retrograde conduction time increased by an average of 80 msec in eight patients; in the remaining five patients the average increase was only 9 msec. The tachycardia was terminated in all 13 patients after intravenous administration of verapamil, 10 mg. This drug acts predominantly on the atrioventricular (A–V) node, and during termination of an A–V nodal reciprocal tachycardia both the antegrade and retrograde conduction times would be expected to be prolonged. During termination of the tachycardia antegrade conduction was prolonged by an average of 43 msec and retrograde conduction by an average of 79 msec in eight patients. However, in five patients antegrade conduction was prolonged by an average of 101 msec and retrograde conduction by an average of only 3 msec. The minimal effect of this drug on retrograde conduction and the minimal increase in retrograde conduction during ventricular pacing in these five patients is strong evidence for the presence of an A–V nodal bypass that was not apparent from the surface electrocardiogram. The potential hazards should atrial fibrillation occur and allow rapid antegrade conduction in an A–V nodal bypass are discussed.

Patients with supraventricular tachycardias thought to be caused by a reciprocal mechanism can be classified in three groups: (1) Patients who manifest reciprocation that probably occurs within the atrioventricular (A–V) node.[1–5] (2) Patients with reciprocation involving the A–V node and an adjacent bypass, such as the posterior internodal tract described by James[6] and Ferrer.[7] These patients usually have a short P–R interval on the surface electrocardiogram and are thought to have the Lown-Ganong-Levine syndrome[8,9] (3) Patients who have reciprocal tachycardias involving antegrade passage of the impulse in the A–V node and retrograde conduction in a Kent bypass in the right or left A–V groove. These patients have the Wolff-Parkinson-White syndrome[10,11] and may have delta waves on the surface electrocardiogram during sinus rhythm.

In this paper we present the results of an electrophysiologic study of 13 patients with paroxysmal supraventricular tachycardia who had no evidence of an A–V nodal bypass on the surface electrocardiogram although the study elicited evidence of a bypass in 5. A reciprocal mechanism was shown to be the basis for the tachycardia in all 13 patients.

TABLE I

Clinical and Electrocardiographic Data in 13 Cases

Case no.	Age (yr) & Sex	Cause of Tachycardia	P–R Interval* (sec)
1	62M	Coronary artery disease	0.16
2	57F	Unknown	0.14
3	45M	Coronary artery disease	0.18
4	22F	Unknown	0.14
5	35M	Unknown	0.15
6	60M	Unknown	0.18
7	45F	Coronary artery disease	0.13
8	44M	Unknown	0.20
9	65F	Unknown	0.19
10	57M	Unknown	0.16
11	46F	Unknown	0.14
12	53M	Unknown	0.17
13	49F	Unknown	0.15

* P–R intervals were all within normal limits (0.12 second considered lower limit of normal). No delta waves indicating ventricular preexcitation were seen.

Material and Methods

Thirteen patients, 7 male and 6 female, were studied. The relevant clinical and electrocardiographic data are presented in Table I. All 13 patients had documented attacks of paroxysmal supraventricular tachycardia. In 3 patients coronary artery disease was thought to be the underlying cause; in the remaining 10 patients no specific etiology was discovered.

Informed consent was obtained in all cases, and an electrophysiologic study was carried out with patients in the postabsorptive, nonsedated state. Three electrode catheters were introduced percutaneously through one or both femoral veins. Two catheters were positioned in the right atrium, one hexapolar catheter for recording the high and low atrial electrograms and the other for pacing the atrium. The third catheter, positioned across the tricuspid valve, was used to record the His bundle electrogram by the technique of Scherlag et al.[12] The recordings were made on an eight channel Elema Mingograf 81. A surface electrocardiogram was recorded simultaneously with a high and low atrial electrogram and the His bundle electrogram. The His bundle electrogram was recorded with the frequency response set at 45 to 500 cycles/sec.

A Devices 4270 stimulator (Devices Instruments Limited, Welwyn Garden City, Herts, England) was used for atrial and ventricular pacing. The heart was driven at a constant rate, thus preventing changes in excitability or refractoriness due to irregularities in rhythm. Single or double atrial or ventricular premature beats were delivered after every eighth beat of the basic driving rhythm. A variable delay circuit triggered by either the R wave of the surface electrocardiogram or the right atrial electrogram was used so that the premature beats could be delivered in the cardiac cycle at a preset delay after the preceding driving beat. In each patient the mode of initiation and termination of the tachycardia and the effect of atrial and ventricular premature beats on the basic rhythm during tachycardia were studied. Atrial and ventricular pacing at a rate of 90 to 180 beats/min was performed to determine the characteristics of antegrade and retrograde conduction. Finally, after initiation of the tachycardia by an appropriate premature beat, the mode of termination after an intravenous injection of 10 mg of verapamil (Cordilox®, Knoll AG, West Germany) was studied. This drug was originally introduced as an antianginal agent[13] but has recently been found to be an effective antiarrhythmic agent in man.[14] Verapamil is not a beta receptor blocking drug and its mode of action does not appear to be similar to that of quinidine.[15] It has been shown to interfere with the transport of calcium across the cell membrane, with the implication that calcium currents may contribute to abnormalities of cardiac rhythm.[15]

Results

Electrocardiograms

The relevant details are presented in Table I. No patient had evidence of either the Lown-Ganong-Levine syndrome (manifested by a P–R interval of less than 0.12 second) or the Wolff-Parkinson-White syndrome (manifested by a short P–R interval and a delta wave).

Electrophysiologic Study

Initiation of tachycardia: In all 13 patients the tachycardia could be initiated by suitably timed single or double atrial or ventricular premature beats.

During tachycardia: Atrial and ventricular premature beats that were induced during tachycardia

Average increase in antegrade conduction (A′–H) = 101 msec.				
Average increase in retrograde conduction (H–A′) = 3 msec.				

but did not terminate the tachycardia were followed by pauses that were less than compensatory.

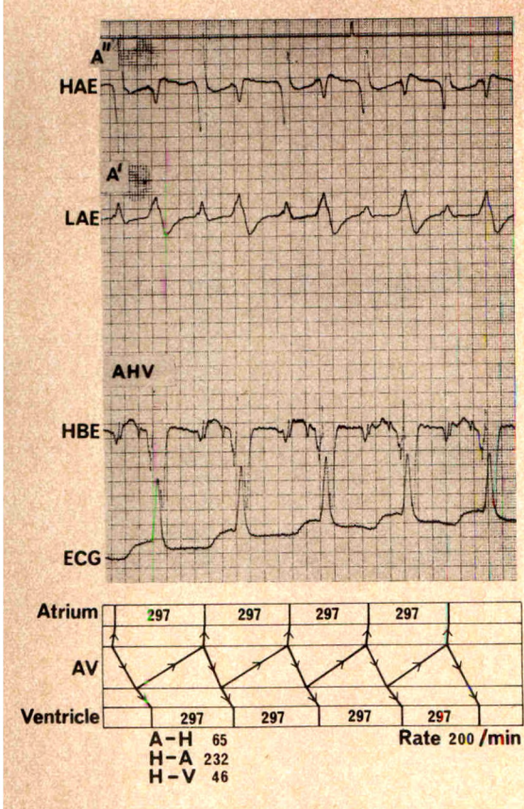
Termination of the tachycardia: In all 13 patients the tachycardia could be terminated by suitably timed single or double atrial or ventricular premature beats.

Atrial pacing: Atrial pacing at a rate of 90 to 180 beats/min was carried out in all patients except Patients 6, 8 and 13 (Table II). In Patients 1 to 5 and 7 the average increase in antegrade conduction time was 53 msec and in Patients 9 to 12 the average increase was 66 msec. These results are in accord with increasing delay in the atrioventricular (A–V) node due to increasing driving rates during atrial pacing[16]; they suggest that in these 10 patients the antegrade passage of the impulse occurred through the A–V node.

Ventricular pacing: All 13 patients underwent ventricular pacing. Retrograde conduction time in all patients except Patients 2 and 4 was longer during ventricular pacing at 180 beats/min than during tachycardia (Tables III and IV). This difference occurred because during tachycardia retrograde conduction is assessed by measuring the time from His bundle depolarization to low atrial depolarization (H–A interval) whereas during ventricular pacing it is measured from the stimulus artefact at the onset of ventricular activation to the low atrial depolarization (V–A interval); thus, an additional conduction time during ventricular activation and conduction through the bundle branches to the His bundle is incorporated in this measurement.

Table IIIA lists the values for retrograde conduction time in Patients 1 to 8. Right ventricular pacing was performed at a rate of 90 to 180 beats/min, and retrograde conduction time was measured from the onset of ventricular activation to the intrinsic deflection in the low atrial electrogram. In these patients the average increase in retrograde conduction time was 80 msec; this increase was attributed to greater delay within the A–V node as a result of the increased ventricular rate.

In patients with a normal conduction system retrograde conduction time has been shown to increase when ventricular premature beats are induced progressively earlier in the cardiac cycle during ventricular pacing.[1] This finding accords with normal values obtained in our laboratory for the increase in retrograde conduction time observed when ventricular premature beats[17] are induced progressively earlier



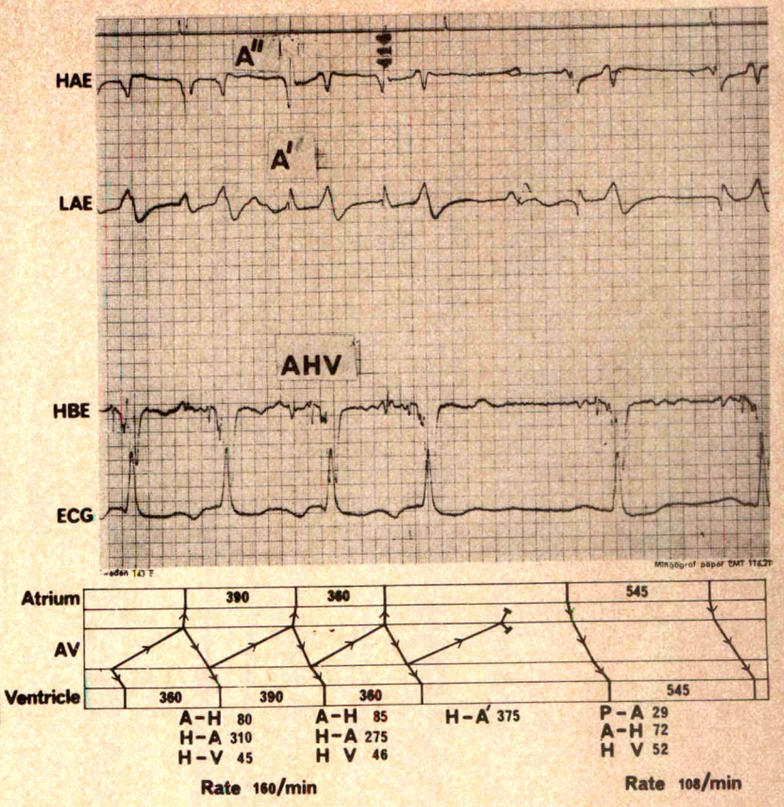


FIGURE 1 (left). Case 4. Tracings obtained during tachycardia before verapamil was administered. A = retrograde atrial depolarization on the His bundle electrogram (HBE). A′ = retrograde atrial depolarization in the low right atrium (LAE). A″ = retrograde atrial depolarization in the high right atrium (HAE), A–H = antegrade conduction in milliseconds from the low atrial depolarization as recorded on the His bundle electrogram to the His bundle deflection; AV = atrioventricular; ECG = surface electrocardiogram; H = His bundle deflection; H–A = retrograde conduction in milliseconds from the His bundle deflection to the low atrial depolarization.

FIGURE 2 (right). Case 4. Tracings obtained during termination of the tachycardia with verapamil. The tachycardia is terminated after the fourth beat with block in the retrograde pathway. The fifth and sixth beats are sinus in origin.

and when the ventricular rate is increased during ventricular pacing.

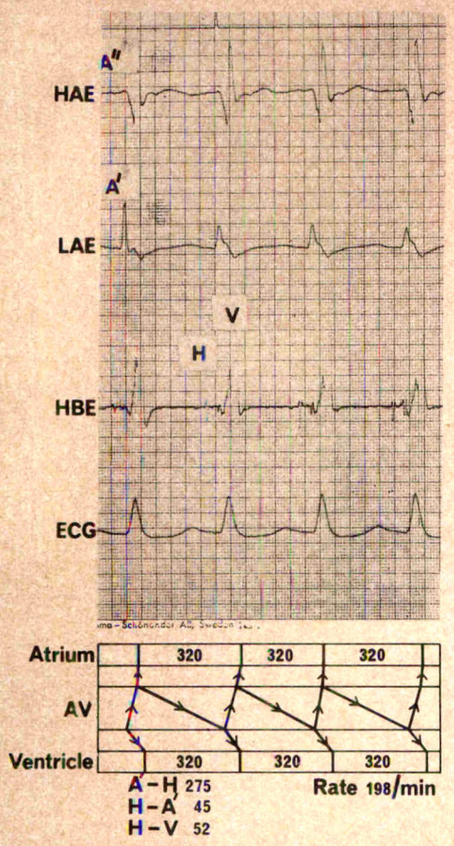
Table IIIB lists the comparable values for retrograde conduction time in Patients 9 to 13. The average increase in these patients was only 9 msec. This finding suggests that the impulse was returning to the atrium by a pathway that did not have the properties of the A–V node; hence, retrograde conduction time was not prolonged as ventricular rates increased.

Termination of the tachycardia with verapamil: After initiation of the tachycardia by a suitably timed atrial or ventricular premature beat, 10 mg of verapamil was administered intravenously to all 13 patients. In each patient the tachycardia was terminated 60 to 90 seconds later. Figure 1 shows the intracardiac recording obtained from Patient 4 during tachycardia, and Figure 2 shows recordings obtained from the same patient during termination of the tachycardia after administration of verapamil. The antegrade conduction time (A–H interval) was prolonged from 65 to 85 msec and retrograde conduction time (H–A interval) from 232 to 310 msec. The tachycardia was terminated with block in the retrograde pathway as illustrated on the ladder diagram.

Table IVA lists the effects of verapamil on antegrade and retrograde conduction during termination of the tachycardias in Patients 1 to 8. Antegrade conduction is prolonged by an average of 43 msec and retrograde conduction by an average of 79 msec. His bundle studies[17,18] have shown that verapamil acts predominantly by prolonging antegrade conduction within the A–V node in patients with a normal conduction system. In such patients it also prolongs retrograde conduction during ventricular pacing and after ventricular premature beats. This prolongation in retrograde conduction is thought to occur within the A–V node.[17] Therefore our findings in Patients 1 to 8 suggest that both the antegrade and retrograde pathways of the reciprocal circuit in tachycardia lie within the A–V node.

Figure 3 shows the intracardiac recordings obtained from Patient 12 during tachycardia, and Figure 4 shows the recordings obtained from the same patient during termination of the tachycardia after administration of verapamil. Antegrade conduction (A′–H interval) was prolonged from 275 to 450 msec whereas retrograde conduction (H–A′) was unchanged at 45 msec before and after administration of verapamil.

Table IVB lists the effects of verapamil on antegrade and retrograde conduction times in Patients 9



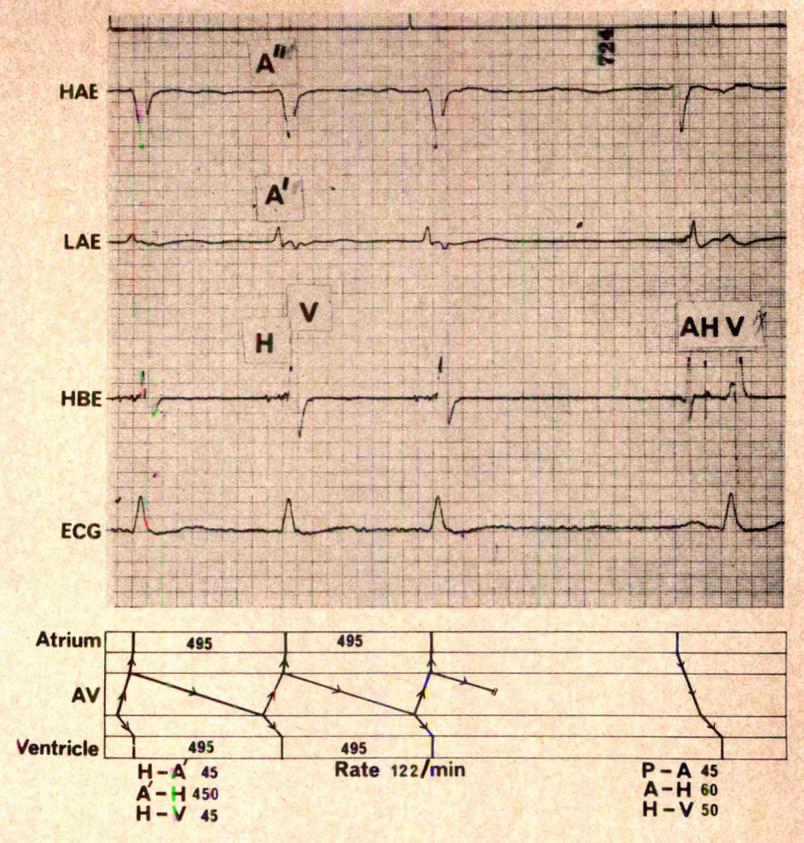


FIGURE 3 (left). Case 12. Tracings obtained during tachycardia before administration of verapamil. A′–H = antegrade conduction in milliseconds from the low atrial depolarization on the low atrial electrogram to the His deflection; H–A′ = retrograde conduction in milliseconds as measured from the His deflection to the low atrial depolarization on the low atrial electrogram.

FIGURE 4 (right). Case 12. Tracings obtained during termination of the tachycardia after administration of verapamil. The tachycardia is terminated after the third beat with block in the antegrade pathway. The fourth beat is sinus in origin.

to 13. Antegrade conduction was prolonged by an average of 101 msec whereas retrograde conduction was prolonged by an average of only 3 msec. This small effect on the retrograde conduction time after the administration of a drug known to prolong A–V nodal conduction time suggests that the retrograde impulse was not passing to the atria by way of the A–V node but was bypassing it in a pathway unaffected by verapamil.

Discussion

Evidence for reciprocating tachycardia: To diagnose a reciprocal mechanism as the underlying basis of a supraventricular tachycardia, three criteria should be fulfilled: (1) It should be possible to initiate the tachycardia with a suitably timed single or double atrial or ventricular premature beat; (2) during tachycardia, induced atrial or ventricular premature beats that do not terminate the tachycardia should be followed by pauses that are less than compensatory; and (3) it should be possible to terminate the tachycardia with single or double atrial or ventricular premature beats.[19] These criteria were met in all 13 cases.

In the absence of evidence of preexcitation on the surface electrocardiogram (a short P–R interval or short P–R interval and delta wave, for example) patients with reciprocating paroxysmal supraventricular tachycardia are thought to have the antegrade and retrograde pathways of the reciprocal circuit within the A–V node.[1–5] None of our 13 patients studied had evidence of preexcitation on the surface electrocardiogram. However, as a result of the electrophysiologic study Patients 1 to 8 appeared to have both pathways of the reciprocal circuit within the A–V node and Patients 9 to 13 had evidence of an A–V nodal bypass such that during reciprocating tachycardia the antegrade pathway was within the

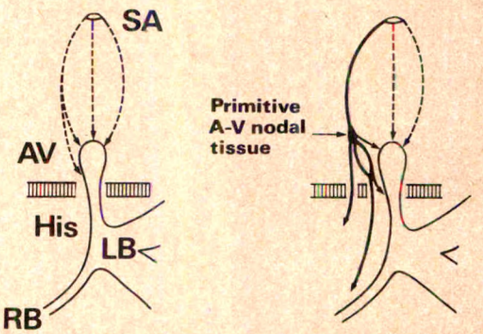

FIGURE 5. Diagram showing the specialized conduction pathways in the normal heart **(left)** and the abnormal pathways arising from primitive A–V nodal tissue and bypassing the true A–V node to enter the septum and bundle of His **(right).** See text.

A–V node and the retrograde pathway in an extranodal bypass. In the absence of evidence for the Wolff-Parkinson-White syndrome this bypass was thought to be closely adjacent to the A–V node.

The significance of a bypass that does not have the properties of A–V nodal tissue is that it provides an alternative conduction pathway down which impulses can pass and activate the ventricles. Likewise an impulse can pass in retrograde manner from the ventricles in the bypass and activate the atria. In Patients 9 to 13 antegrade conduction appeared to occur by way of the A–V node-His pathway alone both during atrial pacing and tachycardia, whereas only retrograde conduction occurred in the bypass. It is not known why retrograde but not antegrade conduction occurs in the bypass, but this phenomenon may be due to "mismatched impedance."[20]

Clinical implications: Under normal circumstances the ventricles are protected by the A–V node from bombardment by impulses traveling at high frequency, as occurs in atrial fibrillation. However, if an A–V nodal bypass is present, particularly if it has a short refractory period, then under circumstances in which the mismatched impedance might be dissipated, impulses may pass to the ventricles at high frequency by way of this bypass and the risk of ventricular fibrillation is then present. This situation has been described in the Wolff-Parkinson-White syndrome.[21,22] We believe that patients with A–V nodal bypasses of the type described here are at risk should atrial fibrillation suddenly develop. There is also an increased risk that atrial fibrillation will develop in this group of patients: An early ventricular extrasystole can be conducted rapidly to the atria, in the bypass, arrive in the atrial vulnerable period and precipitate atrial fibrillation[23] which, in turn, may lead to ventricular fibrillation for the reasons given.

Figure 5 illustrates the anatomy of the conduction system in a 35 year old man who had atrial fibrillation of unknown etiology and complained of several syncopal episodes on exertion; during one of these he died. Histologic examination of his heart demonstrated the presence of primitive A–V nodal tissue leading to tracts that bypassed the A–V node and joined the main bundle of His and ventricular septum. We postulate that this man's death was due to ventricular fibrillation after rapid antegrade conduction of impulses from the fibrillating atria down the bypass tracts to the ventricles. Our electrophysiologic study provided evidence for the occurrence of retrograde but not antegrade conduction by way of a bypass tract. We are unable to determine the physiologic conditions required for the occurrence of antegrade conduction in the bypass in the presence of atrial fibrillation with its potential for inducing ventricular fibrillation. It may be that increased sympathetic activity plays an important part in this respect since the syncopal episodes and death of the patient described occurred during exercise.

Electrophysiologic Properties of Procainamide in Man

MARK E. JOSEPHSON, MD
ANTHONY R. CARACTA, MD
MICHAEL A. RICCIUTTI, PhD
SUN H. LAU, MD
ANTHONY N. DAMATO, MD

Staten Island, New York

The electrophysiologic properties of procainamide were studied in 16 patients and correlated with plasma levels. Procainamide caused a minimal prolongation of atrioventricular (A–V) nodal conduction in 11 of 16 patients during sinus rhythm, but His-Purkinje conduction time was significantly prolonged in 15 of 16 patients. The effective refractory period of the atrium was prolonged by procainamide in 14 of 16 patients. The effective refractory period of the A–V node decreased in 8 of 9 patients. This may have been due to (1) anticholinergic properties of procainamide, (2) production of an A–V nodal "gap" by procainamide, or (3) an apparent A–V nodal block that actually represented decremental conduction in the His bundle; procainamide then caused delay in the A–V node allowing improved intra-His conduction and ventricular depolarization. The relative refractory period of the His-Purkinje system was prolonged in 10 of 11 patients. The effective refractory period was prolonged in one patient, unchanged in a second and apparently shortened in a third. In this third patient, procainamide produced a marked delay in proximal His-Purkinje conduction allowing a distal area of refractoriness to recover, thus causing apparent shortening of the effective refractory period. Plasma levels averaged 7.1 mg/liter at the end of the study; no toxicity was noted.

Procainamide is one of the oldest and most useful antiarrhythmic agents.[1–8] Although its clinical efficacy has been well established, its effects on the electrophysiologic properties of various portions of the atrioventricular (A–V) conducting system in man have not been extensively evaluated.[9,10] Most of our knowledge is based on studies of intact animals and tissue preparations.[11-16] These and more recent studies[17–22] have attributed the following effects to procainamide: (1) decreased automaticity, (2) impaired A–V conduction, (3) increased refractoriness, and (4) decreased membrane responsiveness. Several recent articles[23–29] have examined the mechanisms of arrhythmias and the manner in which the electrophysiologic properties of procainamide might influence various arrhythmias. Because of the persistent question of relevance of animal and in vitro studies to effects in man, in this study we evaluated some of the electrophysiologic properties of procainamide in man and correlated them with plasma levels of the drug.

Materials and Methods

Sixteen patients underwent right heart catheterization in the nonsedated postabsorptive state after informed consent was obtained. The clinical data of these patients are given in Table I. No patient was receiving antiarrhythmic agents or digitalis at the time of the study; two patients had discontinued digoxin 3 days before catheterization.

A quadripolar electrode catheter was inserted percutaneously into an antecubital vein and positioned fluoroscopically against the lateral wall of the right atrium. The distal two electrodes were used to pace the atrium and the

proximal pair was used to record a high right atrial electrogram. His bundle electrograms were obtained using a tripolar electrode catheter, as previously described.[30] Four surface electrocardiographic leads were simultaneously recorded (leads I, II, III and V_1). Time lines were generated at 10 and 100 msec.

Conduction studies were carried out during sinus rhythm and at various paced atrial rates up to a maximum of 180 beats/min. Atrial stimulation was performed using a programmed digital stimulator that delivered impulses of 1.5 msec duration at approximately twice diastolic threshold. Measurements of A–V nodal and His-Purkinje conduction times were made at each paced cycle length. The A–H interval as measured in the His bundle electrogram represented conduction time through the A–V node (normal 60 to 140 msec); the H–V interval measured conduction through the His-Purkinje system (normal 35 to 55 msec).

With use of the atrial extrastimulus method,[31] the refractory periods of the atrium, A–V node and His-Purkinje system were determined at various paced cycle lengths to avoid the effect of changing cycle length on refractoriness. Progressively premature atrial depolarizations (A_2) were introduced after every eighth paced atrial beat (A_1) until the effective refractory period of the atrium was reached.

After the initial studies were completed, a control blood sample was withdrawn in heparinized tubes. Each patient received 500 mg of procainamide intravenously at a rate of approximately 50 mg/min. Blood pressure and heart rate were monitored.

Shortly after the end of the infusion another blood sample was drawn. Refractory periods and conduction studies were then repeated with additional blood samples drawn at approximately 10 to 15 minute intervals until the studies were completed, usually within 30 minutes. Plasma levels were analyzed spectrophotometrically according to methods outlined by Koch-Weser.[32] All data were stored on magnetic tape (North American Phillips Tape Recorder, Shelton, Conn.) and later retrieved at paper speeds of 150 and 200 mm/sec (Electronics for Medicine).

Definition of Terms

The effective refractory period of the atrium is defined as the longest S_1–S_2 interval at which S_2 fails to depolarize the atrium, S representing the stimulus artifact.

The effective refractory period of the A–V node is defined as the longest A_1–A_2 interval at which A_2 fails to propagate to the His-Purkinje system.

The functional refractory period of the A–V node is defined as the shortest H_1–H_2 interval that results from any A_1–A_2 interval.

The effective refractory period of the His-Purkinje system is defined as the longest H_1–H_2 interval at which H_2 fails to conduct to the ventricles.

The relative refractory period of the His-Purkinje system is defined as the longest H_1–H_2 interval at which H_2 conducts to the ventricles with a longer H–V time than that of the basic drive beat or with a QRS complex of aberrant configuration.*

Results

Spontaneous sinus rate: Procainamide produced no change or a slight increase in spontaneous heart rate. The mean change was a 7 percent increase in heart rate from the control level. Only two patients (Cases 11 and 16) had increases of 15 percent or more.

Conduction

Conduction times: Conduction times through the A–V node and His-Purkinje system were normal in all but one patient (Case 2, H–V interval 70 msec) before administration of procainamide.

A–V nodal conduction: After administration of procainamide 11 of 16 patients showed prolongation of the A–H interval during sinus rhythm; in 4 there was no change, and in 1 patient a decrease. The mean increase was 7 msec (7 percent) (range of 5 to 25 msec). In the 11 patients whose A–V nodal conduction time was studied during atrial pacing, procainamide produced more variable results; the A–H interval increased in 5, decreased in 4, and did not change in 2 when compared to control values at the same paced rates. Thus, some patients in whom procainamide prolonged the A–H interval during sinus rhythm showed no change or a decrease in the A–H interval at paced atrial rates comparable to control rates.

His-Purkinje conduction: During sinus rhythm procainamide caused H–V prolongation (10 to 33 percent) in 15 of 16 patients. In the remaining patient no change was noted. Pacing produced no further changes. There was a mean increase of 9 msec (19

* Although the His-Purkinje system is a trifascicular system, in the absence of multiple recording sites along individual fascicles it is impossible to measure the effective refractory period versus the relative refractory period of any given fascicle. Thus, for the purpose of this study we elected to consider the His-Purkinje system a single functioning unit.

All measurements are expressed in milliseconds.

A = after procainamide; AVN = A–V node; B = before procainamide; ERP = effective refractory period; FRP = functional refractory period; HPS = His-Purkinje system; RRP = relative refractory period.

percent) in the H–V interval as a group, and in five patients (Cases 3, 7, 9, 13 and 15) procainamide produced abnormal His-Purkinje conduction times (greater than 55 msec). In the single patient (Case 2) with a prolonged control H–V interval, procainamide further increased this interval by 15 msec. Procainamide caused no change in QRS configuration in any patient and had a minimal effect on QRS duration, causing an increase of 20 msec or more in only three patients (Cases 6, 9 and 15), none of whom had a QRS duration exceeding 0.12 second.

Refractory Periods

Table II lists the effects of procainamide on refractoriness in all patients at various paced cycle lengths.

Effective refractory period of the atrium: Procainamide increased the effective refractory period of the atrium in 14 of 16 patients. The effective refractory period decreased in only one patient and was unchanged in the remaining patient. The mean change was +31 msec.

Effective refractory period of the A–V node: The effective refractory period of the A–V node could be measured in only nine patients. In the remaining patients the effective refractory period of the atrium was reached before that of the A–V node. The effective refractory period of the A–V node was decreased in eight of nine patients and was variably altered in one, depending on the paced cycle length. The mean decrease in the effective refractory period was 55

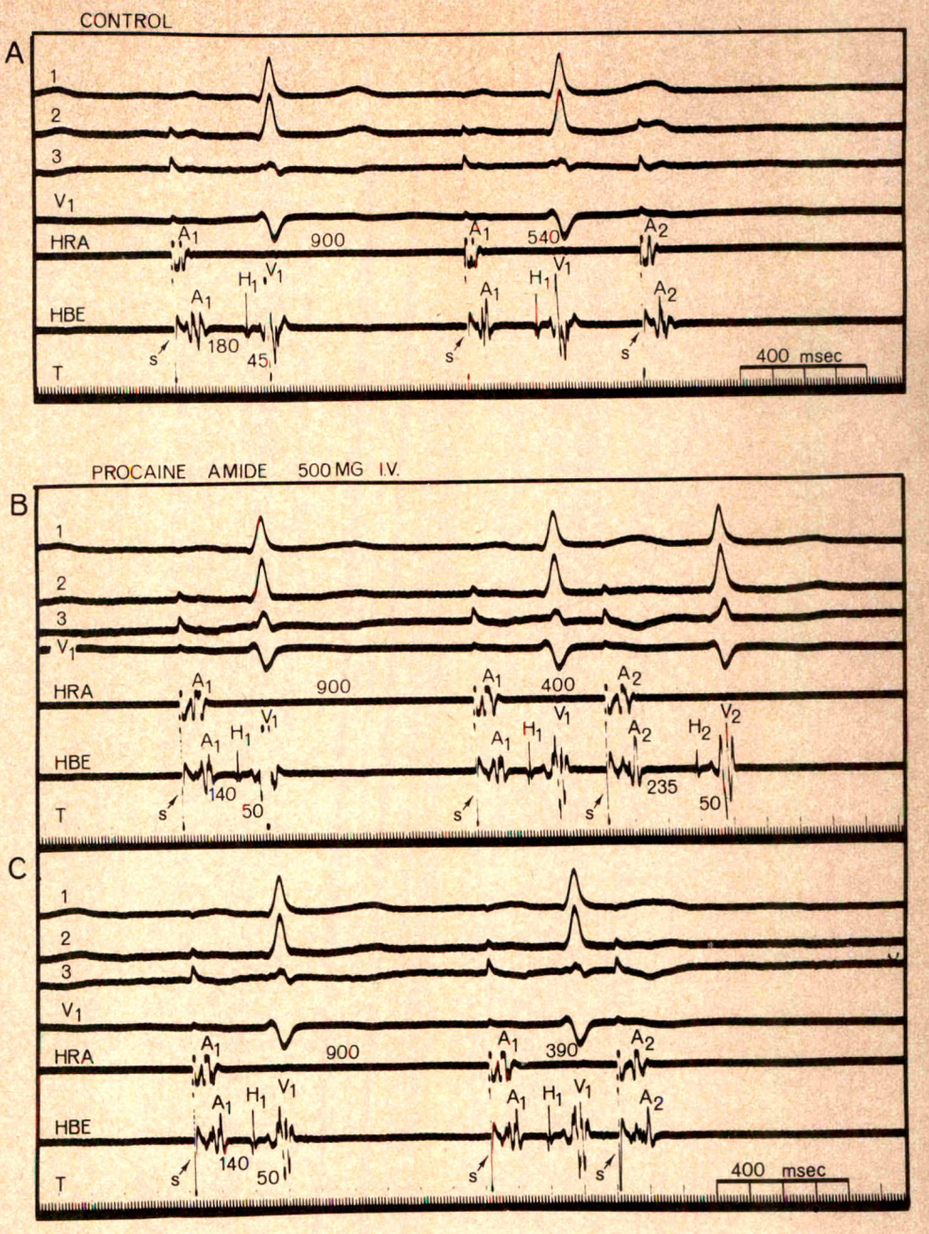

FIGURE 1. Effects of procainamide on the effective refractory period of the A–V node. Each panel is organized as follows: from top to bottom, standard leads I, II, III, V_1, high right atrial electrogram (HRA), His bundle electrogram (HBE) and time lines (T) of 10 and 100 msec. The basic paced atrial cycle length is 900 msec. In the control panel **(A)** the effective refractory period of the A–V node is reached at an atrial coupling interval (A_1–A_2) of 540 msec. After administration of procainamide, A_2 continues to conduct to the His-Purkinje system at an A_1–A_2 interval of 400 msec **(B).** When the A_1–A_2 interval is decreased to 390 msec **(C)** block of A_2 above the His bundle occurs and the effective refractory period of the A–V node is reached. Thus, procainamide shortened the effective refractory period of the A–V node by 150 msec. The 40 msec decrease in the A–H interval of the basic drive beat produced by procainamide is compatible with the anticholinergic properties of the drug (see Discussion). The H_1–V_1 interval was prolonged by 5 msec after infusion of procainamide. s = stimulus.

msec. Two patients (Cases 14 and 15) had a decrease of greater than 100 msec at the slowest paced cycle length, and in both patients A–V nodal conduction was enhanced during atrial pacing compared to control values. The results from one of these patients are shown in Figure 1.

Functional refractory period of the A–V node: Procainamide had no consistent effects on the functional refractory period of the A–V node although there was a mean increase of 10 msec. There was also no consistent relation between the effects of procainamide on the effective and functional refractory periods of the A–V node.

Relative refractory period of the His-Purkinje system: The relative refractory period increased in 10 of 11 patients by a mean of 18 msec. In one patient there was no change. In an additional two patients the effect of procainamide on the relative refractory period could not be analyzed because a comparable H_1–H_2 interval was not reached in the control study. Figure 2 is representative and demonstrates that procainamide prolonged the relative refractory period by 40 msec.

Effective refractory period of the His-Purkinje system: Only three patients had block within the His-Purkinje system during control conditions. In one patient at a paced atrial rate just above sinus rate the effective refractory period of the His-Purkinje system was increased by 30 msec (Fig. 3); at a slightly shorter paced cycle length, at which no block within the His-Purkinje system was noted during the control period, procainamide induced block within the His-Purkinje system. In the second patient the effective refractory period of the His-Purkinje sys-

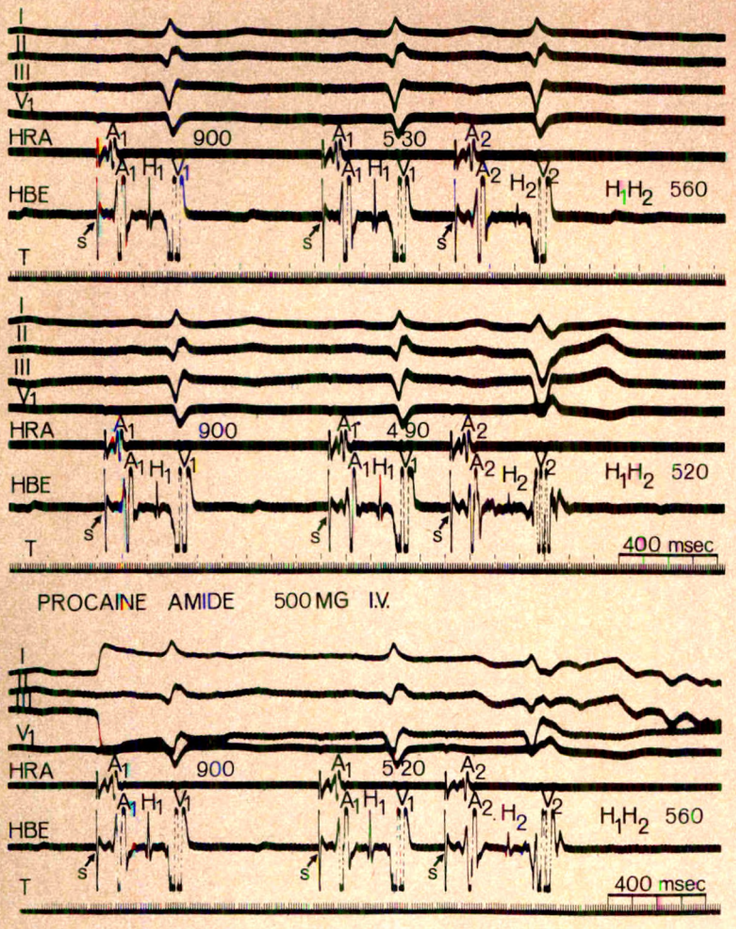

FIGURE 2. Effect of procainamide on the relative refractory period of the His-Purkinje system. The basic paced atrial cycle length is 900 msec. In control panel **(top),** A_2 is introduced at an atrial coupling interval (A_1–A_2) of 530 msec. The H_1–H_2 interval is 560 msec and the QRS configuration is the same as that of the basic drive beat. As the A_1–A_2 interval is decreased to 490 msec **(center panel)** the resulting QRS complex is aberrant with a configuration of right bundle branch block and left axis deviation. The critical H_1–H_2 interval is 520 msec and defines the relative refractory period of the His-Purkinje system during the control period. After infusion of procainamide **(bottom panel)** at an H_1–H_2 interval of 560 msec the QRS complex manifests a configuration of right bundle branch block and left axis deviation; at this H_1–H_2 interval during the control period the QRS configuration was normal. Therefore, procainamide produced a 40 msec increase in the relative refractory period of the His-Purkinje system.

tem was unchanged. In the third patient procainamide appeared to decrease the effective refractory period by 35 msec at a basic paced cycle length just above sinus rate; at a faster paced cycle length procainamide prevented block within the His-Purkinje system at any coupling interval (Fig. 4). However, in this latter case procainamide induced a marked prolongation between the His and right bundle potentials.

Effect of changing cycle lengths on refractoriness: In 12 patients refractory period studies were carried out at two or more cycle lengths. In 11 of 12 patients the effective refractory period of the atrium decreased at faster rates. In the remaining patient atrial fibrillation occurred, preventing accurate analysis. The effective refractory period of the A–V node increased in 6 of 6 patients as atrial cycle length decreased. Paced atrial cycle lengths had variable effects on the functional refractory period of the A–V node; shorter cycle lengths decreased this period in seven, increased it in three, and did not change it in two. Both the effective and relative refractory periods of the His-Purkinje system decreased as the paced atrial cycle length was decreased. Procainamide did not significantly alter these relations.

Plasma levels of procainamide: Table III lists the plasma levels of procainamide in our patients after infusion and at the end of the study.

Side effects: No patient experienced procainamide toxicity. Although in most patients the blood pressure decreased approximately 10 mm Hg during infusion of procainamide, no patient had significant hypotension. No patient manifested widening of the QRS interval of 25 percent or more or demonstrated ventricular irritability. There were no central nervous system or gastrointestinal complaints.

Discussion

Our results on the effects of procainamide on conduction through the A–V node and His-Purkinje system are similar to those reported by Rosen et al.,[9] who made similar measurements in man. In both studies procainamide produced a variable prolongation of A–V nodal conduction time. Other studies[1,5,12,15,18,19,21,24,27,29] have demonstrated a more consistent prolongation of A–V nodal conduction time in animals, but the doses of procainamide used were higher than those used in man. Prolongation of His-Purkinje system conduction time has been a consistent finding in man as well as in animals and in vitro tissue preparations.[1,2,4,7,15,16,18,19,21,23,24,27] In our study, procainamide did not produce significant changes in QRS duration and configuration, thus suggesting that the drug caused a uniform delay in

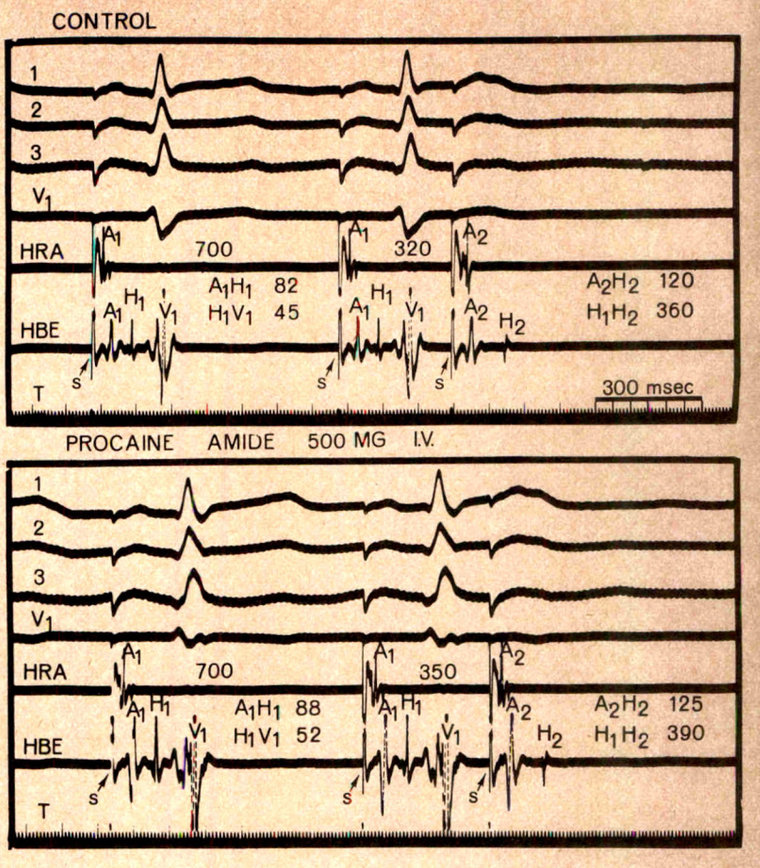

FIGURE 3. Effect of procainamide on the effective refractory period of the His-Purkinje system. The basic paced atrial cycle length is 700 msec. During control studies block developed within the His-Purkinje system at an A_1–A_2 interval of 320 msec. The H_1–H_2 interval is 360 msec and defines the effective refractory period of the His-Purkinje system. After infusion of procainamide, at a less premature atrial coupling interval (A_1–A_2 interval 350 msec), block within the His-Purkinje system is noted; the H_1–H_2 interval is 390 msec. Thus, procainamide increased the effective refractory period of the His-Purkinje system by 30 msec. Conduction time through the A–V node and His-Purkinje system during the basic drive beats (A_1–H_1 and H_1–V_1 respectively) was prolonged by procainamide.

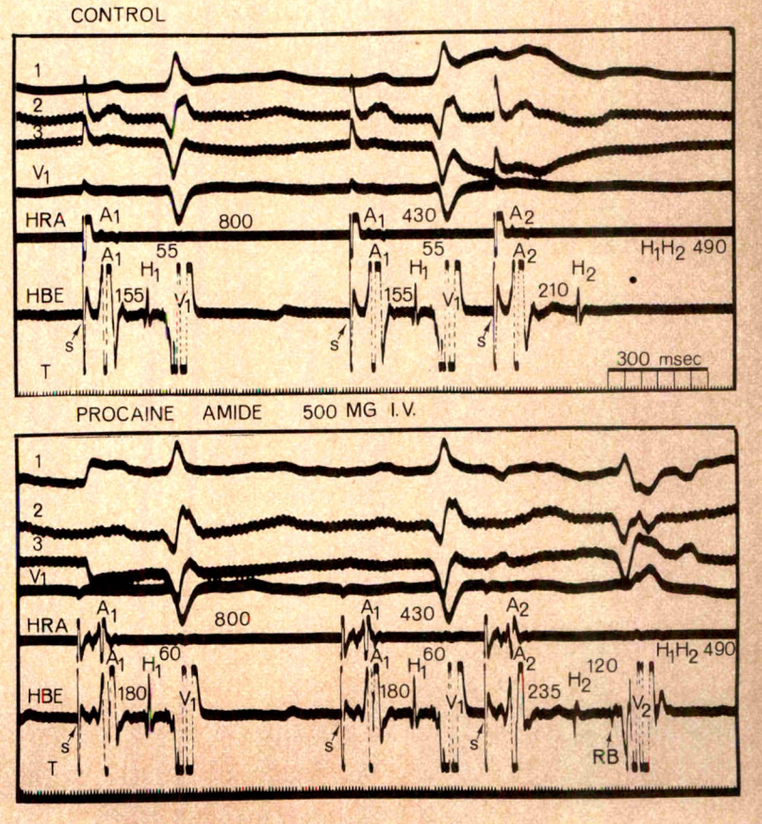

FIGURE 4. Effect of procainamide on the effective refractory period of the His-Purkinje system. The basic paced atrial cycle length is 800 msec. During control studies block occurs within the His-Purkinje system at an atrial coupling interval (A_1–A_2) of 430 msec. The critical H_1–H_2 interval determining the effective refractory period of the His-Purkinje system is 490 msec. After infusion of procainamide, at the same H_1–H_2 interval that defined the effective refractory period of the His-Purkinje system in the control period, conduction to the ventricles resumes. However, there is a marked delay between the His bundle potential and the right bundle potential (RB) of the conducted beat. This suggests that procainamide actually prolonged refractoriness in the proximal His-Purkinje system, thus allowing a more distal area of refractoriness to recover, and resulting in ventricular depolarization (see Discussion). The conduction time through the A–V node (A_1–H_1) and His-Purkinje system (H_1–V_1) of the basic drive beats was prolonged by procainamide.

His-Purkinje system conduction and had little effect on ventricular muscle.

Previous studies[1,2,4,7,13,15,16,23,24,27,29] using microelectrode techniques and anesthetized dogs have demonstrated that procainamide prolongs the refractory periods of the atrium and His-Purkinje system. Our results are in general agreement with these findings. One apparent discrepancy occurred in one patient in whom procainamide appeared to shorten the effective refractory period of the His-Purkinje system. As shown in Figure 4, procainamide caused a marked delay in conduction between the His bundle and right bundle branch deflections. This delay probably allowed a more distal area of refractoriness to recover, thus permitting conduction to the ventricles.[33] The shortening of the effective refractory period of the A–V node was somewhat unexpected in light of the variable prolongation of A–V nodal conduction time induced by procainamide. There are three possible explanations for this somewhat unexpected result: (1) During control studies the apparent block in the A–V node was actually a block within the His bundle itself, the His deflection not being recorded because of a low density of current.[34] Procainamide, by causing delay in conduction within the A–V node, permitted the impulse to arrive at the bundle of His at a later time in the cardiac cycle when the structure was no longer refractory, and consequently A–V conduction resumed. (2) If the site of initial block was in fact within the distal A–V node, then one can postulate that, by a similar mechanism, procainamide caused delay in the proximal A–V node, thus allowing the previously refractory distal area to recover. (3) Shortening of the effective refractory period of the A–V node may be due to the antivagal effects of procainamide.[12,13,17] Because the clinical effects of procainamide depend on a balance of its direct effects (impairing conduction and prolonging refractoriness) and its indirect antivagal effects (shortening A–V nodal conduction time and refractoriness), it is conceivable that procainamide could shorten the effective refractory period of the A–V node while variably affecting A–V nodal conduction. Any one of these mechanisms may have been operative in our patients.

In our study procainamide produced a small increase in spontaneous heart rate. This is at variance with results in dogs[18,19] which showed depression of sinus rate of up to 20 percent after administration of procainamide. Clinical experience has shown that the effects of procainamide on heart rate are unpredictable.

Effect of cycle length on refractoriness: Our study confirms the results of prior microelectrode studies[35] which showed that at shortened paced cycle lengths the refractory period of the atrium and His-Purkinje system decrease. The effective refractory period of the A–V node, however, increased at shorter paced cycle lengths. This finding has been further substantiated in our laboratory.[36]

Plasma procainamide levels: Plasma levels of procainamide were in the therapeutic range[2,4,32] during our studies, and no toxic reactions were noted. Woske et al.[15] found no effects of procainamide in dogs until concentrations of 20 mg/liter were infused. The slow rate of infusion used in our study apparently allowed the volume of distribution to be reached by the end of the infusion in several patients. This explains the lack of a marked initial peak and severe toxicity when the drug is infused more rapidly.[32]

Clinical correlates: Our study reveals that the major effects of short-term infusions of procainamide were to prolong conduction and refractoriness in the His-Purkinje system. These properties suggest caution in using this agent in the presence of bundle branch block. In addition these properties may be responsible by way of a reentry mechanism for the occasional ventricular tachyarrhythmias seen after toxic doses of procainamide. These arrhythmias have previously been attributed to enhancement of automaticity.[14,16] These effects of procainamide are in contrast to the electrophysiologic properties of lidocaine[37] and diphenylhydantoin (Dilantin®)[38] in man. The latter drugs shorten the refractoriness of the His-Purkinje system and do not affect His-Purkinje system conduction and therefore they may be safer to use in the presence of intraventricular conduction disturbances. Since the effects of procainamide on A–V nodal conduction are minimal, the use of this drug in the presence of first degree A–V block or classic Mobitz type I second degree block may not be as dangerous as previously suggested. In addition, the shortening of the effective refractory period of the A–V node and lengthening of the effective refractory period of the atrium may increase the ventricular response in atrial flutter or fibrillation by decreasing concealed conduction in the A–V node.

Arrhythmias After Cardiac Transplantation

JOHN S. SCHROEDER, MD, FACC
DAVID K. BERKE, MD
ANTHONY F. GRAHAM, MD
ALAN K. RIDER, MD
DONALD C. HARRISON, MD, FACC

Stanford, California

To determine the nature and frequency of arrhythmias that affect the denervated transplanted human heart, we examined sequential electrocardiograms in 45 of the first 47 cardiac allograft recipients at Stanford University Hospital. Atrial arrhythmias were detected in 72 percent of patients and were frequently associated with acute or chronic rejection episodes. Ventricular premature beats were noted in 57 percent of patients. Two patients had electrocardiographically documented ventricular fibrillation, and two additional patients died suddenly from presumed ventricular arrhythmias. Preliminary data indicate that these arrhythmias can be treated successfully with antiarrhythmic drugs, cardioversion or treatment of the underlying rejection process. Our experience suggests that autonomic innervation of the heart is not a prerequisite for the development of cardiac arrhythmias and is not required for response to antiarrhythmic therapy.

A unique population of patients surviving with denervated allografted hearts has resulted from the successful cardiac transplantation program at Stanford University Medical Center. As of September 1, 1972, a total of 47 patients had received cardiac allografts, and 17 had survived up to 44 months after transplantation. The functional capabilities of the denervated heart have been well described by our group and others.[1,2] In contrast, the electrophysiologic characteristics of the denervated heart are only currently undergoing analysis.[3] These studies are particularly relevant because of the high rate of observed cardiac arrhythmias after cardiac transplantation in both dogs and man. Lower et al.[4] reported that 29 (58 percent) of 50 homografted canine hearts demonstrated some form of arrhythmia during daily electrocardiographic monitoring. Most of these arrhythmias either heralded or accompanied rejection episodes.

Current theories on the genesis of cardiac arrhythmias have implicated the central and autonomic nervous systems.[5–7] Reinnervation has been reported in dogs with experimental surgical neural ablation of the heart and after cardiac transplantation.[8,9] Possible reinnervation has also been reported in the dog with an allografted heart 140 days after transplantation.[10] In contrast, there has been no evidence of autonomic reinnervation of the human cardiac allograft up to 44 months after transplantation.[1,11] In this report we describe the prevalence and type of documented arrhythmias in the denervated human heart and discuss possible alternate pathogenetic factors.

Methods

Details of the cardiac transplant program at Stanford, including donor and recipient selection, surgical technique and postoperative management, have been described elsewhere.[12] Table I lists the medications currently used in the immediate and 1 year postoperative periods. Approximately 70 percent of the patients require constant or intermittent diuretic therapy because of fluid-dependent edema. Serum potassium levels are determined at least

weekly in these patients, with appropriate replacement. Digitalis therapy is not used in long-term patients. Electrocardiograms are recorded one to three times daily during the initial hospitalization period of 4 to 8 weeks. Each electrocardiogram is reviewed for rate, arrhythmias and QRS voltage changes to guide in the diagnosis and therapy of rejection. After the patient is discharged from the hospital, electrocardiograms are recorded once or twice weekly indefinitely. All electrocardiograms are reviewed, and additional arrhythmia documentation is obtained from bedside cardiac monitoring records. An arrhythmic episode is defined as any abnormal rhythm detected singly or recurrently within a week's time. Thus, multiple premature ventricular contractions recorded on the standard electrocardiogram daily for 5 days would be recorded as a single episode of premature ventricular contractions in the prevalence tables. In 14 long-term survivors 10 hour ambulatory electrocardiograms have been obtained on a regular basis and bicycle ergometer stress electrocardiograms have been obtained once monthly. These data are reviewed to assess the type and frequency of arrhythmias in the long-term ambulatory transplant patient. An arrhythmic episode in these studies is defined as any abnormality of rhythm occurring during the monitoring period.

Denervation Data

The presence of a residual innervated recipient atrium to which the donor heart is sutured allows comparison of innervated and denervated sinus nodal responses to cardiovascular reflexes and autonomic blocking drugs.[13] The residual innervated recipient sinus nodal rate is 70 to 80 beats/min and responds appropriately to vagal blockade produced by the intravenous administration of atropine, whereas the donor atrial rate, which actually controls the transplanted heart, shows no such response (Fig. 1). Other physiologic or pharmacologic maneuvers such as rate response to the Valsalva maneuver or transient systemic hypertension have been used to document complete denervation and the lack of reinnervation in all patients. Studies are under way to confirm histochemically the apparent complete short- and long-term autonomic denervation. It should be noted that the recipient sinus node and atrial P waves are "dissociated," as observed on the electrocardiogram, and have never been shown to control or affect the donor heart in our patients (Fig. 2).

Results

Table II lists the type and frequency of arrhythmias in relation to time after transplantation. The 45 patients represent a total of 37.4 years (449 months) of survival. During this period, 168 atrial, 28 junctional and 89 ventricular arrhythmic episodes were detected. There was a very high rate of atrial irregularities in the first 6 months after transplantation. Atrial arrhythmias represent 70 percent of the total arrhythmic episodes, with atrial premature contractions observed in 26 patients (52 percent) and atrial flutter in 4; six episodes occurred in the immediate postoperative period. One patient had recurring atrial bigeminy for 1 1/2 years and ultimately required a demand pacemaker for periods of sinus arrest. The most frequent junctional rhythm was premature beats in the first month postoperatively.

Ventricular arrhythmias were not unusual and were detected in 26 patients (57 percent). During intensive therapy for severe rejection, two patients had electrocardiographically documented ventricular fi-

FIGURE 2. Electrocardiogram, lead II, from a patient after cardiac transplantation. Note the constant P–R interval of the donor atrial wave with conduction to the ventricle. The P waves marked "R," representing the residual recipient's atrium, are dissociated from the QRS complexes.

brillation, responding to electrical defibrillation at 400 watt seconds. One patient subsequently died from unremitting rejection. Two long-term survivors died suddenly at home, without premonitory symptoms or chest pain. Autopsy studies of these patients, who died 33 and 45 months, respectively, after transplantation, demonstrated severe coronary atherosclerosis.

Arrhythmias during exercise testing: In the first 6 months after transplantation, 36 submaximal bicycle ergometer tests were performed (Table III). Heart rate response was slow and ranged from 110 to 140 beats/min, consistent with denervation. There was a low rate of arrhythmias in response to 10 minutes of exercise, with no obvious relation to time after transplantation. Detected arrhythmias during exercise usually consisted of an occasional premature beat (fewer than 1 in 100 beats) and were not repetitive.

Arrhythmias during tape-recorded monitoring: A total of 600 hours of tape-recorded ambulatory electrocardiographic monitoring were reviewed in 14 patients. Only three patients had no arrhythmia. Monitoring frequently documented arrhythmias not seen on supine routine electrocardiograms, but these usually consisted of only a rare premature beat, usually atrial in origin. No ventricular tachycardia or other life-threatening arrhythmias were detected.

Prevalence of Arrhythmias During Rejection

Cardiac arrhythmias frequently herald the onset of an acute rejection episode.[14] We reviewed all 110 diagnosed and treated rejection episodes in the 45 patients (Table IV) and noted a particularly high percent of rejection episodes per 1,000 patient days during the first month after transplantation. Forty-one percent of the rejection episodes were associated with arrhythmias, mostly atrial in origin.

Aggressive treatment of the associated rejection episode resulted in resolution of the arrhythmia within 1 week in 97 percent of these episodes. Antiarrhythmic drugs, including quinidine and procainamide, were used for 2 to 3 day periods to suppress a recurrent supraventricular arrhythmia until a rejection episode was controlled. Studies are presently under way to assess more carefully the effectiveness of quinidine and procainamide in denervated hearts, but both agents appear to be useful in these cases. Electrical cardioversion was successful in treating atrial fibrillation or atrial flutter in eight instances. Settings of 25 to 200 watt seconds have been used during cardioversion without causing significant postconversion arrhythmias or sinus arrest.

Discussion

We have reviewed the possible etiologic or contributing factors in the high rate of arrhythmias in patients after cardiac transplantation. Only two patients required digitalis postoperatively, and neither had an increased prevalence of arrhythmic episodes during that period. Between 80 and 90 percent of our patients required diuretic agents for treatment of fluid retention secondary to corticosteroid therapy, but neither use of these agents nor hypokalemia

could be related to the prevalence or type of arrhythmias. All patients receive potassium replacement therapy and have weekly serum potassium determinations.

Several investigators[15–17] have demonstrated sensitization to circulating catecholamines after experimental cardiac denervation. Studies are under way to determine whether this observation can be confirmed in man. The relatively low rate of arrhythmias in the long-term, nonrejecting cardiac transplant survivor at rest and during exercise suggests that such sensitization may be a contributory but not a primary mechanism. The contribution of lack of vagal tone is difficult to determine, but this factor may account for the increased propensity to arrhythmias during rejection-induced myocardial injury or its associated stress.

The 40 percent rate of occurrence of arrhythmia during a cardiac rejection episode, and the almost invariable resolution of the arrhythmia with suppression of rejection, indicates a pathogenetic relation. Pathologic studies during rejection show cellular infiltration, interstitial edema and various degrees of myocardial cell injury, with resolution of these changes on therapy. Although a definite etiologic "agent" requires further definition, one likely sequence of events is local myocardial and conductive tissue injury during rejection, with the development of arrhythmias that are perhaps aggravated by lack of vagal tone and hypersensitivity to catecholamines.

Severe coronary atherosclerosis was documented in 6 of the 12 patients who died more than 6 months after transplantation. Exercise-induced premature ventricular contractions were observed in three patients with documented coronary artery disease, two of whom died suddenly. Ischemia-induced injury or sensitization to fatal ventricular arrhythmias, or both, may have been a major factor in the sudden death of these two patients.

Hinkle et al.[18] reported that 76 percent of middle-aged men studied by a 6 hour ambulatory electrocardiographic recording had one or more supraventricular premature contractions, and 62 percent had one or more ventricular premature contractions. Less than 10 percent had more than 10 ventricular or supraventricular premature contractions per 1,000 beats. In contrast, an arrhythmic episode was defined in our report as any arrhythmia occurring *or* recurring during a week's time. Our impression is that cardiac allograft recipients have a quantitatively higher rate of recurring arrhythmias, particularly in the first 3 months after transplantation.

In conclusion, cardiac arrhythmias are common in the transplanted denervated human cardiac allograft. Local injury secondary to acute rejection may be an important pathogenetic factor. Lack of the normal "suppressant" vagal tone or hypersensitivity to catecholamines, or both, may contribute to this high prevalence rate. Preliminary observations suggest that these arrhythmias may be treated successfully with antiarrhythmic drugs, cardioversion or treatment of the underlying rejection episode. These data suggest that autonomic neural control of the heart is not necessary for production of cardiac arrhythmias, including ventricular fibrillation resulting in sudden death.

Criteria for Electrocardiographic Differentiation of Right Ventricular Hypertrophy from True Posterior Myocardial Infarction

P. MANOHAR KINI, MD, FACC
HUBERT V. PIPBERGER, MD, FACC

Washington, D.C.

Electrocardiograms recorded from patients with true posterior myocardial infarction show an abnormal anterior shift in the QRS forces. Differentiation of these records from those of right ventricular hypertrophy has been recognized as a difficult problem for a long time. An attempt was made to establish criteria for separating electrocardiograms of posterior myocardial infarction from those of right ventricular hypertrophy exhibiting a similar pattern. Frank lead electrocardiograms obtained from 81 patients with posterior myocardial infarction were compared with electrocardiograms recorded from 71 patients with right ventricular hypertrophy.

With two measurements that can be easily obtained, 70 percent of the posterior myocardial infarction records were classified correctly with 15 percent of the right ventricular hypertrophy records being misclassified. A set of three measurements for right ventricular hypertrophy correctly identified 55 percent of cases of right ventricular hypertrophy; however, 13 percent of the posterior myocardial infarction records were misclassified as right ventricular hypertrophy.

With seven measurements obtained on the basis of multivariate analysis, 78 percent of the posterior myocardial infarction and 79 percent of right ventricular hypertrophy cases were correctly classified. These measurements were found to be useful in classifying records that could not be categorized by hand measurements. Classification procedures were also tested in 23 autopsy cases with results equal to or slightly better than those obtained in clinical samples.

Several measurements on the QRS vector loop previously considered useful in the differentiation of right ventricular hypertrophy from posterior myocardial infarction gave disappointing results when tested in our samples.

Electrocardiographic and vectorcardiographic changes that occur as a result of true posterior myocardial infarction closely resemble those caused by right ventricular hypertrophy. True posterior infarction, also referred to as high posterior, strictly posterior or posterobasal infarction, involves the posterior aspect of the left ventricle just beneath the atrioventricular groove. Both posterior myocardial infarction and right ventricular hypertrophy are associated with an abnormal increase in anterior electromotive forces manifested in the Frank lead electrocardiogram by a prominent Q wave in lead Z and an abnormally increased Q/R amplitude ratio in that lead. In the 12 lead electrocardiogram an abnormally tall R wave in leads V_1 and V_2 with an R/S ratio greater than 1 occurs in true posterior myocardial infarction as well as in right ventricular hypertrophy. Differentiation of the

two conditions from an electrocardiographic tracing when no clinical data are available is difficult and often impossible. To our knowledge there has been only one quantitative investigation performed so far with the purpose of improving the differentiation. Mathur and Levine,[1] in an attempt to search for the best discriminators between the two conditions, measured several scalar and vectorial parameters of the Frank vectorcardiogram in 203 patients with right ventricular hypertrophy and 85 patients with posterior myocardial infarction. Using three angular and one amplitude measurements, they were able to identify correctly 80 to 90 percent of the cases in each group.

In view of the importance of the differentiation of right ventricular hypertrophy from posterior myocardial infarction in clinical and epidemiologic studies, we considered that another quantitative investigation of this problem was justified. In this study we attempted to define simple criteria that could be used in day to day reading of the Frank lead electrocardiogram and to provide a separate set of criteria for differentiating the two groups by using the more complex statistical technique of multivariate analysis. We also tried to separate the two groups with use of the criteria proposed by Mathur and Levine.[1]

Material and Methods

Electrocardiograms were selected from a large library of taped records obtained during a cooperative study conducted at eight Veterans Administration hospitals. All recordings were made on frequency modulation magnetic tape, using Frank's corrected orthogonal lead system. Tracings were processed by a Control Data Corporation 3200 computer. The recording technique and computer methods have been previously described.[2]

For this study, electrocardiograms were selected on the basis of two measurements: (1) a Q/R ratio in lead Z exceeding 1.21, or (2) a Q wave amplitude in lead Z greater than 0.93 mv, or both. These measurements were previously found to be upper limits of 96th percentile ranges for normal subjects,[3] and electrocardiograms exceeding these measurements were considered to show an abnormal increase in anterior forces or a decrease in posterior forces.

Case material: From a total of 857 cases of myocardial infarction,[4] 81 were selected for study because they satisfied the criteria cited, probably as a result of a decrease in posterior forces caused by true posterior myocardial infarction. All patients had an unequivocal prior or recent history of myocardial infarction. The presence of previous infarction was confirmed by a review of records of previous hospital admissions and electrocardiograms, and serial examinations of serum enzymes such as glutamic oxaloacetic transaminase and creatine phosphokinase. Cases were not excluded from study because of electrocardiographic evidence of infarction in more than one location.

Records of patients with chronic pulmonary emphysema (843 cases) and mitral stenosis (121 cases) formed the right ventricular hypertrophy group. The clinical diagnosis of emphysema was confirmed by radiologic examination or pulmonary function tests, or both. In 77 patients with mitral stenosis the clinical diagnosis was supplemented by cardiac catheterization data. Of the total 964 records, 71 (63 with pulmonary emphysema and 8 with mitral stenosis) were found to satisfy the criteria cited. These cases were used for comparison with the cases of posterior myocardial infarction showing a similar QRS pattern. In both groups, electrocardiograms with QRS prolongation of 0.126 second or more indicating ventricular conduction defects were excluded from the study. The mean age was 58 ± 14 years for the patients with posterior myocardial infarction and 56 ± 12 years for those with right ventricular hypertrophy.

Diagnostic criteria: Two different sets of diagnostic criteria were chosen to separate the two groups of records. The first set consisted of relatively simple measurements that could easily be obtained by hand from a standard orthogonal electrocardiogram. Practically all simple scalar and vectorial measurements used in routine electrocardiographic interpretation were tested by the following method: 96th percentile ranges were computed for all of these measurements for both groups, and the number of cases in one group outside the 96th percentile range of the other was determined for each measurement. Measurements that separated the maximal number of cases of one group from the other were selected as the best criteria for discrimination between the groups.

The second set of criteria was selected strictly for multivariate analysis in which a group of measurements is used simultaneously in the form of so-called patient vectors. More than 300 different measurements comprising practically all spatial and scalar parameters that have been proposed for electrocardiographic analysis were computed originally for each record. Measurements that were potentially good discriminators between groups were identified by comparing the 96th percentile ranges in the cases of posterior myocardial infarction and right ventricular hypertrophy. With use of this method, 42 candidate measurements were found to be of use in separating the groups. Previous experience had shown, however, that too large a number of measurements leads to overly optimistic results which cannot be duplicated on new and independent case material. Cornfield[5] has suggested that this number should not exceed 1/20th of the number of cases under study. Since the total number of records in our investigation was 152, a maximum of seven measurements could be used if the resulting percentages of correct classification were to be reproducible on independent test tracings.

To reduce the 42 candidate measurements to the optimal number of 7, a sequential stepdown procedure[6] was utilized. At first, a mean vector was computed for each group with use of all 42 measurements. The measurement that contributed the least amount to the multivariate distance between the two groups was determined, then eliminated, and the discriminant function recomputed using the remaining 41 measurements. At the next stage, the least important of the 41 measurements was eliminated. This procedure was continued until the seven most important measurements were found. These seven measurements were then used to compute posterior probabilities in the manner described previously for electrocardiographic analysis at our laboratory[7]:

$$P(RVH|x) = \frac{g \cdot f\ (x|RVH)}{g \cdot f(x|RVH) + h \cdot f(x|PMI)} \qquad (1)$$

where x is the vector of 7 measurements, g is the prior probability of right ventricular hypertrophy, h is the prior probability of posterior myocardial infarction, $f(x|\ RVH)$ and $f(x|\ PMI)$ are the probability density functions of the vector x within the populations of right ventricular hypertrophy and posterior myocardial infarction, respectively.

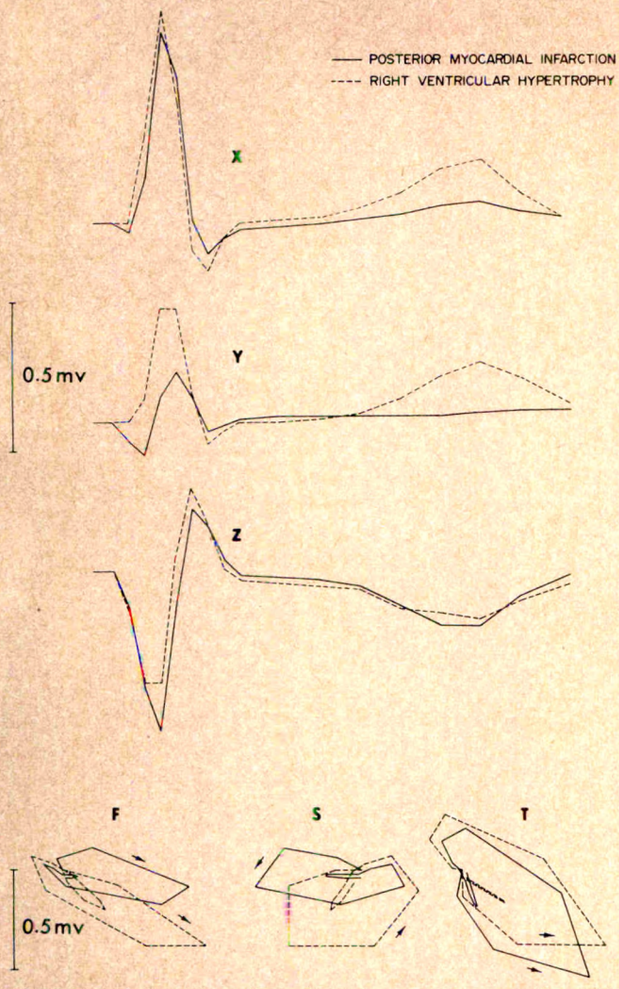

FIGURE 1. Averaged scalar leads and vector loops based on 81 records of posterior myocardial infarction and 71 records of right ventricular hypertrophy. QRS and ST–T complexes were normalized for time by dividing the duration of each into eight equal parts. Note the prominent Q wave in lead Y and the superior displacement of the initial QRS forces in the frontal and sagittal planes of the posterior myocardial infarction cases. The T loop in posterior myocardial infarction is more anterior and superior than in right ventricular hypertrophy. F = frontal; S = sagittal; T = transverse.

The posterior probability for posterior myocardial infarction is then

$$P(PMI|x) = 1 - P(RVH|x) \qquad (2)$$

Equal prior probabilities were assigned to right ventricular hypertrophy and posterior myocardial infarction in this analysis. Each individual record was classified into the category for which its posterior probability was greatest.

In addition to using the above procedure, we tried separation of the two groups by using the measurements suggested by Mathur and Levine[1] for differentiation of right ventricular hypertrophy and posterior myocardial infarction. The criteria were:

1. Direction of the mean QRS axis (half area axis) in the frontal plane.
2. Direction of the mean QRS axis (half area axis) in the transverse plane.
3. Direction of the 0.04 second instantaneous vector in the transverse plane.
4. Magnitude of the terminal rightward force.
5. Direction of inscription of the loop in the transverse plane.

The method for determining half area vectors has been described previously.[8] It should be emphasized that the measurements in the present study were made by computer from scalar Frank electrocardiographic tracings, whereas Mathur and Levine measured the different parameters visually from frontal and horizontal plane loops.

Autopsy cases: Detailed autopsy information and electrocardiograms were available for an independent sample of 449 patients. Of these, 336 had myocardial infarction at autopsy, 70 had mitral stenosis and 43 had pulmonary emphysema. From the total of 449 records, 23 were selected for analysis because they had a prominent Q wave in lead Z with an abnormal Q/R_z ratio. Of these cases, 14 had postmortem evidence of right ventricular hypertrophy with the right ventricular wall thickness exceeding 4 mm, and 8 had infarction involving the posterobasal part of the left ventricle. One patient with chronic obstructive lung disease and coronary artery disease had, at autopsy, marked right ventricular hypertrophy as well as a large posterior myocardial infarction. The 23 records were subjected to analysis by sets of measurements already obtained from the clinically diagnosed cases and were classified as showing either right ventricular hypertrophy or posterior myocardial infarction.

Frank vs. conventional electrocardiogram: Twelve lead electrocardiograms were available for comparison with results obtained on the Frank lead electrocardiogram in only a few cases. Of the 30 conventional electrocardiograms obtained in cases of myocardial infarction, only 20 satisfied the generally accepted criteria for true posterior infarction.[9] Of 17 electrocardiograms obtained in cases of right ventricular hypertrophy, only 8 had an abnormal R/S ratio in the right precordial leads. These findings suggest that in comparison with the V leads of the 12 lead electrocardiogram, the Z lead of the Frank electrocardiogram is more sensitive in recognizing an increase in anterior forces. The total number of cases manifesting abnormal anterior forces in the 12 lead electrocardiogram was too small to permit performance of any meaningful analysis to differentiate between right ventricular hypertrophy and posterior myocardial infarction.

Results

Electrocardiographic and vectorcardiographic configuration: Mean QRS and ST–T configurations of the scalar X, Y and Z leads and the vector loop projections in the frontal, left sagittal and transverse planes are shown in Figure 1. These means were derived from 81 cases of posterior myocardial infarction and 71 cases of right ventricular hypertrophy. The QRS duration and the time interval from the end of the QRS interval to the end of T wave were each normalized in time by being divided into eight equal parts. The means of each eighth were calculated and then used for drawing the averaged scalar and vector loops.

The differences between the two groups are strikingly apparent in lead Y in which the patients with posterior myocardial infarction manifest a significantly larger Q wave and an R wave that is distinctly smaller than in cases of right ventricular hypertro-

phy. The T wave amplitude in leads X and Y is considerably reduced in posterior myocardial infarction. In lead X, the S wave is more prominent in cases of right ventricular hypertrophy and the T wave more upright compared to findings in the records of posterior myocardial infarction. The averaged Z lead is similar in configuration in the two groups of records.

Differences in loop configurations correspond to their scalar counterparts. The QRS loop in posterior myocardial infarction is smaller, and its initial forces show a more superior disposition in the frontal and sagittal planes, when compared to the loop in right ventricular hypertrophy. There is some rightward displacement of the terminal part of the front plane QRS loops in right ventricular hypertrophy. Also noteworthy is the almost identical appearance of the QRS loops in the transverse plane in both groups. The rotation of the averaged QRS loops in all the three planes is similar in both groups. The T loop in posterior myocardial infarction is more superior and anterior than in right ventricular hypertrophy.

Measurements on routine orthogonal electrocardiograms: Of the several simple measurements used to separate the two groups, a Q/R ratio greater than 0.25 in lead Y proved to be the most useful. By use of this criterion, 51 percent of the cases of posterior myocardial infarction were correctly classified, but 8 percent of records in cases of right ventricular hypertrophy were misclassified as posterior myocardial infarction (Table I). The addition of a T wave measurement—namely, maximal T vector angle in the transverse plane between 90° and 180°—further increased recognition of posterior myocardial infarction to 70 percent with 15 percent of right ventricular hypertrophy cases being misclassified as posterior myocardial infarction. Only records that were not separated by the first criterion were subjected to analysis by the second to make the classification cumulative. The QRS criterion in lead Y is based on inferior wall involvement that frequently occurs in association with true posterior myocardial infarction. Use of this measurement does not permit classification of records that show an increase in anterior forces without abnormalities in the Y lead.

Several measurements were again tested in an attempt to identify the right ventricular hypertrophy records. The set of three measurements shown in Table I leads to recognition of 55 percent of the right ventricular hypertrophy records with 13 percent of the posterior myocardial infarction cases misdiagnosed as right ventricular hypertrophy. Many other scalar and vector parameters, including amplitudes, durations, angles and ST–T measurements, did not improve separation of the two groups, either because of their low sensitivity or the high rates of misclassification. Fifteen electrocardiograms (nine of posterior myocardial infarction and six of right ventricular hypertrophy) satisfied one or more criteria for both right ventricular hypertrophy and posterior myocardial infarction, and these records were not considered classifiable by the proposed measurements.

* Measurements labeled 1/8, 2/8, and so on are amplitudes derived from time-normalized QRS complexes, obtained by dividing these complexes into eight equal parts. All measurements represent amplitudes expressed in millivolts.

SD = standard deviation.

Classification by multivariate analysis: The seven best measurements obtained for multivariate analysis are listed in Table II with means and standard deviations for each group. With use of these measurements, 78 percent of cases of posterior myocardial infarction and 79 percent of the cases of right ventricular hypertrophy were correctly classified (Table III). The error rate of classification was nearly equal for both categories.

Measurements of QRS loops: Results of classification using the criteria proposed by Mathur and

TABLE III

Results of Multivariate Classification of Cases of Posterior Myocardial Infarction and Right Ventricular Hypertrophy

	Posterior Myocardial Infarction (%)	Right Ventricular Hypertrophy (%)
Posterior myocardial infarction (81 cases)	78	22
Right ventricular hypertrophy (71 cases)	21	79

Levine[1] were disappointing. Either the rate of recognition was poor or the misclassification rates were unacceptably high. The most efficient discriminator was the direction of the mean QRS vector in the frontal plane, but only 17 percent of cases of right ventricular hypertrophy could be separated from cases of posterior myocardial infarction with the criterion suggested by these investigators. Clockwise rotation of the QRS loop in the transverse plane was observed in 20 cases (28 percent) of right ventricular hypertrophy and 14 cases (17 percent) of posterior myocardial infarction.

Autopsy data: Six of the eight cases of posterior myocardial infarction (75 percent) were correctly classified by hand measurements for posterior myocardial infarction; the hand measurements for right ventricular hypertrophy diagnosed correctly 8 of the 14 cases of right ventricular hypertrophy (57 percent). The case with combined right ventricular hypertrophy and posterior myocardial infarction satisfied hand measurements for posterior myocardial infarction. When the criteria obtained by multivariate analysis were used, the computer correctly classified 77 percent of cases of right ventricular hypertrophy and 88 percent of cases of posterior myocardial infarction. The single case that had both abnormalities was diagnosed as posterior myocardial infarction with a probability slightly higher than that for right ventricular hypertrophy. The small number of cases makes meaningful conclusions on the basis of these results difficult. However, the high percentage of correct diagnoses tends to confirm the reliability of the criteria used for classification.

Discussion

Many criteria have been proposed and used for the diagnosis of right ventricular hypertrophy in the electrocardiogram and vectorcardiogram.[10–14] Several investigators[9,15–19] have also reported on the electrocardiographic and vectorcardiographic features of posterior myocardial infarction. However, the available studies have not sufficiently stressed that differentiation of the two conditions can be difficult or even impossible in the presence of increased anterior forces.

In right ventricular hypertrophy, the initial anteriorly directed forces are usually enlarged by the increasing muscle mass of the right ventricle, which is located more anteriorly. In infarction of the posterior wall of the left ventricle, the anterior forces, being unopposed, lead to the same effect. If the right ventricular hypertrophy is sufficient to cause a marked shift of the frontal plane mean QRS axis to the right and rotate the entire QRS loop clockwise in the transverse plane, no difficulty is usually experienced in distinguishing this lesion from posterior myocardial infarction. However, moderate degrees of right ventricular hypertrophy often result in insignificant rightward deviation of the frontal plane axis and yet may shift the major part of the QRS axis anteriorly in the transverse plane without reversing the rotation. In such cases, differentiation from posterior myocardial infarction on the basis of the electrocardiogram or vectorcardiogram becomes difficult. Furthermore, since the condition of older patients is often complicated by emphysema, clinical findings may be of insufficient help in the differentiation.

The best diagnostic criteria in the Frank leads: Our data show that use of a simple QRS measurement from an orthogonal electrocardiogram permitted recognition of 51 percent of cases of posterior myocardial infarction with misclassification of 1 in 12 cases of right ventricular hypertrophy. The most useful criterion proved to be the Q/R ratio of more than 0.25 in lead Y. This ratio has been used in our laboratory for the diagnosis of posterodiaphragmatic infarction.[20] Thus, 51 percent of the cases of posterior myocardial infarction in our series had electrocardiographic evidence of inferior myocardial infarction. Since both the posterior and diaphragmatic surfaces of the heart receive their blood supply from the right coronary artery, simultaneous infarction of both areas is common, as others[15,17,19] have noted. Simple QRS measurements obtained by visual observation of an electrocardiogram fail to differentiate between right ventricular hypertrophy and posterior myocardial infarction when there is no evidence of associated involvement of the inferior wall in the latter.

In posterior infarction the T loop tends to be directed anteriorly especially in cases of acute infarction. With increasing right ventricular hypertrophy, the T loop is displaced posteriorly. The use of a single angular measurement of the T loop improved separation of cases of posterior myocardial infarction from cases of right ventricular hypertrophy. However, measurements based on the T loop are less reliable than QRS criteria, and the results may not always be reproducible in independent test samples.

The use of criteria for right ventricular hypertrophy permitted diagnosis of 55 percent of all cases of right ventricular hypertrophy with the misclassification of 13 percent of cases of posterior myocardial infarction as right ventricular hypertrophy. This classification rate is poor, but this was the best separation that could be obtained after testing several criteria. Failure to achieve a better rate of separation only emphasizes the inherent difficulty in electrocardiographic differentiation of right ventricular hypertro-

phy from posterior myocardial infarction in the population studied.

Multivariate analysis: The use of seven measurements obtained by sequential stepdown procedure enabled us to correctly identify almost 80 percent of the cases in both groups. To confirm the reliability of the results of multivariate analysis, we tested these measurements in 37 of the 81 cases of posterior myocardial infarction that we were unable to classify with use of simple QRS hand measurements. These records did not have an abnormal Q/R ratio in lead Y. Use of the computer classification method permitted correct identification of 67 percent of cases of posterior myocardial infarction. This finding confirms the high efficiency of criteria obtained by multivariate analysis in the separation of the two diagnostic categories. The high percentage of correct classification of the autopsy cases, although based on small numbers, also attests to the reliability of these criteria.

Vector loop criteria: The criteria found by Mathur and Levine[1] to be helpful in the differentiation of right ventricular hypertrophy from posterior myocardial infarction gave disappointing results when applied to our subjects. This discrepancy may be attributed to differences in the two patient groups with right ventricular hypertrophy. Their cases of right ventricular hypertrophy included several patients with congenital heart disease and mitral stenosis. Patients with pulmonary emphysema formed 14 percent of their total right ventricular hypertrophy group and 89 percent of our group.

Clinical implications: Differentiation of right ventricular hypertrophy from posterior myocardial infarction becomes clinically important only in older patients who may have coronary artery disease or pulmonary emphysema, or both. An adequate clinical history may not always be obtainable in these patients. Our study is based on adult male subjects of comparable age groups in whom clinical differentiation of right ventricular hypertrophy and posterior myocardial infarction is frequently impossible in the presence of electrocardiographic changes compatible with both conditions. We believe that our criteria will be more realistic in clinical situations in which discrimination between right ventricular hypertrophy and posterior myocardial infarction is a real problem in diagnosis.

Comparative Prevalence of the Fourth Heart Sound in Hypertensive and Matched Normal Persons

MICHAEL SWISTAK, BS
HARRY MUSHLIN, MD
DAVID H. SPODICK, MD, FACC

Boston, Massachusetts

Occurrence of the fourth heart sound (S_4) as a physiologic phenomenon would limit its usefulness as a discriminator of disease. Reports of a high prevalence rate of S_4, as determined by auscultation and by phonocardiography in normal older persons, have provoked support and rebuttal. A blind, randomized phonocardiographic study of 50 normal and 50 age- and sex-matched hypertensive persons (mean age 53.9 ± 6.6 years) drawn from an outpatient screening clinic showed a high and virtually equal prevalence of S_4 (35 instances in each group) or possible S_4 (3 and 5 cases, respectively). It appears that in middle-aged persons, as in older persons, there is a high and equal prevalence rate of S_4. Quantitative studies appear to be indicated to determine when this sound can be considered a presystolic gallop.

Auscultatory or graphic evidence of a distinct "atrial," or fourth, heart sound (S_4) has been uniformly considered a sign of ventricular abnormality.[1–4] Recently, this view was challenged in epidemiologic studies utilizing controlled protocols. These demonstrated in both normal and abnormal older subjects a 70 to 75 percent prevalence rate of S_4, as determined by blind auscultation plus phonocardiography[5,6] and also, in larger groups, by blindly interpreted phonocardiograms.[7,8] This unexpectedly high and unexpectedly equal prevalence rate is indirectly supported by the laboratory studies of other investigators[9] and by certain clinical experience.[10] Moreover, the occurrence of S_4 as a normal phenomenon in older persons appears to explain the finding in aortic stenosis that the presence of an S_4 correlates reliably with the severity of the lesion up to age 40 but thereafter is lost as a discriminator.[11]

The elaborately blinded protocols of the epidemiologic S_4 investigations[5–8] should have eliminated bias in the results. These studies demonstrated that the auscultators were not deceived by the relative amplitude of S_4 (S_4/S_1 ratio), by phonocardiographically split high frequency components of the first heart sound (S_1) or by a large low frequency component of S_1.[5,6] Any subaudible presystolic pulsations should have been eliminated or sharply attenuated by the frequency range utilized (35 to 70 Hz). Moreover, the microphone in these studies was positioned between the apex and the left sternal border to avoid the low frequency vibrations corresponding to chest wall displacement during the apical *A* wave.[12] Nevertheless, although no other blind investigations have been reported, the common finding of S_4 as a physiologic event has been both challenged[4,13] and supported[10] by expert observers in carefully reasoned, authoritative analyses of experience with this phenomenon and its auscultatory and graphic documentation.

Because of the controversy and the evident importance of the issue of the "atrial" sound as a sign of cardiac abnormality, we investigated the phonocardiographic prevalence of S_4 in a different, somewhat younger, patient population using different technical equipment (al-

though in the same filter range) and a different protocol for assigning patients but equally stringent blinding of observers. The previous investigations covered from 122 to 250 consecutively studied 50 to 80 year old normal persons and patients with a variety of cardiovascular disorders.[5–8] This investigation involves 41 to 65 year old normal persons matched by sex and age with ambulatory hypertensive subjects. The ambulatory status of both groups implies better cardiovascular function than in hospitalized groups (and thus a reduced prevalence of abnormal heart sounds). Hypertensive subjects were studied because this group is expected to have a high prevalence rate of S_4.[10,14,15]

Male	53.5 ± 6.83	19	1	5
Female	54.3 ± 6.50	16	4	5
Total	...	35	5	10

Material and Methods

We investigated 100 subjects aged 41 to 65 years drawn from 530 consecutively recorded individuals on a predetermined basis: After exclusion of patients with evidence of myocardial or valvular disease, 50 patients with sinus rhythm whose brachial arterial pressure was 150/90 mm Hg or greater were matched by sex and by age with an equal number of normotensive subjects who had no evidence of cardiovascular abnormality by history, physical examination, 12 lead electrocardiogram or chest roentgenogram. Phonocardiograms were registered on a Siemens (Elema-Schönander) Cardirex recorder in the filter ranges 35 and 70 Hz, using an EMT 25B microphone that was positioned well away from the apex (between the apex and the left sternal border but somewhat closer to the latter).

No clinical data were revealed until all phonocardiograms were studied in random order and all results tabulated. S_4 was defined as distinct low frequency vibrations consistently following every P wave and preceding the QRS complex of the electrocardiogram (Fig. 1 and 2). Thus, phonocardiograms were scored "S_4–yes," "no" or "maybe" without knowledge of the patient's status. (Because of thicker base lines the "maybe" category was included for less distinct vibrations). The diagnostic data were independently scored "yes" or "no" for hypertension without knowledge of the phonocardiographic data. The results were then matched.

Results

Table I summarizes the results. When the blinding code was broken, 35 (70 percent) of the 50 hypertensive patients and the identical proportion of the 50 normal subjects had scores of "S_4–yes." Phonocardiograms in five hypertensive and three normal subjects were judged as "S_4–maybe" (Fig. 1 and 2). Insignificant sex differences are apparent in the table. The mean age for all subjects was 53.9 ± 6.62 years.

Discussion

The presence of S_4 in at least 70 percent of this normal group and the matched hypertensive patients confirms previous data showing comparable and equal prevalence of S_4 in a somewhat older (50 to 80 years) population of normal subjects and patients with mixed (mainly coronary) cardiovascular abnormalities.[5–8] Registration of S_4 by phonocardiogram does not prove its audibility. Yet the exact significance of the audible S_4 in older persons has also been questioned[5,6,9,10] although there is general agreement that a very loud "atrial" sound correlates well with ventricular overloading.[4,10] (The exact loudness of this sound would be a subject for quantitative studies: If the mere presence of S_4 can be normal in older persons, when does it become a presystolic gallop?). In this investigation, care was taken to ensure elimination or attenuation of low frequency precordial movements associated with the presystolic left ventricular *A* wave by placing the microphone well away from the apex, keeping the patient supine (thus avoiding the left lateral decubitus) and utilizing a low frequency filter cutoff of 35 Hz. We did not record an apex cardiogram[16] because (1) the criteria used to identify the timing of S_4 have proved sufficient[5,8,10] (that is, no other event is being registered), and (2) the *A* wave of the apex cardiogram merely indicates a presystolic precordial movement approximately synchronous with a left ventricular S_4.

The results of our study suggest that (1) S_4 is as common in middle age as it is in old age, and therefore its presence is not in itself a sign of cardiovascular abnormality; and (2) phonocardiographic and further auscultatory studies of S_4 may be desirable to elucidate any quantitative characteristics that distinguish the S_4 gallop from the normal S_4.

Sinus Nodal Reentry

Effect of Quinidine

KARLEN L. PAULAY, MD
GERALD M. WEISFOGEL, MD
ANTHONY N. DAMATO, MD

Staten Island, New York

The recently developed experimental model for sinus nodal reentry was used to assess the effect of quinidine in 20 dogs. Sinus nodal reentry was demonstrated in 19 dogs and was abolished in all dogs when plasma levels of quinidine (average 4.8 mg/liter) were in the therapeutic range after an average infusion time of 7 minutes. Characteristically in 15 dogs, quinidine increased atrial refractoriness and slowed atrial conduction so that the arrival time of the atrial premature beat (A_2) in the region of the sinus node fell outside the reentry zone and sinus nodal reentry was terminated. Conduction delay along the reentrant pathway preceded loss of sinus nodal reentry in 6 of these 15 dogs, thereby suggesting that quinidine-induced conduction delay and block along the reentrant pathway may be another mechanism for abolishing sinus nodal reentry. In the four remaining dogs in which sinus nodal reentry was abolished when the premature beat continued to fall within the reentry zone, the latter mechanism seems likely.

An experimental model for demonstrating sinus nodal reentry in the dog has recently been developed in our laboratory.[1,2] In this model a closely coupled premature atrial beat, A_2, introduced at either the tip of the right or left atrial appendage or the coronary sinus region is followed within 100 to 300 msec by an accelerated beat, A_3, that is consistent with a sinus nodal reentrant beat for the following reasons: (1) Both the atrial activation sequence and P wave configuration of A_3 and the spontaneous sinus beats are similar; (2) the occurrence of A_3 is dependent upon the arrival time of excitation of A_2 in the sinus nodal region and is *independent* of the atrial site at which A_2 is introduced; (3) A_3 can be clearly distinguished from reentry in the region of the atrioventricular (A–V) node or at the site of stimulation and, also, from sinus nodal entrance block; and (4) clamping the region of the sinus node or relatively strong vagal stimulation consistently prevents the early appearance of A_3, presumably by blocking the reentrant pathway. Somewhat similar findings on sinus nodal reentry have been reported recently by Childers et al.[3]

Because sinus nodal reentry may be the basis for some atrial tachyarrhythmias in man,[4,5] in this study we examined the effect of a commonly used antiarrhythmic drug, quinidine, on this phenomenon.

Methods

Twenty mongrel dogs weighing 9 to 23 kg were anesthetized with sodium pentobarbital, 30 mg/kg body weight intravenously. The trachea was cannulated and the animal mechanically ventilated with room air. The heart was exposed by a mid-sternal splitting incision and pericardiotomy and cradled in the pericardial sac. Both vagi were sectioned in the neck and the stellate ganglia and sympathetic chains (T_1–T_4) excised so that variability in the sinus escape time would be essentially eliminated.[2] Body temperature was monitored by a rectal temperature probe and maintained at 37 ± 1° C by an electric heating pad. Teflon®-coated bipolar plunge wire electrodes[6] were in-

serted into the regions of the sinus node, Bachmann's bundle, coronary sinus, right atrial appendage, left atrial appendage and the low atrial septum (His bundle electrogram).

Recording and stimulating techniques have recently been described.[2] In brief, basic pacing pulses were delivered to selected atrial sites (right atrial appendage, left atrial appendage and coronary sinus) at a rate of 120 to 185/min. After every 10th basic beat (A_1), a premature beat (A_2) was introduced through the same stimulating electrodes and the atrial cycle scanned at decreasing coupling intervals (10 to 20 msec decrements of A_1–A_2) until the atrial effective refractory period was reached. For each basic cycle length the sinus nodal escape time was determined by omitting A_2 after the 10th basic beat.

Definition of Terms

A_1 = the atrial depolarization of a basic atrial beat.

A_2 = the atrial depolarization of an induced atrial premature beat.

A_3, A_4, A_5 . . . = subsequent atrial beats.

A_1–A_1 = the atrial interval measured during atrial pacing.

A_1–A_2 = the coupling interval measured from the last paced beat (A_1) to the induced atrial premature beat (A_2).

A_2–A_3 = the interval measured from the induced atrial premature beat (A_2) to the subsequent atrial beat, A_3.

A_1–A_3 = the sum of the A_1–A_2 and A_2–A_3 intervals.

A_3–A_4, A_4–A_5 . . . = the intervals between atrial depolarizations subsequent to A_3.

All atrial intervals were measured from the electrogram recorded in the region of the sinus node unless otherwise stated.

S_1 = the basic beat stimulus.

S_2 = the premature beat stimulus.

Functional refractory period of the atrium = the shortest A_1–A_2 interval measured in the sinus nodal region when S_1 and S_2 are applied to a distant atrial site (right atrial appendage, left atrial appendage or coronary sinus). The functional refractory period measured in this manner is a function of the arrival time of premature atrial excitation in the sinus nodal region and is related to both atrial conduction velocity and refractoriness.

Relative refractory period of the atrium = the S_1–S_2 interval at which the delay between S_2 and the response in the sinus nodal region increases over that for the basic drive. This occurs when the S_1–S_2 interval becomes less than the A_1–A_2 interval measured in the sinus nodal region.

Effective refractory period of the atrium = the S_1–S_2 interval at which S_2 no longer is followed by a propagated atrial response.

Conduction time (CT) = the interval between activation of the left atrial appendage electrogram during left atrial appendage pacing (or right atrial appendage electrogram during right atrial appendage pacing) and the sinus nodal electrogram. CT_1 and CT_2 refer to conduction time for basic and premature beats, respectively. CT_2 after quinidine is calculated for the earliest A_2 that can be recorded in either the right or left atrial appendage. CT_2 before and after quinidine is measured for the same A_1–A_2 interval recorded at the stimulation site and at the same basic pacing rate.

Protocol

After stable sinus nodal reentry was demonstrated in 19 dogs and control electrophysiologic data were obtained, a control blood sample was collected. Quinidine gluconate was then infused intravenously at an average rate of 0.6 mg/kg per min (range 0.5 to 0.7 mg/kg per min) using a constant rate infusion pump until sinus nodal reentry was abolished. The infusion was then discontinued and a blood sample collected; postinfusion electrophysiologic data were then recorded. Another blood sample was collected when sinus nodal reentry reappeared (14 dogs). Plasma quinidine

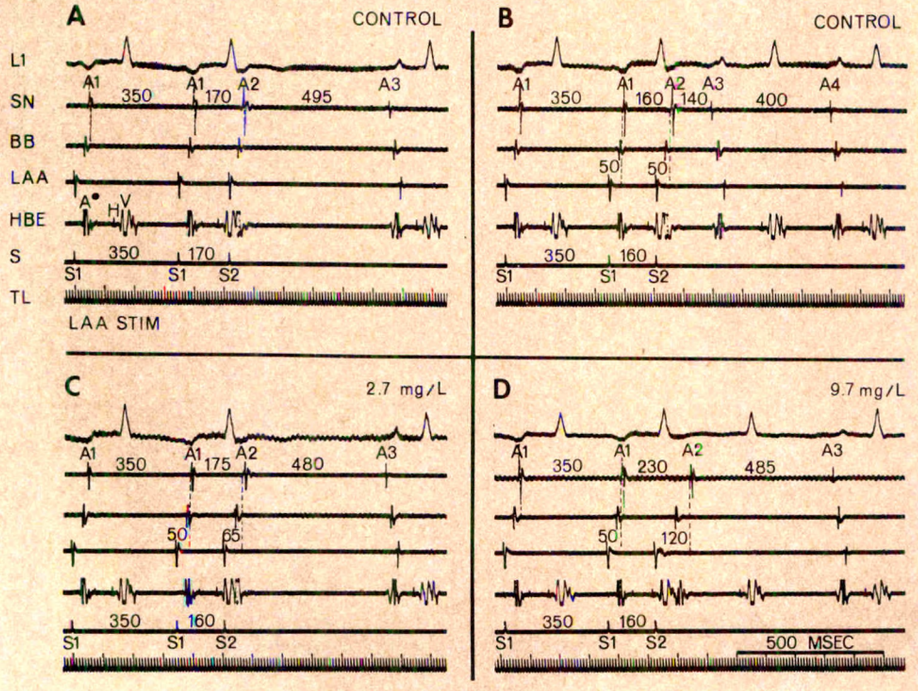

FIGURE 1. Sinus nodal reentry **(B)** during stimulation (STIM) of the left atrial appendage (LAA) and its abolition by quinidine **(C** and **D).** BB = Bachmann's bundle; HBE = His bundle electrogram recorded from the low atrial septum; L1 = standard lead I; S = stimulus for the basic (S_1) and premature (S_2) beats; SN = sinus nodal region; TL = time lines recorded at 10 and 100 msec intervals. was assayed by the photofluorometric method of Cramer and Isaksson.[7]

Results

Group A: Sinus nodal reentry could be demonstrated in 19 of the 20 dogs before quinidine. After an average infusion time of 7 minutes, quinidine abolished sinus nodal reentry in all 19 dogs. Characteristically in 15 dogs (Group A), quinidine increased atrial refractoriness and slowed atrial conduction so that the arrival time of excitation in the region of the sinus node was delayed. A_2 then fell outside the reentry zone* and sinus nodal reentry did not occur. A representative record is shown in Figure 1. In panels A to D basic and premature stimuli were applied to the left atrial appendage. In panel A, the S_1–S_2 and A_1–A_2 intervals were 170 msec and sinus suppression occurred. In panel B, the S_1–S_2 and A_1–A_2 intervals were 160 msec and sinus nodal reentry occurred. The conduction time from the left atrial appendage stimulating site to the sinus nodal region was 50 msec for both basic and premature beats. In panel C, the plasma quinidine concentration 5 minutes after the onset of infusion was 2.7 mg/liter. Although the S_1–S_2 interval was 160 msec, the A_1–A_2 interval had increased to 175 msec, and sinus nodal reentry was abolished. Atrial conduction time for the premature beat increased 15 msec, from 50 (panel B) to 65 (panel C), thus accounting for the increase in the A_1–A_2 interval. In panel C, A_2 arrived in the sinus nodal region outside the outer limit of the original reentry zone (160 msec, panel B) and sinus nodal reentry did not occur. In panel D, at the higher plasma quinidine level of 9.7 mg/liter the effect of quinidine on atrial conduction for the premature beat was even more evident and sinus nodal reentry remained absent. Typically, infusion of quinidine increased the outer limit of the original reentry zone by 5 to 20 msec (average 12 msec) before abolishing reentry.

In four dogs in Group A a progressive increase in the A_1–A_2 interval during quinidine infusion was associated with a progressive increase in the A_2–A_3 interval before sinus nodal reentry was abolished (Fig. 2). S_1–S_2 is 160 msec in panels A to C. During the control sinus nodal reentry (panel A), the A_1–A_2 interval of 155 in the sinus nodal region was 5 msec less than the S_1–S_2 interval of 160. This phenomenon was due to a so-called supernormal phase of intraatrial conduction for A_2 (between the left atrial appendage and sinus nodal region) as previously described.[8] Six minutes after the onset of infusion, the A_1–A_2 interval increased from 155 (panel A) to 170 msec (panel B), and the A_2–A_3 interval increased from 190 (panel A) to 290 msec (panel B). The change in the A_2–A_3 interval between panels A and B was gradual. In panel B, the A_1–A_3 interval of 460 was less than the basic drive escape time of 560 msec and confirmed that sinus nodal reentry was still present; that is, A_2 was not simply interpolated between the last basic drive beat and a normal sinus escape beat. Atrial conduction time for A_2 increased from 30 in panel A to 45 msec in panel B, thus accounting for the increased A_1–A_2 interval of 170. In panel C, after 8 minutes of infusion when the plasma quinidine level was 4.8 mg/liter, atrial conduction time for A_2 increased an additional 20 msec to 65, the A_1–A_2 interval in the sinus nodal region was 190, and sinus nodal reentry was abolished. The gradual increase in the A_2–A_3 interval and termination of sinus nodal reentry (abrupt increase in A_2–A_3) may represent progressive conduction delay and then block in the reentrant pathway.

In two dogs in Group A, the A_2–A_3 interval first increased as described (Fig. 2) but then unexpectedly returned toward control value during quinidine infusion before sinus nodal reentry was abolished. Possibly in these dogs an increasing proximal conduction delay allowed for more complete distal recovery[9] along the reentrant pathway, the net effect being a

* The reentry zone is the range of A_1–A_2 intervals measured in the sinus nodal region within which sinus nodal reentry occurs.[2] In this study the range averaged 15 msec, but occasionally was 45 to 55 msec in duration.

decrease in the A_2–A_3 interval. Another possibility is that when quinidine suppresses phase 4 within the sinus node, conduction improves as occurs with other automatic foci.[10]

Group B: In the remaining four dogs (Group B), sinus nodal reentry was abolished during quinidine infusion although A_2 fell *within* the original reentry zone. In these dogs a change in the A_2–A_3 interval was consistently observed during quinidine infusion before sinus nodal reentry was abolished, thereby suggesting that quinidine blocked sinus nodal reentry in these dogs by its depressant effect on conduction within the reentrant pathway.

Plasma quinidine concentration: When sinus nodal reentry was abolished, plasma quinidine concentration averaged 4.8 mg/liter (range 1.7 to 10.0 mg/liter). The plasma concentration was ≤8.0 mg/liter in 18 dogs and 10.0 mg/liter in 1 dog. Sinus nodal reentry reappeared in 14 dogs after plasma quinidine concentration had decreased to an average of 2.1 mg/liter 25 minutes (average) after quinidine infusion was stopped. In 10 of these dogs sinus nodal reentry reappeared when the outer limit of the reentry zone averaged 10 msec (range 5 to 20 msec) greater than the preinfusion value.

Electrophysiologic data: Cumulative electrophysiologic data are presented in Table I. Statistically significant increases ($P < 0.05$) occurred in all variables when sinus nodal reentry was abolished. Atrial effective, relative and functional refractory periods increased 28, 27 and 30 msec, respectively. Atrial conduction time increased 6 msec (CT_1) for the basic drive beats and 32 msec (CT_2) for the premature beat. This increase in CT_2 occurred mainly because of the increase in the relative refractory period after infusion of quinidine. Thus for the same S_1–S_2 intervals before and after quinidine, A_2 was introduced earlier in the relative refractory period after quinidine and, consequently, conduction time (CT_2) was increased. A–V conduction was minimally affected by quinidine, the A–H and H–V intervals increasing 6 and 3 msec, respectively. The duration of ventricular activation and repolarization increased 6 msec (QRS interval) and 35 msec (Q–T interval), respectively. Sinus cycle length increased (sinus rate slowed) from 453 to 521 msec.

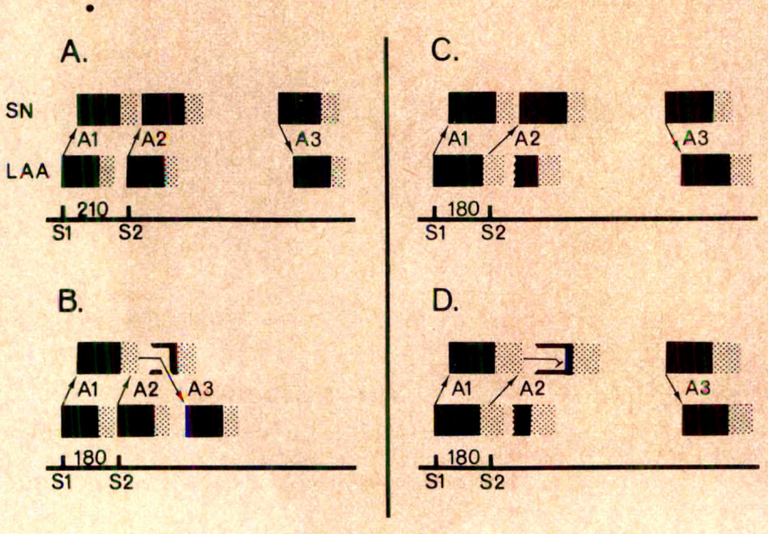

FIGURE 3. Schematic representation of conditions before administration of quinidine **(A** and **B)** and two mechanisms **(C** and **D)** that might account for the abolition of sinus nodal reentry **(B)** by quinidine. See text. Abbreviations as in Figure 1.

Hemodynamic data: When sinus nodal reentry was abolished mean arterial pressure had decreased 20 mm Hg (P <0.01) from 66 before infusion to 46 mm Hg after infusion. Preinfusion arterial hypotension resulted from opening the chest and extrinsic cardiac denervation, and occurred despite negligible (<5 cc) blood loss. Abolition of sinus nodal reentry was not considered related to a quinidine-induced decrease in arterial pressure for the following reasons: (1) in three dogs arterial pressure was restored to its preinfusion level by intravenous administration of dextran (30 to 150 cc) and sinus nodal reentry did not recur, and (2) in three dogs sinus nodal reentry was abolished when arterial pressure was unchanged from control value.

Quinidine effect when control sinus nodal reentry was absent: Sinus nodal reentry was absent before infusion of quinidine in only one dog. In this dog atrial reentry developed during quinidine infusion and appeared at times to originate from the sinus nodal region. Reentry first appeared at a toxic quinidine level of 14.0 mg/liter and was associated with an increase in the effective, relative and functional refractory periods of 60, 110 and 115 msec, respectively. The thresholds for atrial capture and conduction time were both significantly increased when compared to control values.

Discussion

The results of this study confirm our previous observations using this experimental model for the production of sinus nodal reentry and demonstrate that quinidine consistently abolished sinus nodal reentry when plasma quinidine was at a level considered to be within the therapeutic range for man.[11–14]

Schematic representation of quinidine effects on sinus nodal reentry: On the basis of the known effects of quinidine on atrial and sinoatrial tissue[10,15–20] and the results of this study, we postulate that quinidine may abolish sinus nodal reentry as schematically depicted in Figure 3. In panel A, solid and stippled rectangles correspond to effective and relative refractory periods, respectively. The total duration of refractoriness of the sinus node exceeds that of the left atrial appendage, consistent with the known disparity in refractory period duration between sinus nodal and atrial tissue.[21,22] Stimuli are applied to the left atrial appendage, and relative conduction times are depicted by arrows. When the S_1–S_2 interval is 210 msec, A_2 arrives at the sinus node outside its relative refractory period and sinus suppression occurs. A_3 represents a sinus escape beat. In panel B, at an S_1–S_2 interval of 180 msec, A_2 arrives at the sinus node within its relative refractory period and sinus nodal reentry occurs. After infusion of quinidine, atrial refractoriness is increased (panel C). As a consequence of this increase, when the S_1–S_2 interval is 180 msec, S_2 falls within relatively refractory atrial tissue and conduction time for A_2 from the left atrial appendage to the sinus nodal region is increased. If refractoriness in the sinus node is increased proportionately less than in the left atrial appendage, as shown, then A_2 will arrive at the sinus node outside its relative refractory period and sinus nodal reentry will not occur. If the S_1–S_2 interval is decreased further, the increasing latency* will prevent A_2 from arriving earlier[23] and sinus nodal reentry will remain absent. If refractoriness increases to the same degree in the sinus node and the left atrial appendage (panel D), then sinus nodal reentry will continue until conduction delay and then block occur along the reentrant pathway. The degree of change in refractoriness and conduction velocity in atrial and sinoatrial tissue during quinidine infusion determines the type of response seen.

Absence of a vagolytic effect of quinidine: Because the dogs in this study had extrinsically denervated hearts the well known vagolytic effect of quinidine[24] was not observed. Thus, the direct effect of quinidine on sinus automaticity was not opposed by the indirect vagolytic effect of quinidine, and sinus rate decreased. Presumably for the same reason, more rapid A–V nodal conduction was not observed.

Therapeutic implications: The possibility that sinus nodal reentry may be the basis for certain atrial tachyarrhythmias in man has recently been suggested.[4,5] In this study when a premature atrial beat was electrically induced, quinidine abolished the subsequent sinus nodal reentrant beat. In the absence of an induced atrial premature beat there was no sinus nodal reentrant beat. Therefore, it is reasonable to suppose that in man if sinus nodal reentrant beats (singly or in the form of a sustained tachycardia) arise after a spontaneous ectopic atrial premature beat, then quinidine might abolish sinus nodal reentry by its well known suppressive effect on ectopic atrial premature beats.[10,16] In addition, quinidine might also abolish sinus nodal reentry by delaying the arrival time at the sinus nodal region of a spontaneous ectopic atrial premature beat or by conduction block along the reentrant pathway. The last mechanism could abolish sinus nodal reentrant beats if they arise spontaneously. Of course, if sinus nodal dysfunction coexists with sinus nodal reentry then use of quinidine alone might be dangerous.

Because the effect of quinidine on sinus nodal reentry in man has not yet been reported, its effect cannot be predicted with certainty. Since vagal stimulation in the dog abolishes sinus nodal reentry,[2] the indirect vagolytic effect of quinidine in man could conceivably counteract the direct depressant effects of quinidine on sinus nodal reentry. The net effect of this interaction remains to be determined.

* In this context latency refers to the interval measured from the stimulus to the atrial electrogram recorded in the sinus nodal region.

Functional Anatomy of the Canine Left Bundle Branch

RALPH LAZZARA, MD
BILLY K. YEH, MD, PhD
PHILIP SAMET, MD, FACC

Miami Beach and Miami, Florida

To elucidate the architecture of the left bundle branch, activation of Purkinje (P) and myocardial (M) cells of the canine left ventricular endocardial surface was mapped in vitro before and after lesions were placed in the proximal left bundle branch. Close bipolar electrodes or microelectrodes were employed to record P and M potentials by standard techniques. The left bundle branch has conspicuous and straight border fibers that continue as bridging strands to the papillary muscles. In addition, there is a less conspicuous network of serpentine interwoven fibers in the interior of the septal portion of the bundle that has interconnections with the border fibers. Below the mid-septum and over the free wall the P fibers form a densely interwoven network. The interior septal fibers are activated nearly simultaneously with equidistant points on the border fibers. The apparent conduction velocity of the border fibers was 1.8 m/sec as opposed to 1.45 m/sec in the interior network. The bridging strands provide a shortcut across the chamber to upper portions of the free wall and septum. The pattern of activation of M cells is represented by concentric rings with an island of earliest activation (at 15 to 25 msec) in the central septum. The M cells latest to be activated are at the tips of the papillary muscles and the upper septum below the valves. Interruption of one group of border fibers may delay by 5 to 8 msec activation of P and M cells of the upper paraseptal free wall and upper septum. Lesions in the interior network delay by 2 to 4 msec activation of the P and M cells of comparatively small areas of the septum. Activation of the mid-papillary free walls, the bases of the papillary muscles and the lower septum is not affected by proximal lesions partially interrupting the bundle branch. Transection of both groups of border fibers does not produce complete block. The left bundle branch is best represented as a fan-shaped network of interwoven fibers whose diverging border fibers are specialized for rapid, distant transport.

It has become commonplace to represent the left bundle branch as a bifascicular structure.[1–4] This representation implies that the fibers of the left bundle branch are concentrated in two discrete channels before they are disseminated in the interconnected peripheral network. The left bundle branch has also been described as a "fan" or diverging network of interconnected fibers, currently a less popular description.[5] In a diverging network of interwoven fibers, small lesions should not delay activation over large regions, whereas in a bifascicular structure a small lesion interrupting a fascicle should delay activation of approximately half of the Purkinje network. Small lesions interrupting both fascicles near their origin should result in complete left bundle branch block.

To evaluate these opposing descriptions, we minutely traced the activation of the endocardial surface of the dog before and after interruption of various portions of the left bundle branch. For this pur-

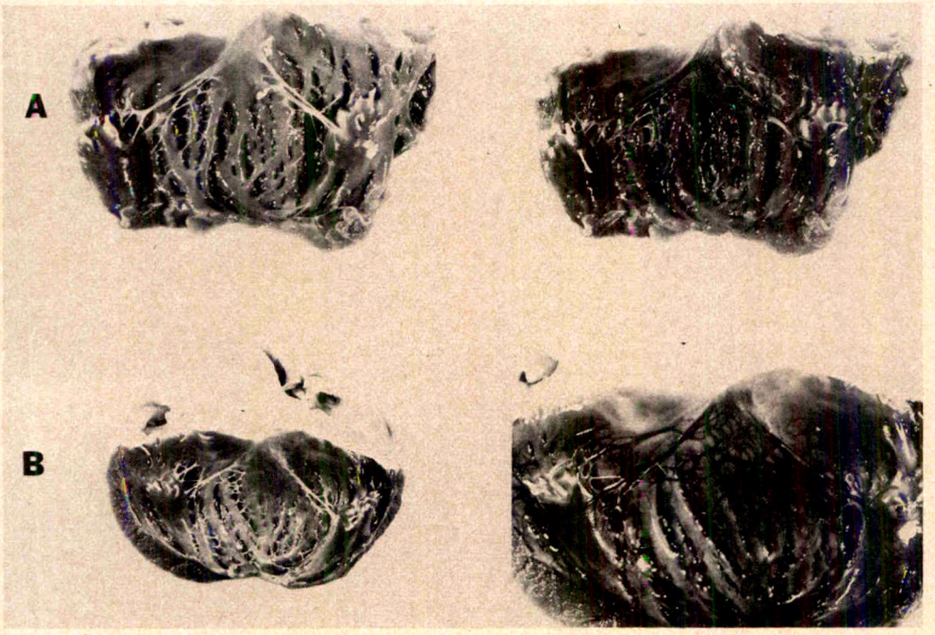

FIGURE 1. Two preparations (**A** and **B**) of the left ventricular endocardial surface unstained **(left)** and stained **(right)** with Lugol's solution. The free wall was bisected by an incision extending from base to apex. The valves and the main bundle branch are at the top, the apex at the bottom. In the unstained specimens, the relatively straight and conspicuous border fibers impart a bifascicular appearance. The interior fibers are manifest in the stained specimens.

pose we utilized recording techniques that allowed high resolution as well as discrimination between activation of Purkinje (P) and ordinary myocardial (M) cells. In other studies,[6,7] activation of subendocardial P and M cells has been mapped in some detail. However, these studies did not specifically focus on the validity of the concept of a bifascicular structure versus that of a diverging network.

Method

The entire endocardial surface of the left ventricle was included in the preparation. In 11 mongrel dogs anesthetized with pentobarbital, the heart was excised and the free wall of the left ventricle bisected by an incision extending from the base to the apex. The specimen was trimmed and pinned, endocardial surface upward, with the flaps of the bisected free wall spread flat along side the septum (Fig. 1). It was superfused with a solution held at 37°C, bubbled with 95 percent O_2 and 5 percent CO_2 and containing (in millimoles per liter): Na^+ 151.1, K^+ 4.0, Ca^{++} 1.4, Mg^{++} 2.0, Cl^- 132.3, HCO_3^- 24.0; $HPO_4^=$ 1.8 and dextrose 5.5.

Intracellular recordings were made with ultramicroelectrodes of tip resistance of 10 to 40 megohms when filled by boiling with 3M KCl. The first stage amplifier (Bioelectric NFl) had low gain (3×), high input impedance (greater than 10^{12} ohms) and negative capacitance feedback. Extracellular recordings were made with bipolar electrodes of adjacent fine, Teflon®-coated stainless steel wires (0.005 inch in diameter) led into differential amplifiers. The outputs of the preamplifiers were led into the plug-in amplifiers (Tektronix 3A74) of a dual beam oscilloscope (Tektronix 565) and photographed (Grass C4 camera). Stimulation was accomplished with a specially constructed circuit that triggered the oscilloscopic sweeps and two pulse generators (Tektronix 160 series). Radiofrequency isolation units (Bioelectric 1S2) were interposed between the pulse generators and two Teflon-coated silver wires (0.007 inch in diameter) that were in contact with the most proximal visible portion of the left bundle branch. Selective stimulation of the left bundle branch was accepted if myocardial cells closely adjacent to the bundle at the level of the stimulating electrodes were activated with a latency of at least 30 msec. The bundle was stimulated at a rate of 60/min. The activation times were essentially independent of the rate of stimulation at rates below 300/min.

A detailed drawing to scale of the preparation was made at the beginning of the experiment, and distances were measured to the nearest 100 μ with a micrometer in the eyepiece of a dissecting microscope. Each recording site was located on the drawing by means of fixed landmarks, and its distance from the stimulating electrodes was measured. For the calculation of "apparent" conduction velocity in the Purkinje system, the straight line distance from the recording to the stimulating electrodes was measured; it was recognized that this line did not necessarily indicate the true path of the impulse. In each experiment there were three fixed recording sites, two points on the anterior and posterior papillary muscles where they were joined by false chordae, and a point on the central lower septum at about the same distance from the stimulating electrode as the other two points. A fourth bipolar electrode or a microelectrode was used as a rover for detailed mapping. Incisions were made with a scalpel blade or needle tip. At least 50 separate sites on the endocardial surface were explored in each experiment. The recording sites were regularly spaced 1 to 2 mm apart over the entire surface, except in areas of the upper free walls and septum where conduction was relatively slow because Purkinje fibers were sparse. The specimens were stained with iodine (Lugol's solution) at the end of the experiment.

Results

Gross Anatomy of Left Bundle

Figure 1 shows the unstained (left side) and stained (right side) appearances of two representative specimens. In the unstained specimens, the borders of the bundle and the two groups of bridging strands to each of the papillary muscles were conspic-

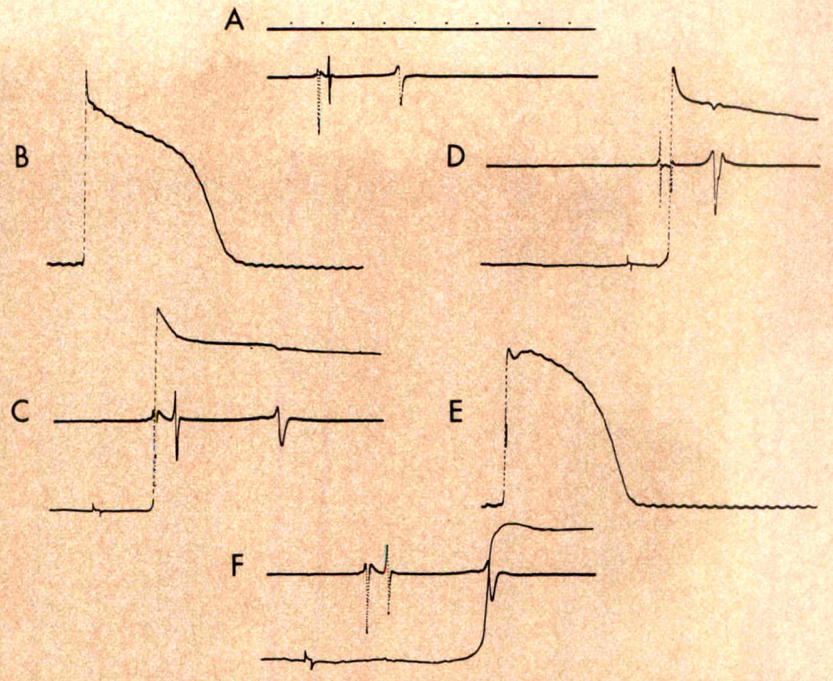

FIGURE 2. Microelectrode exploration in the immediate vicinity of a bipolar extracellular electrode. The composite electrogram recorded by the extracellular electrode **(A)** contains two early rapid components designated P deflections and a later, slower component designated M deflection. Typical P action potentials in the vicinity **(B)** had upstrokes coincident with the first **(C)** or second **(D)** rapid component of the extracellular electrogram. Typical M action potentials in the vicinity **(E)** had upstrokes coincident with the late, slower deflection **(F).** Time markings are at 10 msec intervals.

uous, imparting a bifascicular appearance. However, iodine stain invariably disclosed an interior interwoven network of serpentine fibers that had different degrees of density in different specimens. There were radial interior fibers that appeared to originate in the most proximal portion of the main left bundle branch and to connect at irregular intervals with one another and with the border fibers and the bridging strands.

The border fibers of the proximal left bundle branch pursued relatively straight paths. Approximately one fourth of the distance down the septum, border fibers departed from the endocardial surface to form free strands (false chordae) that, like suspension bridges, spanned the distance across the left ventricular cavity to the superior portions of the papillary muscles. From the points of juncture with the papillary muscles, these fibers proceeded to branch and ramify over the free walls. In many stained specimens inconspicuous fibers exterior to the prominent border fibers appeared to curl back superiorly.

Purkinje and Myocardial Cell Electrograms

P and M electrograms were usually readily distinguishable on extracellular recordings because of their different durations (Fig. 2). P electrograms were 1 to 3 msec in duration, whereas M electrograms were 6 to 10 msec in duration. Extracellular potentials attributed to P or M cells could be and frequently were verified by intracellular exploration in the vicinity of the extracellular electrodes. Verification by intracellular recording was used most often at sites where P and M deflections were close and the distinction between them was unclear (tracings 3 and 7, Fig. 3). The tracings in Figure 2 show microelectrode explo-

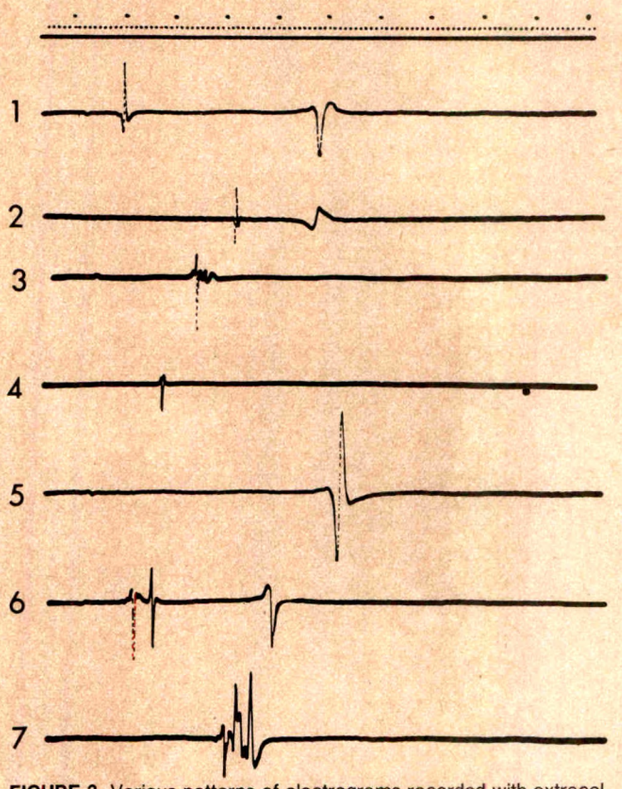

FIGURE 3. Various patterns of electrograms recorded with extracellular bipolar electrodes at different sites on the left ventricular endocardial surface. See text for description. Time markings are at intervals of 1 and 10 msec.

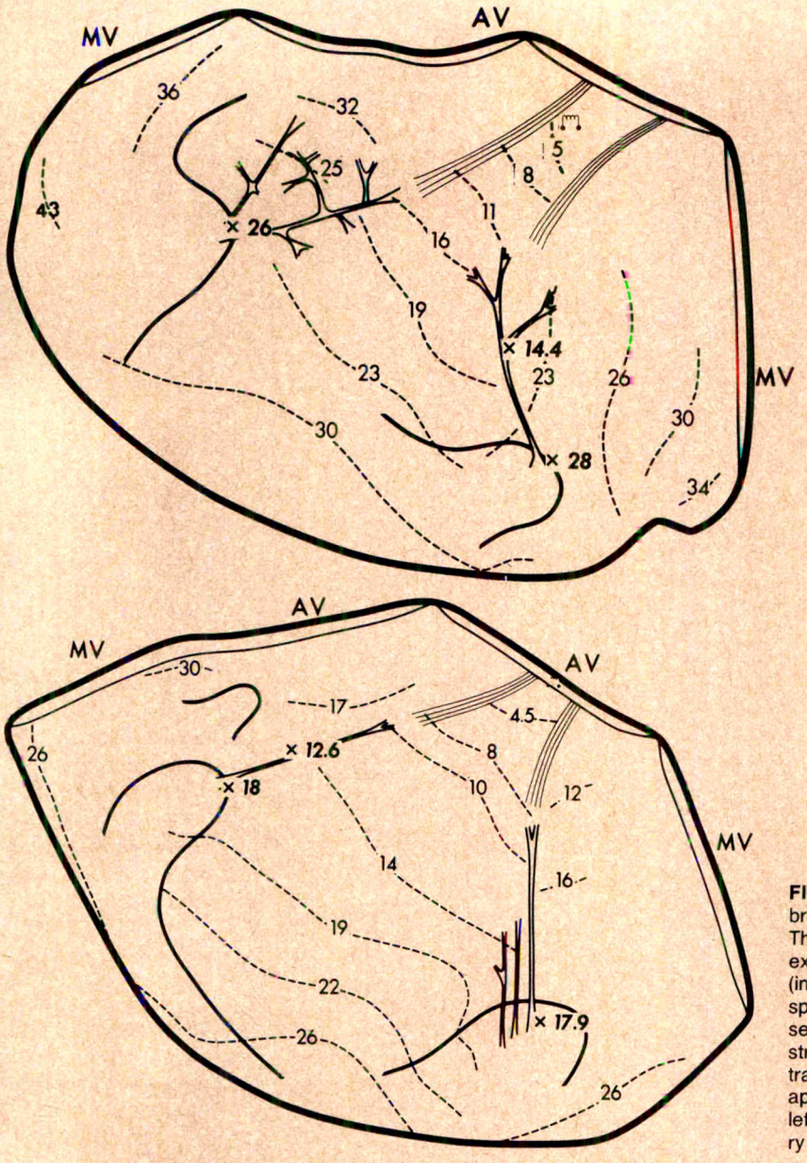

FIGURE 4. Sequences of activation of the left bundle branch Purkinje fiber (P) network in two preparations. The **dashed lines** are isochronous lines constructed exclusive of the bridging strands. The activation times (in msec) after stimulation are shown along the corresponding dashed lines. The **figures in bold type** represent activation times at sites (X) along the bridging strands and border fibers. The split aortic (AV) and mitral (MV) valves are at the top of the figure and the apex of the heart is at the bottom. The borders of the left bundle branch, the bridging strands and the papillary muscles are shown schematically.

ration in the vicinity of the bipolar electrode that recorded a composite electrogram. The first two rapid deflections in the top extracellular recording (panel A) were attributed to P cells and the third, slower deflection to M cells. Intracellular recordings in the vicinity disclosed characteristic P action potentials (panel B) with upstrokes that were coincident with either the first (panel C) or second (panel D) deflection of the electrogram but not the third. Characteristic M action potentials (panel E) were found with upstrokes coincident with the third deflection (panel F) but not the first or second. The mean maximal upstroke velocity of Purkinje fibers in these preparations was 485 ± 28 (standard deviation) v/sec.

A sample of the various patterns of electrograms encountered is illustrated in Figure 3. Tracing 1 is typical of patterns recorded near the proximal left bundle branch where P cells are activated early but underlying M cells are activated quite late. Tracing 2 is the type recorded more distally but still proximal to sites downstream where electrical continuity between P and M cells is established. Such recordings were typically obtained on the distal portions of the papillary muscles or the middle third of the septum. Tracings 3 and 7 are representative of recordings obtained at sites where electrical continuity between P amd M cells occurs. In tracing 3 the P electrogram is most prominent, and slow muscle electrograms immediately follow. In tracing 7 prominent P and M electrograms closely abut, and the distinction between them is less clear. Tracing 4 shows a pure P electrogram obtainable over bridging strands (false chordae); tracing 5 shows a pure M electrogram obtained over the upper septum outside the borders of

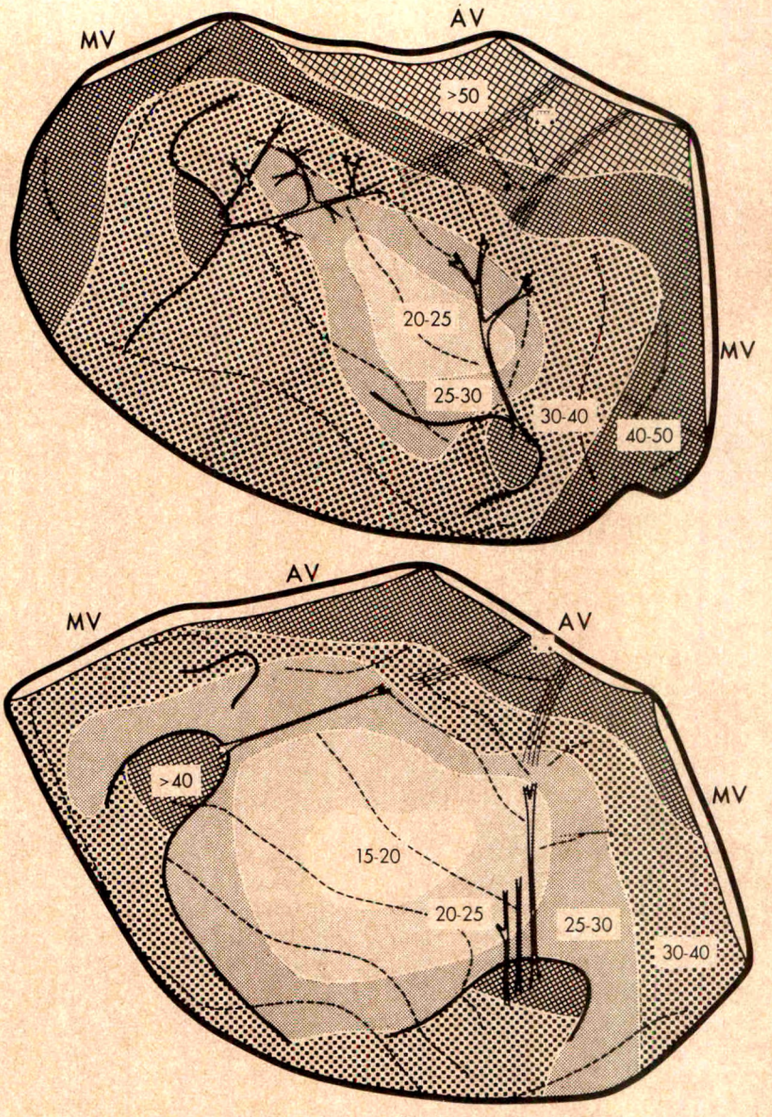

FIGURE 5. Sequential activation of subendocardial left ventricular M cells in two preparations. The corresponding sequences of P activation in the same preparations were shown in Figure 4. The numbers represent the activation times (in msec) encompassed in the areas demarcated. See legend to Figure 4.

the left bundle branch. Tracing 6 shows multiple P spikes, a pattern frequently recorded on the septum where the bridging strands originate.

The resolution of the bipolar extracellular electrode was assessed by recording electrograms with the tips of the electrodes gently touching the strand and at various distances from the strand. The amplitude of the electrogram was reduced approximately exponentially to half value at a distance of 125 μ from the strand. Comparable findings were reported in another study[8] in which similar electrodes were used. Thus, it is unlikely that activity arising more than 0.5 mm from the electrode was analyzed on the electrograms. Potentials generated by fibers at this distance from the electrodes would be reduced to about 6 percent of their value, and they would be overshadowed by potentials generated by tissues just below the recording electrodes.

Activation times of P fibers: Isochronous lines describing the wave front of activation of P cells in the left bundle branch formed arcs with slight or no central indentations. The border fibers and bridging strands were activated slightly before points in the interior network equidistant to the stimulating electrodes, but the difference was not more than a few milliseconds. Two representative samples of activation of the P fibers of the left bundle branch are depicted by means of isochronous lines in Figure 4. These isochronous lines were constructed *exclusive* of points on the bridging strands. Apparent conduction velocities for P activation could be calculated from each of the many recording sites since each site was a datum point associated with a time and a distance from the stimulating electrodes. In each experiment mean values were calculated from 5 to 10 points along each set of border fibers and from 10 to 20

points at various distances within the interior network. Calculated from seven preparations, the mean apparent conduction velocity in the interior network was 1.43 ± 0.09 (mean ± standard error) m/sec, whereas the apparent conduction velocity along the relatively straight border fibers and bridging strands was 1.73 ± 0.09 m/sec. Analyzed separately, the bridging strands themselves had a higher mean conduction velocity—2.09 ± 0.08 m/sec. The values are all significantly different from one another ($P < 0.02$). Activation of the fibers exterior to the border fibers was later than equidistant points in the interior. The exterior fibers often appeared to turn back upward (Fig. 4). The upper septum outside the borders of the left bundle branch contained no P fibers. P fibers were relatively sparse in the uppermost portions of the free walls and the distal portions of the papillary muscles; they were most abundant in the lower half of the septum and the free wall between the papillary muscles. In these areas P and M electrograms were closely adjacent (within 3 msec). Although a lacework of pale interweaving P strands was visible in these areas, even in the pinker islands between the strands P potentials often were obtained. With the microelectrode it was found that the first one to three layers had action potentials characteristic of P cells (or transitional cells), covering the lower septum and much of the lower free walls like a sheet. The total time required for P activation of the left ventricular endocardial surface was 30 to 45 msec. P activation continued for 15 to 20 msec after M activation had begun.

Activation times of M cells: The activation of M cells had a different pattern, dependent both on the pattern of P activation and on the areas where electrical continuity between P and M cells occurred. P and M continuity did not occur in the upper septum and upper halves of the papillary muscles. Two representative experiments are illustrated in Figure 5, top and bottom, which corresponds to Figure 4, top and bottom, depicting the P activation in the same preparations. Initial M activation appeared as an island in the central septum, usually in the middle third. It began 15 to 25 msec (mean 21 msec) after stimulation. The activation pattern was in the form of concentric bands around this island. The concentric bands do not represent actual conduction pathways, since the pattern of M activation is influenced by P conduction pathways as well as M conduction pathways. M cells of the papillary muscle were activated from base to apex. The last M cells to be activated were on the distal papillary muscles and the upper portion of the septum. In these areas the impulse was spread entirely by M conduction. Activation of the last M cells occurred 50 to 70 msec (mean 59 msec) after the stimulus. Activation of all M cells required 30 to 50 msec (mean 38 msec).

Effect of incisional interruption of left bundle branch fibers: The anterior or posterior border fibers were transected with transverse incisions, 3 to 6 mm long, placed about midway between the origin of the main left bundle branch and the origin of the bridging strands. Incisions interrupting less than 30 percent of the width of the left bundle branch did not produce changes in distal activation exceeding 2 msec in any of five experiments. Incisions that interrupted 30 to 60 percent of the left bundle branch resulted in delay over an area that included the upper portion of the papillary muscle, the upper portion of the paraseptal free wall and a part of the upper septum external to the main left bundle branch. Delay never occurred in more than a third (mean 27 percent) of the endocardial surface in any experiment. The maximal delay within this area was 5 to 8 msec (mean 6.8). Figure 6 shows the results of one of eight such experiments. In each of these experiments P and M cells within the area of delay were delayed proportionately. The magnitude of the delay decreased near the borders of the delayed area.

Transection of the border fibers of both sides of the left bundle branch did not produce complete heart block as long as there was a small isthmus of intact endocardium between the incisions. Figure 7 shows data from an experiment in which an isthmus of 1 mm remained between two incisions extending inward from the borders of the left bundle branch. Nonetheless activation of distal sites occurred. The distal bundle was not activated by a narrow isthmus in only one of eight experiments. In this single experiment iodine staining failed to disclose P strands within the isthmus. In the other seven experiments the isthmus contained intact P strands (interior fibers) that preserved conduction.

In six experiments the interior fibers were transected with incisions 4 to 8 mm long. There was delay of approximately 2 to 5 msec (mean 3.3 msec) in the area of the septum just distal to the incisions. The

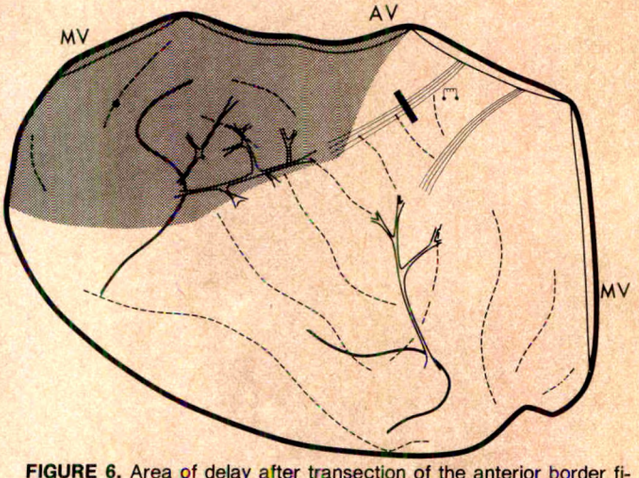

FIGURE 6. Area of delay after transection of the anterior border fibers. The incision was placed about midway between the origin of the bundle and the takeoff of the bridging strand and extended for about 40 percent of the visible width of the bundle. In the **shaded area** P and M potentials were delayed a maximum of 7 msec after the transection. See legend to Figure 4.

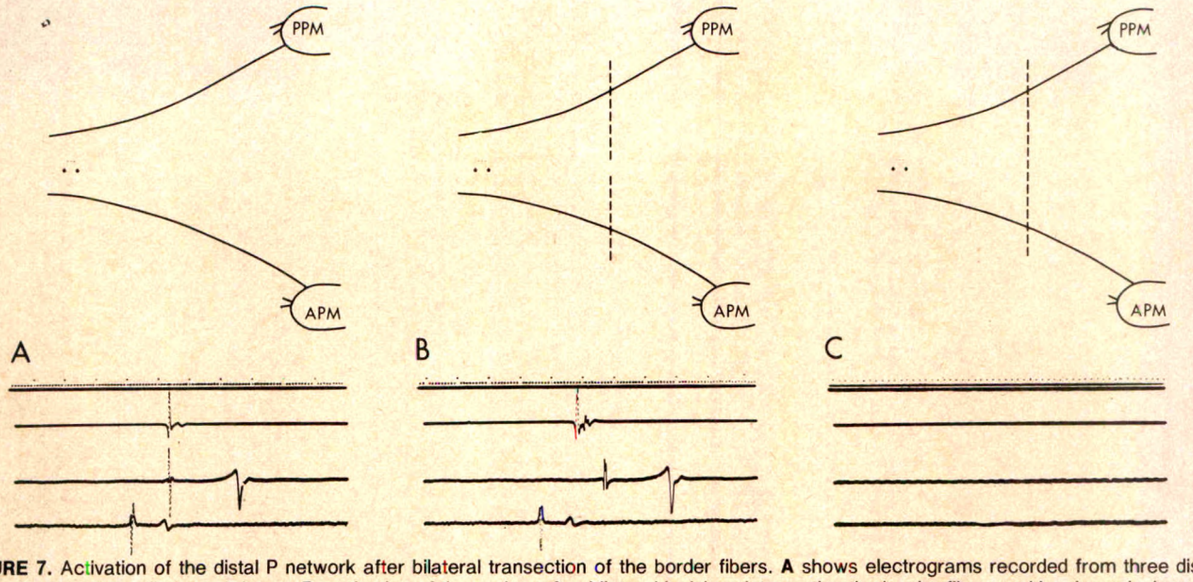

FIGURE 7. Activation of the distal P network after bilateral transection of the border fibers. **A** shows electrograms recorded from three distal sites with the left bundle branch intact. **B,** activation of these sites after bilateral incisions interrupting the border fibers and leaving only 1 mm of intact endocardium in the center of the bundle. Although the sequence of activation and configuration of the electrogram was changed, complete block did not occur. **C,** complete block after the two incisions were joined. Time markings are at intervals of 1 and 10 msec in **A** and **B** and 10 msec in **C.** The left bundle branch is schematically represented at top. APM and PPM designate the anterior and posterior papillary muscles, respectively. The incisions are represented by **dashed lines.**

area of delay was relatively small compared with the area of delay after border incisions. It was not more than one fifth (mean 12 percent) of the total area of the left ventricular endocardial surface in any experiment. A representative experiment is illustrated in Figure 8.

Discussion

Possible sources of error in methodology: The methods used in these experiments allowed detailed and discriminate mapping of Purkinje and myocardial activation of the entire left ventricular endocardial surface. Nevertheless, there were limitations and sources of error. The incision opening the ventricle necessarily interrupted fibers in the left bundle branch system. The location and direction of the incisions should have minimized alterations of the normal activation pattern if either the bifascicular representation or the diverging network is a valid representation of the left bundle branch. If the bundle is bifascicular, the incision would be placed about midway between the two fascicles in the peripheral ramification and should not significantly alter the normal activation pattern. If the bundle is a diverging network, the incision would be parallel to the general direction of the radially fanning fibers, resulting in minimal interruption of major centrifugal paths.

Some investigators have found P potentials several millimeters deep to the endocardial surface.[9,10] Others have disputed these findings.[11,12] In our preparations it is unlikely that cells deep to the first few layers survived in a nearly normal electrophysiologic state. If deep Purkinje fibers influence endocardial distribution by coursing in a direction parallel to the plane of the endocardium, their deterioration in this preparation would alter the normal activation pattern. We have not completely ruled out this possible source of error, which would have the effect of eliminating possible conduction pathways and prejudice the data in favor of the more parsimonious bifascicular representation. However, certain comparisons indicate that the preparation reproduces with little distortion the activation pattern existing in vivo. The interval from stimulus artifact to earliest M activa-

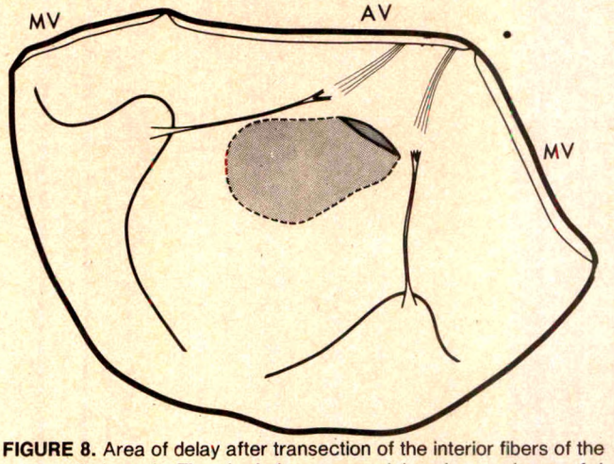

FIGURE 8. Area of delay after transection of the interior fibers of the left bundle branch. The shaded area was delayed a maximum of 4 msec. The incision was 8 mm long and interrupted 70 percent of the total width of the bundle at that level. See legend to Figure 4.

tion (15 to 25 msec, mean 21) is close to the interval from activation of the main left bundle branch to the earliest ventricular activation recorded in vivo.[13] The general pattern of M activation resembled the pattern observed in vivo in numerous studies[14–19]: (1) The earliest M activation occurred in the mid-septum; (2) the latest M activation occurred in the upper septum and tips of papillary muscles; (3) the papillary muscles were activated from base to apex. There is a discrepancy between our findings and those of one study performed in vivo. Venerose et al.[7] found that the total time required for P activation in the left ventricle of the intact heart was as great as 60 msec. In our preparations, the maximal time was 45 msec. This interval may be directly related to the size of the heart. We purposely used small or medium-sized hearts. The total time required for activation of M cells (30 to 50 msec) corresponds with the total time required for activation of the left ventricular subendocardial M cells in vivo according to some investigators,[16] although another group[14] found a somewhat shorter time.

Validity of representation of the left bundle branch as a bifascicular structure: The activation pattern of the left bundle branch network confirmed the visual impression that the interior network is a direct continuation of the proximal left bundle branch, not a derivation from the border fibers. The fibers in the interior network are activated nearly simultaneously with equidistant points on the borders. The isochronous lines of septal P activation showed few or no central indentations (proximal convexity). If these interior fibers were activated from the border fibers, as strict interpretation of the bifascicular representation implies, there should be relatively deep central indentations in the isochronous lines, resulting from the delay produced in transit from the border fibers to central points in the interior fibers. Uhley and Rivkin,[20,21] noting these interior fibers in stained specimens, represented the left bundle branch as a tripartite system composed of two "divisions" (border fibers) and the septal fibers. They observed subtle electrocardiographic changes resulting from incisions within the interior network. Myerburg et al[6] demonstrated this interior network by staining with iodine and recording P potentials from these fibers. They also showed nearly simultaneous activation of equidistant points in the interior and on the borders. However, they retained the terminology of the bifascicular representation, referring to the border fibers as "divisions." Our observations on the effects of lesions within the conduction system did not conform with the bifascicular representation. Transection of either group of border fibers (the "fascicles" or "divisions") did not produce delay in half of the endocardial surface. Delay occurred in parts of the paraseptal free wall and peripheral upper septum if the lesions extended substantially across the interior fibers. The area of delay was one third or less of the total endocardial surface (Fig. 8). The magnitude of delay (5 to 8 msec) was the same as that recorded by Myerburg et al.,[8] who produced similar lesions. However, in contrast to our findings they observed delay only in P cells, not M cells. This difference may be related to differences in the extent of the lesions. Most damaging to the bifascicular representation was the finding that interruption of both groups of border fibers ("bifascicular" block) did not produce complete block of conduction of the left bundle branch because of unincised interior fibers that originated in the main bundle branch.

Validity of representation of the left bundle branch as a fanning network: Representation of the left bundle branch as a fan-shaped network implies no functional distinction between border and interior fibers. Yet the border fibers have several distinctive characteristics. They pursue nearly straight paths for relatively long distances, as opposed to the more sinuous interior fibers (Fig. 1). Apparent conduction velocity is greater in the border fibers, particularly in the bridging strands, than in the interior network. The increase in the conduction velocity in the bridging strands is partly but not entirely due to their straight course. The more proximal border fibers, which are also straight, do not conduct as rapidly as the bridging strands, thereby indicating that there is a "real" as well as "apparent" increase in conduction velocity in the bridging strands. This may be due to a relative infrequency of lateral branches. Regardless of their significance with respect to cellular function, these apparent conduction velocities are significant since they measure the actual net rate at which impulses traverse the endocardial surface. Another distinctive feature of the border fibers is that the bridging strands crossing the cavity provide a shortcut to areas on the free walls. As a consequence of these anatomic and functional features, the border fibers are specialized for rapid transport to relatively distant sites on the free walls and papillary muscles. These differences between the serpentine interior fibers of the septum and the straight border fibers coursing to the free walls operate to synchronize activation of the free walls and septum despite the greater distance of the free wall from the main left bundle branch.

Incisional lesions and effect of transverse functional interconnections: These anatomic and functional differences between the border and interior fibers may be relevant to our observation that incisions that transected the border fibers resulted in greater delay over larger areas of the endocardial surface than incisions of comparable or greater size that interrupted the interior fibers. Interior incisions, which involved more than half of the width of the left bundle branch, produced delay of only a few milliseconds over only 10 or 15 percent of the left ventricular endocardial surface. This result indicates that functional transverse interconnections within the interior network provide activation from the unincised portions of the left bundle branch network to the fibers distal to the incision. This conclusion is also suggested by the visual appearance of the stained left bundle

branch network. Since transection of half of the left bundle branch from the border to the center did not result in delay over half of the endocardial surface, these functional interconnections must also provide some activation to the border fibers distal to the incision, thus serving to reduce the area of delay. However, there is no need to assume that the frequency or density of these interconnections is the same in the border fibers as in the interior network. Actually, by inspection the bridging strands usually have only a few lateral interconnections to the endocardial surface. Because the apparent conduction velocity in the interior is less than in the border fibers, and the wave front of activation lags slightly behind that in the border fibers, interconnections between interior fibers and border fibers would be less effective in overcoming delays produced by incisions of the border fibers. Moreover, interconnections with unincised fibers can supply activation from two directions into an area distal to an interior incision, but fibers distal to an incision of the border fibers can be supplied only from the one direction provided by interconnections with unincised interior fibers.

Clinical applications: The relevance of these data to man and clinical electrocardiography is uncertain since there are differences among species in the architecture of the His-Purkinje system.[3] It has been pointed out[4,21,22] that interruption of the border fibers of the left bundle branch of the dog results in axis shifts that are similar in direction but smaller in magnitude than those attributed in clinical electrocardiography to "fascicular block." However, some exponents of the bifascicular representation have attributed these differences in degree to the more vertical position of the canine heart[4] rather than to any essential difference in structure between the canine and human left bundle branch. It has been claimed[4] that if the canine heart is placed horizontally, axis shifts are more marked, like those in man. The left bundle branch of man has been grossly visualized by iodine staining only rarely; two reports[23,24] have shown illustrations from two normal human hearts. In both of these reports the left bundle branch is considered bifascicular and the illustrations are labeled accordingly, although neither illustration shows clear delineation of the two fascicles and interior fibers are apparent. Spach et al.[24] showed a stained canine left bundle branch with many interior fibers and commented on the similarity of the canine and human left bundle branches. Dissection of the left bundle branch is not a reliable means of elucidating its structure, since inconspicuous fibers may be overlooked. Histologic methods require examination of many contiguous samples in order to reconstruct the architecture of the left bundle branch. Two recent painstaking histologic studies[25,26] of the human left bundle branch reported an extensive interior network. These observations were interpreted as invalidating the bifascicular representation.

Our canine electrophysiologic data generally conform with these histologic observations. However, they do not exclude the possibility that certain implications of the bifascicular representation may be valid because of the distinctive features of the border fibers and the comparatively large areas that manifest delay after their interruption. It is acknowledged that shifts of the axis on the electrocardiogram may be associated with minimal or no prolongation of the QRS interval.[4] Therefore, we cannot discount the possibility that delay of activation of one third of the endocardial surface by 7 msec in the dog might result in a shift of the axis to the degree now termed "fascicular block." This question cannot be definitively resolved by our in vitro data.

Interactions of quinidine (5 mg/liter) and bretylium tosylate (20 mg/liter) were studied in isolated perfused rabbit hearts by recording transmembrane potentials from the atrial fibers, the atrioventricular (A–V) junction and the ventricular fibers. The following observations were made on ventricular fibers. As expected, administration of quinidine prolonged action potential duration and reduced the maximal rate of depolarization. Subsequent addition of bretylium to quinidine shortened action potential duration and tended to restore the maximal rate of depolarization. The membrane resting potential, the action potential amplitude and overshoot showed no significant changes. With respect to A–V conduction, bretylium alone shortened intraatrial and His-Purkinje conduction times but prolonged intranodal conduction time. With quinidine, intraatrial and His-Purkinje conduction times were markedly prolonged and intranodal conduction time was only slightly increased. Addition of bretylium to quinidine shortened intraatrial and His-Purkinje conduction times but significantly prolonged intranodal conduction time, resulting in a further prolongation of the total A–V interval. The possible clinical implications of these findings are stressed.

Bretylium tosylate has been shown to be effective in the treatment of acute ventricular arrhythmias including ventricular fibrillation.[1–5] In addition to its postganglionic sympathetic blocking action, bretylium increases the ventricular fibrillation threshold and has a positive inotropic effect.[6,7] Reports differ on the electrophysiologic action of this agent on the myocardium.[8–10] Data from studies by Watanabe et al.[8] in rabbit ventricular fibers and those of Wit et al.[9] in canine Purkinje and ventricular fibers are quite contradictory (Table I). To clarify the electrophysiologic effects of bretylium, and to attempt to explain these discrepancies, we studied the interactions of quinidine and bretylium. Results of our previous studies[8,11] have indicated that these agents have contrasting electrophysiologic actions.

Methods

Experiments were performed in isolated perfused rabbit hearts using previously reported techniques[12] of isolation and perfusion. We used a modified Chenoweth's solution with the following composition in millimoles per liter: sodium chloride 119.8, potassium chloride 4.5, calcium chloride 2.4, magnesium chloride 2.1, sodium bicarbonate 25.0 and dextrose 10.0. The perfusion fluid was saturated with 95 percent oxygen plus 5 percent carbon dioxide.

A ventricular electrogram was recorded by two small surface electrodes attached to the right ventricular apex and the left ventricular base. A stimulating electrode was placed near the sinus node, and the hearts were driven at a constant rate 10 to 15 beats/min higher than the intrinsic sinus rate. Glass microelectrodes filled with 3 molar potassium chloride with tip resistances of 10 to 25 megohms were used to record transmembrane potentials from the atria, the atrioventricular (A–V) junction and the ventricular fibers. The potentials were amplified by a neutralized input capacity amplifier and Tektronix amplifiers. A Grass camera was used to photograph tracings on a Tektronix oscilloscope.

TABLE I

Comparison of Membrane Effects of Bretylium on Ventricular Fibers

	Watanabe et al.[8] (1969)	Wit et al.[9] (1970)
Membrane resting potential	Increase	No change
Action potential amplitude	Increase	No change
Maximal rate of depolarization	Increase	No change
Action potential duration	Decrease	Increase
Effective refractory period	Decrease	Increase

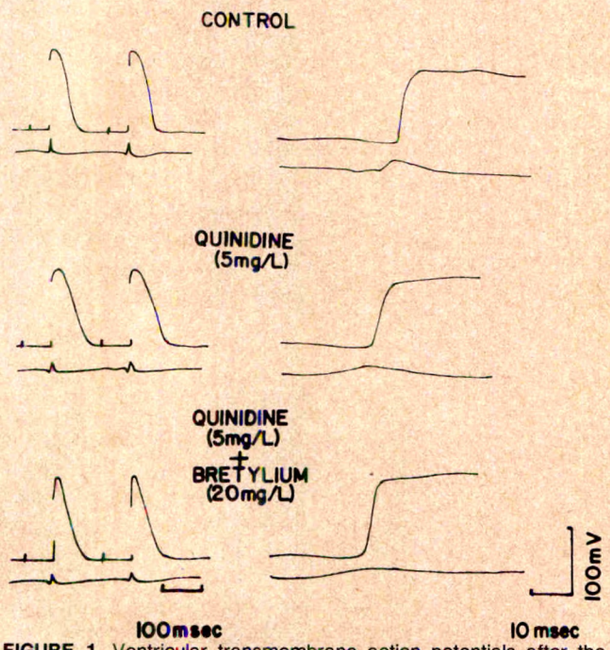

FIGURE 1. Ventricular transmembrane action potentials after the addition of quinidine and bretylium. **Column at right** shows high speed records of phase zero. After the addition of quinidine (5 mg/liter) there was an increase in action potential duration and a decrease in the maximal rate of depolarization. Subsequent addition of bretylium (20 mg/liter) restored the maximal rate of depolarization and reduced the action potential duration toward the control value.

The sequence of perfusion was as follows: (1) control (modified Chenoweth's solution), (2) control with quinidine (5 mg/liter), and (3) control with quinidine (5 mg/liter) and bretylium tosylate (20 mg/liter). Each perfusion lasted at least 30 minutes.

Results

Ventricular Fibers

Table II summarizes the effects of interaction of quinidine and bretylium on the action potential characteristics of ventricular fibers in 10 rabbit hearts. As expected, quinidine decreased the maximal rate of phase zero depolarization from 57.5 ± 14.6 (standard deviation) to 36.0 ± 8.9 v/sec and prolonged the action potential duration from 118.0 ± 22.0 to 147.0 ± 25.6 msec. Addition of bretylium to quinidine shortened the action potential duration to 135.0 ± 25.2 msec and restored the maximal rate of depolarization to 42.1 ± 12.1 v/sec. Thus, addition of bretylium reversed certain membrane effects of quinidine. These changes were statistically analyzed with use of the paired Student t test (Table II). The shortening of action potential duration was statistically significant, whereas the increase in maximal rate of depolarization was not. The membrane resting potential, the action potential amplitude and overshoot showed no changes.

Figure 1 shows the antagonism between quinidine and bretylium relative to the action potential contour of ventricular fibers in a typical experiment. Shortening of the action potential and an increase in the rate of phase zero depolarization after the addition of bretylium are evident.

A–V Conduction

In a secord series of experiments in another group of 10 rabbit hearts, A–V conduction was studied by recording transmembrane potentials from the A–V nodal fibers. Administration of bretylium alone had contrasting effects on different fiber types; action potential duration was prolonged in node-His (NH) fibers of the A–V node and shortened in ventricular fibers (Fig. 2). Figure 3 shows the effects of bretylium on conduction times in different portions of the A–V transmission system. Intraatrial (A) and His-Purkinje (HP) conduction times were shortened, but intranodal conduction time was prolonged. There was an increase in the total A–V interval.

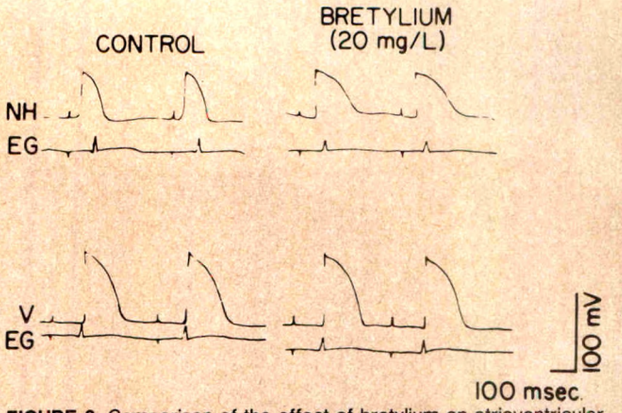

FIGURE 2. Comparison of the effect of bretylium on atrioventricular (A–V) nodal fibers (node-His region) and ventricular fibers. Action potential duration of the N–H fibers was prolonged but that of ventricular fibers was shortened. NH = node-His; EG = electrogram; V = ventricle.

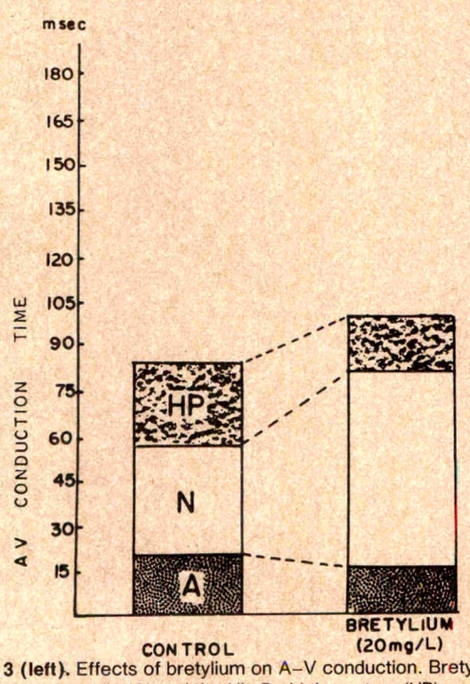
The combined effects of quinidine and bretylium are shown in Figure 4. With quinidine, both intraatrial and His-Purkinje conduction times were markedly prolonged, and intranodal conduction was only slightly delayed. Subsequent addition of bretylium to quinidine shortened the intraatrial and His-Purkinje conduction times but significantly prolonged intranodal conduction time. However, the initial prolongation of the total A–V interval induced by quinidine was further exaggerated by the addition of bretylium. Table III shows the results of statistical analyses of these changes.

A–V nodal block produced by addition of bretylium to quinidine: Depression of intranodal conduction after the addition of bretylium to quinidine resulted in second degree A–V block in 5 of the 10 hearts. An example is shown in Figure 5. In this figure, transmembrane action potentials from an NH fiber and an electrogram are shown together with a ladder diagram. There was a 1:1 response to atrial stimulation in this proximal NH fiber, 3:2 conduction to the ventricles, and Wenckebach periodicity. The most interesting finding in this record is the sequential change in the NH action potentials. The first conducted atrial impulse is associated with a normal



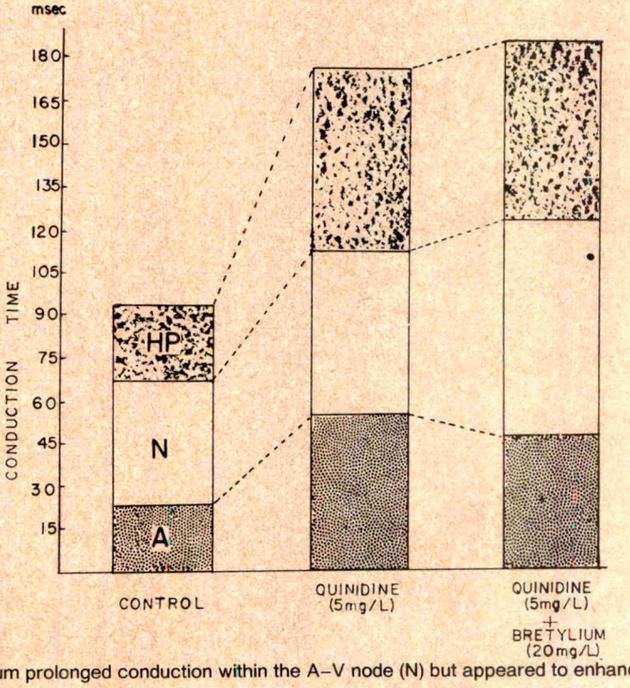


FIGURE 3 (left). Effects of bretylium on A–V conduction. Bretylium prolonged conduction within the A–V node (N) but appeared to enhance conduction within the atria (A) and the His-Purkinje system (HP).

FIGURE 4 (right). Quinidine (5 mg/liter) prolonged total A–V conduction time, with increases within the atria (A) and His-Purkinje (HP) regions. After the addition of bretylium, there was further prolongation of conduction time in the intranodal region (N) but some shortening within the atria and the His-Purkinje system. Hence, the addition of bretylium to quinidine may cause further A–V conduction delay.

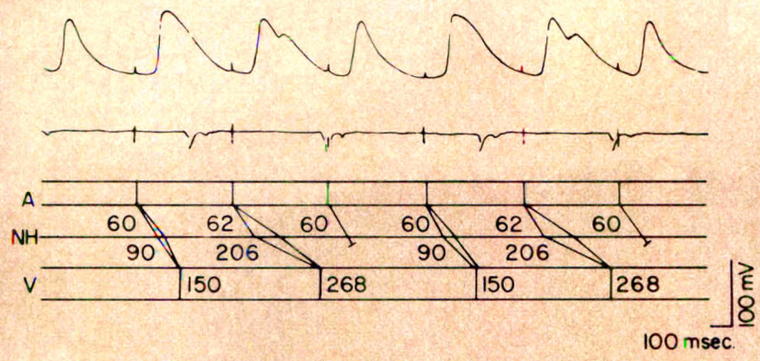

FIGURE 5. Wenckebach periodicity produced by bretylium in the presence of quinidine. The first conducted beat shows a rather normal-looking action potential in this proximal node-His fiber. The second beat shows decreased amplitude of the action potential followed by hump formation; finally, the third action potential is further diminished in amplitude and shows markedly shortened action potential duration. This beat is not conducted to the ventricles. Fragmentation of the wave front within the intranodal region is suspected, as indicated in the ladder diagram. A = atria; NH = node-His; V = ventricle.

action potential contour, but the second impulse produces an action potential with a reduced amplitude and upstroke velocity, showing a prominent hump formation in its repolarization phase. In this beat, conduction time is slightly prolonged between the sinus nodal region (stimulus artifact) and this fiber, and it is markedly prolonged below this layer of the A–V node. Finally, the third atrial impulse is associated with a still smaller and much narrower action potential, which fails to be propagated to the ventricles. The recordings in Figure 6, obtained 4 minutes after those in Figure 5, demonstrate that the site of block is most likely within the A–V node, and perhaps immediately below this fiber. This distal NH fiber shows a 3:2 response to atrial stimulation, again with progressive prolongation of the conduction time (Wenckebach phenomenon).

Discussion

Mechanism of Interaction of Bretylium and Quinidine

Several investigators[9,10,13] have indicated that the electrophysiologic action of bretylium tosylate differs from that of other antiarrhythmic agents such as quinidine. Wit and co-workers[9] and Bigger and Jaffe[10] reached this conclusion on the basis of their observations of initial enhancement of Purkinje fiber automaticity and the lack of significant effect on conduction velocity after bretylium was added to the perfusate. They reported that bretylium, like quinidine, prolongs action potential duration. In sharp contrast, Watanabe et al.[8] have shown a shortening of the ventricular action potential and an increase in conduction velocity after administration of bretylium. This discrepancy prompted us to study the interaction of quinidine and bretylium. We found that bretylium shortened the action potential duration initially prolonged by quinidine (Table II, Fig. 1). Bretylium also tended to restore the maximal rate of phase zero depolarization, which had been reduced by quinidine, although the change was statistically not significant. These results appear to reconfirm our previous observations.[8] They are in contrast with the results of Wit et al.[9] and Bigger and Jaffe,[10] who reported a prolongation of the action potential duration and the refractory period by bretylium.

In a previous study,[8] we showed by means of a tissue bath that bretylium increased the membrane resting potential, the action potential amplitude and the maximal rate of depolarization of ventricular fibers, although Wit et al.[9] and Bigger and Jaffe[10] observed no significant changes in these variables. However, Bigger and Jaffe reported an increase in membrane resting potential in fibers with an initial resting potential of lower than normal value. Similarly, Wit et al.[9] noted occasional hyperpolarization induced by bretylium, especially when the membrane resting potential was reduced or the tissue was considered hypoxic. They explained such findings by possible release of catecholamines from the sympathetic nerve endings. Although these points will be discussed in greater detail elsewhere (Watanabe et al., in preparation), it is conceivable that this mechanism played a role in the hyperpolarization and increased conduction velocity observed in our previous experiments.[8] It is unlikely that the same mechanism

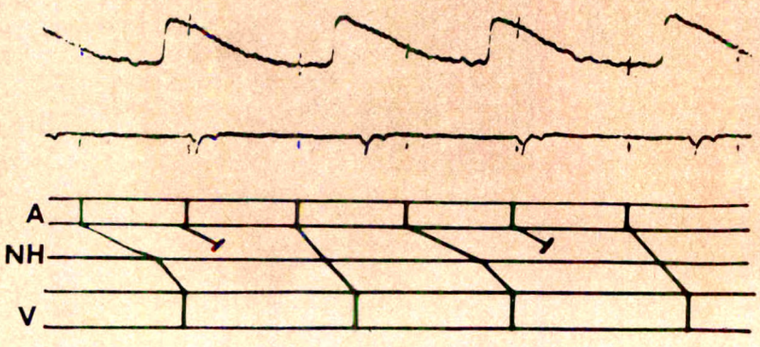

FIGURE 6. Wenckebach periodicity after administration of quinidine and bretylium, with 3:2 conduction and block above the distal node-His fiber. The ladder diagram shows the sequence of conduction. Abbreviations as in Figure 5.

prevailed in the present study of isolated hearts perfused through the coronary system since myocardial oxygenation in this setting should be better than in a tissue bath experiment and recirculation of released catecholamines could not play a major role. Absence of this mechanism may explain why the addition of bretylium to quinidine did not change the membrane resting potential or the action potential amplitude and overshoot in the present study (Table II).

All the effects of bretylium cannot be attributed to catecholamine release since this agent shortened the action potential duration both alone in the tissue bath experiments and in the perfused heart in the presence of quinidine. Furthermore, if catecholamine release were solely responsible for the electrophysiologic action of bretylium, one would not expect significant depression of intranodal conduction by this agent, whether used alone or after perfusion with quinidine. Cervoni et al.[14] showed that bretylium increased fibrillation threshold in both reserpine-pretreated and chronically sympathectomized dog hearts and concluded that the antiarrhythmic effects of bretylium are due to a direct action on the myocardium rather than to its adrenergic blocking action or its ability to release norepinephrine. In their study the positive inotropic effect of bretylium was apparently not dependent on catecholamine release since it was demonstrated after sympathectomy[6] and in reserpinized dogs.[7]

We have previously pointed out that extracellular potassium concentration significantly modifies the membrane effects of various antiarrhythmic agents[11,15] as well as the effects of electrolytes such as magnesium.[16] Since Bigger and Jaffe[10] used Tyrode solution with a much lower potassium concentration (2.7 millimoles) than that of ours (4.5 millimoles), the difference between their results and ours may be explained on this basis. However, since Wit et al.[9] used a concentration (4.0 millimoles) similar to that of our study, the discrepancy between their results and ours remains unexplained by this hypothesis. One might argue that bretylium tends to correct disturbances in membrane permeability and ion flux caused by either anoxia or quinidine medication, thereby restoring normal membrane resting potential and action potential characteristics, but has no or little effect on these variables in the absence of such disturbances. However, this hypothesis is speculative and does not explain the depression of intranodal conduction induced by bretylium. Another possible explanation for the discrepancy in results is the difference in species used. Both Wit et al.[9] and Bigger and Jaffe[10] studied canine hearts whereas we used rabbit hearts. Thus it may be of interest to study the interaction of quinidine and bretylium in canine preparations.

Clinical Implications

Antagonistic effects of bretylium and quinidine: Our present study clearly indicates antagonistic effects of bretylium and quinidine on the duration of action potential and the refractory period in ventricular fibers. Earlier, Bacaner[2] had indicated that the ideal effects of bretylium might not be achieved in the presence of quinidine-like agents. Similarly, Bernstein and Koch-Weser[17] have shown that other antiarrhythmic agents antagonized the clinical efficacy of bretylium when given concurrently or in direct proportion to their duration of use preceding administration of bretylium. Our present results confirm these clinical observations and suggest the following implications.

Bretylium tosylate usually is not chosen as the initial antiarrhythmic drug, but is resorted to when other antiarrhythmic agents have failed to control certain rhythm disorders. Since its electrophysiologic action differs distinctly from that of other agents, it may be able to terminate pathophysiologic mechanisms of arrhythmia that do not respond to other drugs. On the other hand, if bretylium is administered immediately after a quinidine-like agent, it may fail to control the arrhythmia because of antagonism between the drugs. Hence, it may be necessary to withdraw antiarrhythmic agents to utilize the favorable effects of bretylium.

Additive effects of bretylium and quinidine on A–V conduction: Finally, it must be stressed that quinidine and bretylium have contrasting effects on A–V conduction. Indeed, bretylium tended to shorten the intraatrial and His-Purkinje conduction times initially prolonged by quinidine (Table III) although it markedly depressed intranodal conduction, either alone or in the presence of quinidine. As a result, the total A–V interval was prolonged and second degree A–V block developed in some instances. Thus, the combination of quinidine and bretylium may have additive effects on A–V transmission, depressing conduction in all three portions of the A–V conducting system. Some clinical data appear to be at variance with these experimental results. Bacaner[18] (quoting Sanna et al. and adding his own case) reported improved A–V conduction in patients with second degree or higher grades of A–V block. In two cases (Fig. 10 and 11 of Bacaner),[18] the block was associated with narrow QRS complexes and Wenckebach phenomenon. This combination usually indicates an intranodal conduction disturbance,[19,20] but in some instances may be caused by block within the His bundle rather than within the A–V node.[21] Furthermore, Figure 5 of Bacaner's paper[18] (again reproduced from Sanna et al.) clearly indicates that the bretylium-induced improvement of A–V conduction occurred in the presence of A–V block with wide QRS complexes and that bretylium also shortened the QRS duration. Thus, normalization of His-Purkinje rather than intranodal conduction cannot be ruled out in those patients.

Other factors may also be involved in clinical cases. Dhurandher et al.[22] described a patient (their Case 1) who had second degree A–V block during treatment with bretylium, but attributed the block to posterior wall infarction rather than to the effects of the drug. Hence, although production of second degree A–V block by bretylium may be a rare event in the clinical setting, this possibility should be kept in mind, particularly in patients who already have some degree of A–V conduction disturbance.

Effects of Intraperitoneal Administration of Propranolol on the Mouse Heart

Histochemical and Electron Microscopic Observations

EDGAR F. ALLIN, MD
JANICE M. MILLER, DVM, PhD
GEORGE G. ROWE, MD
JAMES A. WILL, DVM, PhD

Madison, Wisconsin

In an earlier investigation, ultrastructural and histochemical abnormalities were reported in the hearts of mice receiving the beta adrenergic blocking agent propranolol. Because of the increasing use of this drug to treat human cardiac disorders, we repeated this investigation. Our findings do not confirm that cardiac lesions are produced by propranolol: No structural or histochemical abnormalities could be related to administration of the drug. We conclude that there is no presently acceptable histologic evidence that propranolol causes myocardial damage.

Because propranolol is widely used to treat patients with heart disease,[1] it is of considerable importance that Sun et al.[2] have reported histochemical and electron microscopic changes in mice receiving this drug. In this investigation we repeated their study.

Material and Methods

The study was performed in three parts referred to as experiments 1, 2 and 3. The animals were 3 week old Swiss white mice averaging 20 g in weight. Propranolol (Inderal®, Ayerst Laboratories) was injected intraperitoneally once daily for 21 days in test animals; all control mice received daily injections of a similar quantity of sterile diluent. On the 22nd day the animals were killed by cervical traction, the thoracic cavity was swiftly exposed and the hearts were promptly treated as described later. Specimens were given code numbers and initial microscopic observations were made without knowledge of the experimental regimen to which they had been subjected. The code was then broken and the sections were reexamined.

In experiment 1, five mice received 0.05 mg of propranolol daily, five received 0.1 mg of the drug and five served as control animals. All hearts were fixed with glutaraldehyde, portions were removed for electron microscopic studies, then the remaining tissue was embedded in paraffin, sectioned and stained with hematoxylin-eosin.

In experiment 2, ten mice were given 0.1 mg of propranolol daily, and five received sham injections for control studies. The hearts of four treated and two control animals were perfused for electron microscopic studies. The remaining nine hearts were frozen for histochemical processing.

In experiment 3, fourteen mice received 0.1 mg of propranolol daily and another 16 mice served as control animals. Both groups gained weight at a similar rate. Three hearts from each group were perfused for electron microscopic studies and three others from each group were frozen for histochemical examination. The remaining 18 hearts were fixed in Bouin's solution, and 2 mm thick transverse slices of the ventricular region were embedded in paraffin, then sectioned for periodic acid-Schiff and hematoxylin-eosin staining. To insure uniform treatment, one experimental and one control specimen were embedded side by side in each paraffin block and processed together.

For electron microscopic studies, 3.5 percent glutaraldehyde in 0.1 molar cacodylate buffer was injected into the left ventricle of the beating heart through a 27 gauge needle. The heart was arrested and removed and the atria plus portions of the ventricles and interventricular septum were immersed in the glutaraldehyde solution for 3 hours, washed overnight in cacodylate buffer, then postfixed for 2 hours in 1 percent osmium tetroxide. After dehydra-

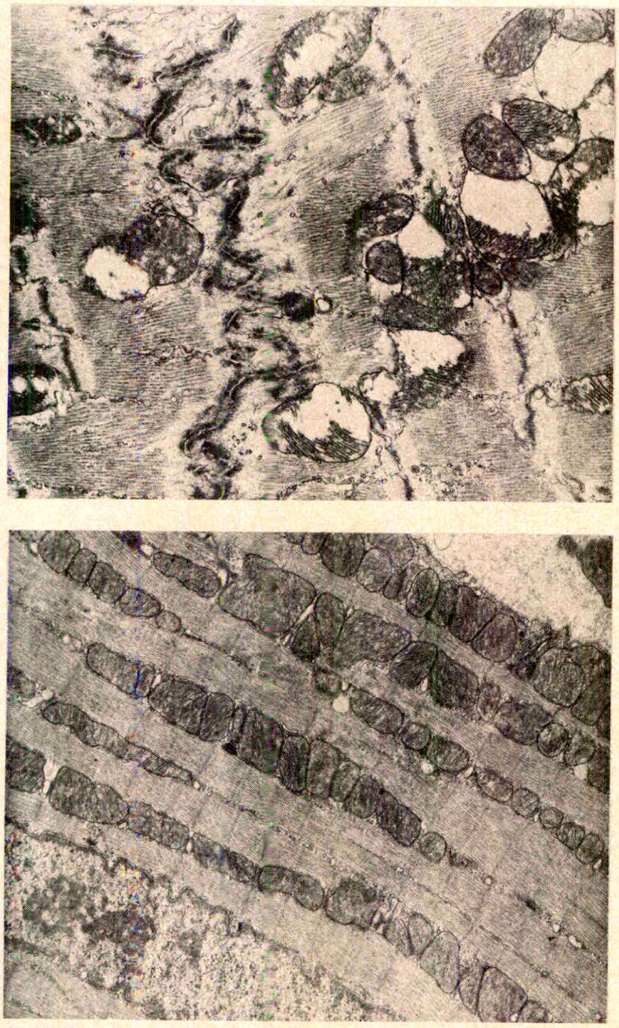

FIGURE 1. Electron micrographs of left ventricular tissue of mice from experiment 3. **Top,** control heart. Many mitochondria are swollen and have disrupted cristae. **Bottom,** treated heart (0.1 mg of propranolol). No ultrastructural abnormalities are present. **Top,** × 13,500; **bottom,** × 10,000, both reduced by 28 percent.

tion, tissue blocks were embedded in an Epon-Araldite plastic mixture.[3] Thin sections were stained in 25 percent uranyl acetate[4] and lead citrate[5] and examined in a Hitachi HU II-B electron microscope. Multiple samples, both adluminal and deeper, were examined from every heart, with several from each atrium, each ventricle and the interventricular septum.

For histochemical processing, hearts of simultaneously killed mice were swiftly excised without pinching or other mechanical injury, assembled in uniform orientation on a copper planchette and frozen in liquid nitrogen or isopentane slurry. Each planchette held one control and one or two treated hearts. Ten μ coronal sections were cut in a cryostat microtome, with at least six whole heart sections including all chambers for each of the following techniques: (1) Sudan black B for lipids[6]; (2) periodic acid-Schiff for glycogen, with diastase controls[6] (fixation by formaldehyde fumes and Carnoy's solution); and (3) enzyme activity determinations: succinic dehydrogenase,[6] nicotinamide-adenine dinucleotide, reduced form (NADH) diaphorase,[6] beta-hydroxybutyric dehydrogenase,[6] 5′-nucleotidase[7] and myofibrillar (calcium-activated) adenosine triphosphatase.[8]

Results

Electron microscopy: No consistent differences were observed between sections from tissues of propranolol-treated and control mice. Although ultrastructural anomalies were sometimes noted, they occurred with equal frequency in the control and treated groups. Occasionally, isolated mitochondria were swollen and cristae were disrupted or absent (Fig. 1, top). Less commonly there was a separation of myofibrils at the region of the intercalated disc. There was considerable variation in the amount of glycogen granules among sections but no difference between propranolol-treated and control groups. The great majority of sections of treated hearts appeared entirely normal (Fig. 1, bottom).

Histochemistry: Experimental animals could not be differentiated from control animals after repeated careful scrutiny. Total glycogen content varied from heart to heart but not in any systematic way. There were occasional features that might be taken as abnormal but they were no more frequent or marked in experimental than in control animals (Fig. 2). Most were probably artifacts, which are unavoidable in histochemical studies. Reduced oxidative enzyme activity was often evident in the region of intercalated discs in all hearts. No differences in blood vessel caliber or staining were evident. No pronounced 5′-nucleotidase activity was observed in myofibers of any of the hearts. Overall enzyme activity levels were similar in control and treated hearts.

Discussion

In our study, in contrast to that of Sun et al.,[2] it was not possible to distinguish the hearts of control and propranolol-treated mice on the basis of ultrastructural or histochemical characteristics. Although we observed occasional features resembling those interpreted as lesions in the earlier study, they were neither more abundant nor more conspicuous in treated than in control animals. We interpret these features as artifactual or, in some instances, normal.

If this interpretation also holds for the "lesions" of Sun et al., as seems probable, then an explanation must be sought for the reported association with administration of propranolol. Systematic artifacts could result if the control and experimental tissues were handled differently although the reported correlation between the dose of propranolol and the degree of abnormality is difficult to explain on this basis.

Alternatively, the drug may have produced true lesions that were overlooked or failed to appear in our study. Since only small samples of tissue can be inspected at sufficient magnification for ultrastructural resolution in the electron microscopic studies, sporadic abnormalities might escape detection, but it is unlikely that frequent or extensive lesions were missed. As for the possibility that true lesions appeared in the earlier study but not in our investigation, various agencies could be responsible. Mice of different age or strain might be differently affected

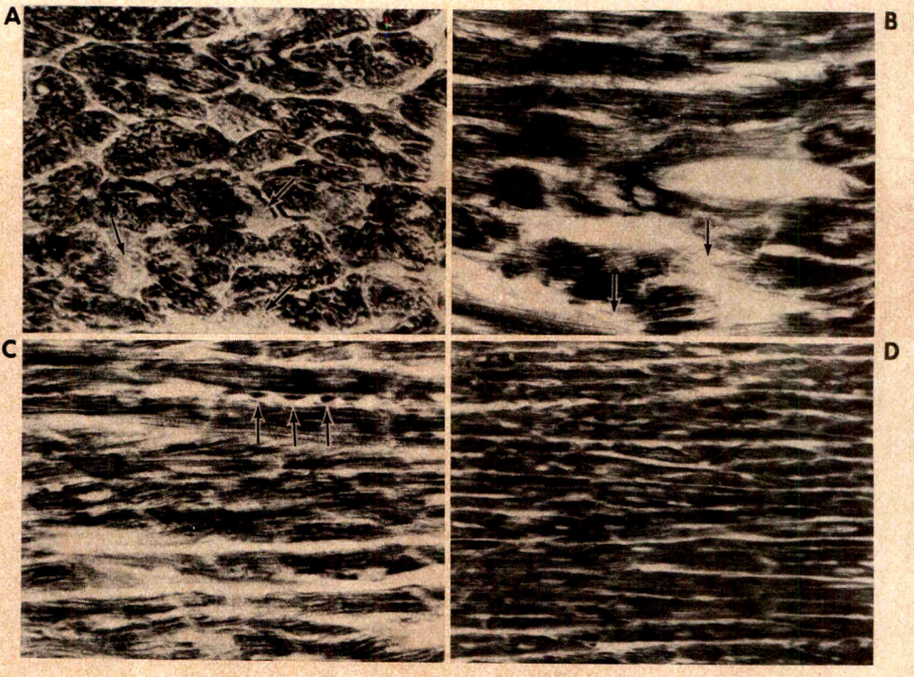

FIGURE 2. Histochemical pseudolesions. All sections are from the left ventricle, and all except one **(A)** are stained for succinic dehydrogenase activity. **A,** control heart: NADH diaphorase activity. Cross section showing areas of low intensity **(arrows)** resembling the "loss of mitochondria" in Figure 1 of Sun et al.[2] **B,** control heart: longitudinal section with discontinuity of fibers **(arrows)** similar to the "fragmentation" in Figure 3 of Sun et al.[2] This is actually a plane-of-section effect. **C,** control heart: longitudinal section showing areas of high intensity **(arrows)** resembling the "clumping of the mitochondria" in Figure 3 of Sun et al.[2] **D,** treated heart (0.1 mg propranolol): representative longitudinal section lacking evident abnormality. **A** to **C** × 600, **D** × 280, all reduced by 38 percent.

by the drug, but in both studies the animals were of the same strain and of similar initial weight. Some aspect of the environment, health or handling of the mice might conceivably have resulted in enhanced susceptibility to the drug in the earlier study. Sun et al. did not state whether their control mice were sham-injected as ours were. If not, differential stress might have been a factor. A difference in the potency or purity of the drug is unlikely since the source was the same. Similarly, the route of administration and largest dose used were alike in both studies. Sun et al. did not indicate how long after the last injection their mice were killed. This might be a significant variable.

In the earlier study the histochemical results were apparently dissimilar for different mitochondrial enzymes. Marked lesions were found for succinic dehydrogenase and "lactic dehydrogenase" (the technique primarily reveals NADH diaphorase activity), yet the authors reported "relatively little change in cytochrome oxidase and alpha-glycerophosphate dehydrogenase activity" and only a "generally increased" activity of beta-hydroxybutyric dehydrogenase. One would expect all mitochondrial enzymes to be affected in areas of mitochondrial abnormality. Virtually identical results were obtained in our study for the three oxidative enzymes examined (succinic dehydrogenase, NADH diaphorase and beta-hydroxybutyric dehydrogenase).

To minimize the risk of interpretive bias, our initial observations were made without foreknowledge of the treatment history of the specimens.

To minimize fixation artifacts in the electron microscopic aspect of the study, we perfused the hearts with glutaraldehyde. Sun et al. excised multiple samples and fixed these by immersion in osmium tetroxide. The delay involved in such a procedure is undesirable in a metabolically active, aerobic tissue. Also, Sun et al. froze for histochemical processing heart tissue remaining after excision of samples for electron microscopic studies, with both delay and mechanical trauma. Although artifacts can never entirely be eliminated, we consider our procedures less likely to produce them.

Clinical implications: Although a negative proposition cannot be proved, our results do not support the contention that propranolol in the doses used produces electron microscopic, histochemical or other histologic evidence of cardiotoxicity in mice. This is reassuring in view of the widespread utilization of propanolol in treatment of cardiac arrhythmias,[9] angina pectoris[10] and hypertension.[11] As recommended by Sun et al.,[2] careful observation must be continued in human subjects receiving propranolol. Clinical surveillance is justified because of the known side effects of this drug, but our study provides no evidence of myocardial damage.

Let's face it. Conventional nitroglycerin is a notably unstable compound. It migrates from tablet to tablet, from tablet to cotton, from cotton to cap. Result: a wide variance in potency and therapeutic effect.

But with Nitrostat your angina patient gets a stabilized nitroglycerin. *Stabilized for uniform potency retention.* Thus, Nitrostat does the job that sublingual nitroglycerin is *supposed* to do. And does it *consistently*—providing the same pain-relieving potency, tablet after tablet. That's why more and more physicians are turning to Nitrostat.

Important facts to know whenever you're prescribing for a patient with a history of angina.

think nitroglycerin!...write

KLORVESS®
Effervescent Tablets

Description: Each dry effervescent tablet contains 20 mEq. each of potassium and chloride supplied by potassium chloride 1.125 g., potassium bicarbonate 0.5 g., l-lysine hydrochloride 0.913 g. Solution of the tablet in water provides the potassium and chloride available for oral ingestion as potassium chloride, potassium bicarbonate, potassium citrate, and l-lysine hydrochloride.

Indications: For prevention or correction of potassium depletion and hypokalemic alkalosis. Especially useful when thiazide diuretics or corticosteroids cause excessive excretory potassium losses.

Contraindications: Severe renal impairment with oliguria or azotemia, untreated Addison's disease, adynamia episodica hereditaria, acute dehydration, heat cramps, and hyperkalemia from any cause.

Precautions: In response to a rise in the concentration of body potassium, renal excretion of the ion is increased. With normal kidney function, it is difficult, therefore, to produce potassium intoxication by oral administration. However, potassium supplements must be administered with caution, since the amount of the deficiency or daily dosage is not accurately known. Frequent checks of the clinical status of the patient, and periodic ECG and/or serum potassium levels should be made. High serum concentrations of potassium ion may cause death through cardiac depression, arrhythmias or arrest. This drug should be used with caution in the presence of cardiac disease. Potassium supplements should be given cautiously to digitalized patients. To minimize the possibility of gastrointestinal irritation associated with the oral ingestion of concentrated potassium salt preparations, patients should be carefully directed to dissolve each tablet completely in the stated amount of water.

Adverse Reactions: Vomiting, diarrhea, nausea and abdominal discomfort may occur with the use of potassium salts. The symptoms and signs of potassium intoxication include paresthesias of the extremities, flaccid paralysis, listlessness, mental confusion, weakness and heaviness of the legs, fall in blood pressure, cardiac arrhythmias and heart block. Hyperkalemia may exhibit the following electrocardiographic abnormalities: disappearance of the P wave, widening and slurring of QRS complex, changes of the S-T segment, and tall, peaked T waves.

Dosage and Administration: Adults: 1 tablet (20 mEq. each of potassium and chloride) completely dissolved in 3 to 4 ounces of cold water 2 to 4 times daily depending upon the requirements of the patient. The approximate minimum adult daily requirement of potassium is 40 mEq. Deviations from this recommendation may be indicated, since no average total daily dose can be defined but must be governed by close observation for clinical effects.
NOTE: Klorvess should be taken with meals.

Overdosage: Potassium intoxication may result from overdosage of potassium or from therapeutic dosage in conditions stated under "Contraindications." Hyperkalemia, when detected, must be treated immediately because lethal levels can be reached in a few hours.

How Supplied: Klorvess Tablets (white, round) in boxes of 60 (2 Rx units of 30, NDC 43-100-87). Each tablet is individually foil wrapped.

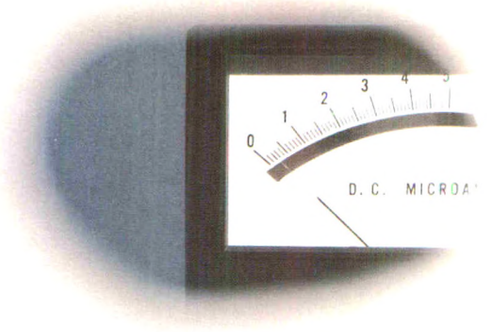
TRANTEC®

Physiological Pressure Transducers

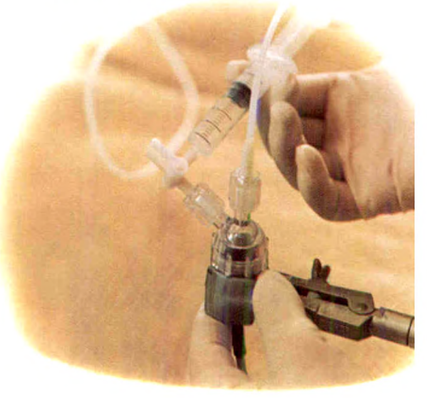
ıre Transducers by **Bentley** Trantec

The careful selection of materials and experience in design have produced devices that will withstand a 10,000 volt insulation test. Using ceramic and other non-conductive material throughout the construction of these transducers have reduced potential leakage currents to less than 0.2 x 10^{-6} amps. This provides patient safety that is at least ten times safer than others document.



When defibrillating or using an electrocautery, the Bentley Trantec Transducer is safe without disconnection from the monitoring equipment. The high insulation materials used provide protection of both the device and the patient. This major advantage allows continuous monitoring of the patient during the critical time when these procedures are necessary.

During normal operation a pressure catheter is periodically flushed to keep it open, this thermal and pressure shock interrupts the monitoring of the patient at this tim and the delay required to obtain stability is critical. The Bentley Trantec Transducers recover rapid in comparative studies they have proved to recover six times faster than other devices.



All Bentley Trantec Pressure Transducers are manufactured and tested to rigid specifications. Provided with a spare lexan dome which has two male linden fittings which allows connection to any standard catheter or blood connection fitting.

The clear lexan dome allows visual bubble detection and ease of elimination.

Bentley Trantec Pressure Transduc are compatible with most pressure monitors and can be pre-wired to directly inter-changeable with any other units.

Fitted with a connector that is spec fied for your monitoring equipment, the transducer is standardized ready for use.

Arterial

Pressure Range	0 to 300 mm of mercury
Overload Rating	6,000 mm of mercury
Excitation	10 volts maximum, DC or RMS carrier
Sensitivity	50 microvolts per volt per cm of mercury (±1%)
Volume Displacement	0.04 cu mm per 100 mm of mercury
Size	2.5 cm diameter by 3.6 cm long, exclusive of fittings
Weight	20 grams, exclusive of cable
Nominal Bridge Resistance	400 ohms
Pressure Connection	2 male linden fittings
Electrical Connection	Connector to operate with customer specified monitor
Non-Linearity & Hysteresis	1% of full scale, maximum
Leakage Current	Less than 0.2 micro-ampere RMS maximum, at 118 volts RMS AC, 60 Hz
Insulation	Withstands 10,000 volts DC
Sterilization Capability	Ethylene oxide gas, liquid disinfectants or emergency steam autoclave
WARRANTY	UNCONDITIONALLY GUARANTEED FOR ONE YEAR

Venous

Pressure Range	−10 to 60 mm of mercury
Overload Rating	3,000 mm of mercury
Excitation	10 volts maximum, DC or RMS carrier
Sensitivity	250 microvolts per volt per cm of mercury (±1%)
Volume Displacement	0.4 cu mm per 100 mm of mercury
Size	2.5 cm diameter by 3.6 cm long, exclusive of fittings
Weight	20 grams, exclusive of cable
Nominal Bridge Resistance	400 ohms
Pressure Connection	2 male linden fittings
Electrical Connection	Connector to operate with customer specified monitor
Non-Linearity & Hysteresis	1% of full scale, maximum
Leakage Current	Less than 0.2 micro-ampere RMS maximum, at 118 volts RMS AC, 60 Hz
Insulation	Withstands 10,000 volts DC
Sterilization Capability	Ethylene oxide gas, liquid disinfectants or emergency steam autoclave
WARRANTY	UNCONDITIONALLY GUARANTEED FOR ONE YEAR

Ordering Information

All transducers are provided with an electrical connector. To make certain that the appropriate connector will be installed, please state the manufacturer of the monitor with which the transducer will be operated when you place the transducer order.

BENTLEY TRANTEC, INC. 17502 Armstrong Avenue • Irvine, California 92705 • (714) 556-4464

SERVICE a new or repaired unit will be shipped within 24 HOURS

Transducers

Experience and advanced transducer technology have enabled Bentley Trantec to provide a superior product line of physiological pressure transducers. The three major advances are COMPLETE ELECTRICAL ISOLATION—NEAR ZERO LEAKAGE CURRENT—RAPID RECOVERY FROM ENVIRONMENT CHANGES. Designed for "complete" electrical isolation, it is not necessary to disconnect during defibrillation or electrocautery usage. They also contain a built-in insensitivity to flushing and possess a recovery six times faster than others. The leakage current of both the arterial and venous unit are ten (10) times lower than major competitors typically report.

THE AMERICAN JOURNAL OF CARDIOLOGY 5 YEAR CUMULATIVE INDEX*

Covers all material published in THE AMERICAN JOURNAL OF CARDIOLOGY from January 1968 through December 1972.

- **CLINICAL STUDIES**
- **EXPERIMENTAL STUDIES**
- **SYMPOSIA**
- **REPORTS ON THERAPY**
- **REVIEWS**
- **SEMINARS**
- **CASE REPORTS**
- **DIAGNOSTIC SHELF**
- **HISTORICAL MILESTONES**

Includes Author Index—and—Subject Index

All subjects are cross indexed for quick and easy reference

*There is a limited supply of the 10 Year Cumulative Index available—January 1958 through December 1967. —Price $10.00. While supply lasts order both for only $15.00.

Please use order form below.

THE AMERICAN JOURNAL OF CARDIOLOGY
P. O. Box 1172, Radio City Station, New York, N. Y. 10019

Send me THE AMERICAN JOURNAL OF CARDIOLOGY Cumulative index or indexes as checked below.

Enclosed is my check for $8 ☐ for 5 YEAR CUMULATIVE INDEX 1968–1972
Enclosed is my check for $10 ☐ for 10 YEAR CUMULATIVE INDEX 1958–1967
Enclosed is my check for $15 ☐ for both the 5 and 10 YEAR CUMULATIVE INDEXES

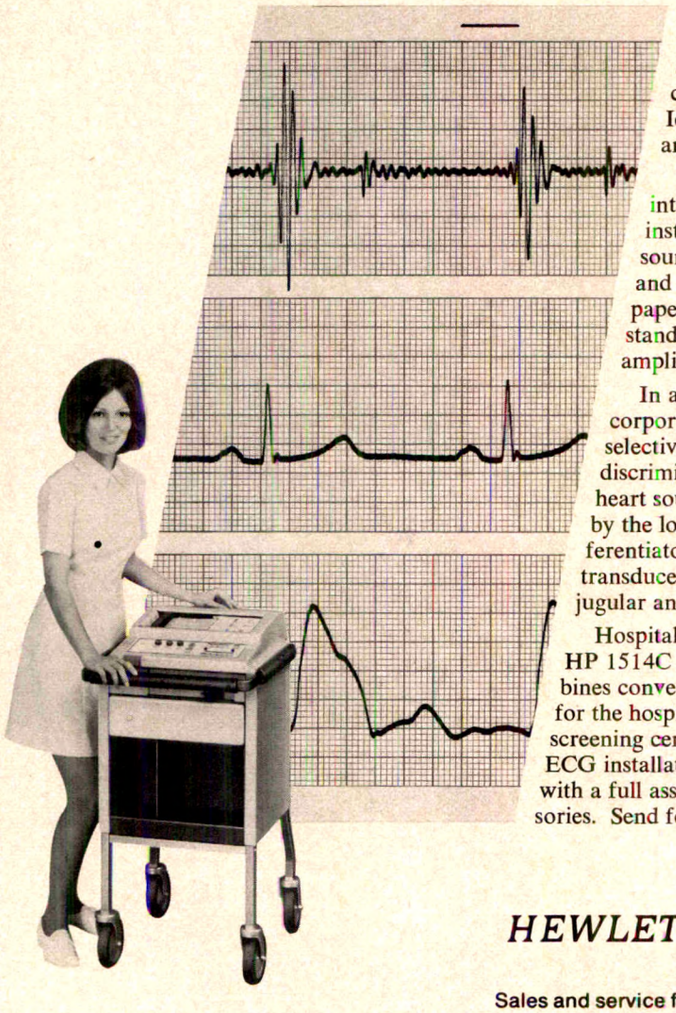
ECGs, PCGs and STIs with one easy-to-use instrument.



It's the new HP 1514C ECG/Phono/Pulse System. A new three-channel cardiograph that automatically records, marks and calibrates a complete 12-lead cardiogram in 10 seconds. Ideal for successive cardiograms before, during and after exercise.

You get complete, non-invasive systolic time interval studies on-the-spot. For example, the instrument can simultaneously record a heart sound on channel one, an ECG on channel two and a carotid pulse on channel three. The new paper drive provides 100 mm/sec as well as the standard chart speeds. And a new heart sound amplifier detects even subtle heart murmurs.

In addition, this easy-to-use instrument incorporates many important features such as selective heart sound filtering which helps you discriminate murmurs and other high frequency heart sounds that might otherwise be masked by the low frequency components . . . a differentiator for the pulse waveforms . . . plus transducers specifically designed for carotid, jugular and apex recordings.

Hospital-rugged yet office-practical, the new HP 1514C ECG/Phono/Pulse System combines convenience with valuable diagnostic help for the hospital heart station, outpatient clinic, screening center, cardiologist's office, or any ECG installation. Complete and ready to run with a full assortment of transducers and accessories. Send for our brochure No. 3658.

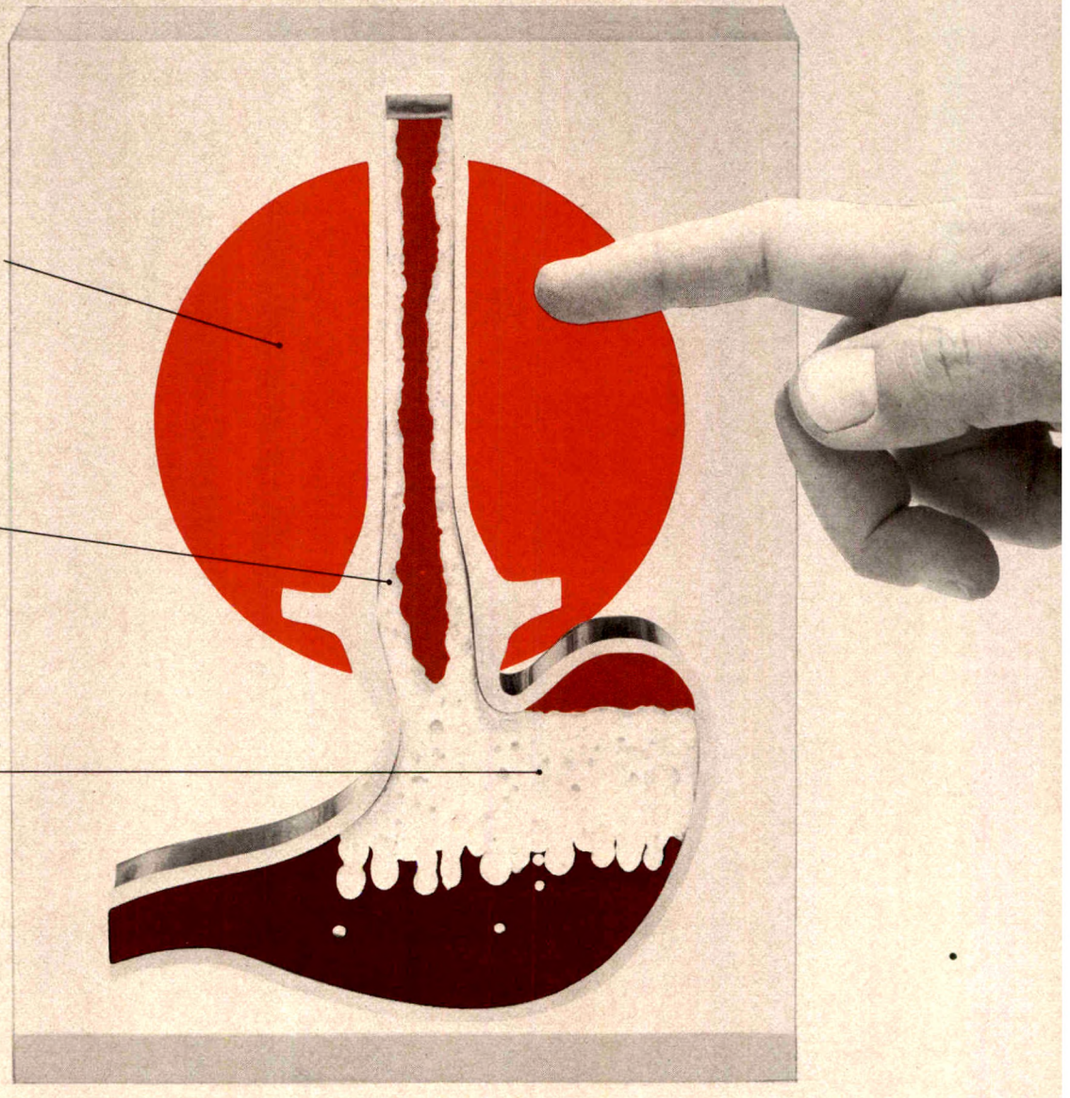
"This is the real Heartburn Zone. This is where GAVISCON® works!"

The Real Heartburn Zone
When gastric juice refluxes into the esophagus, stomach contents irritate sensitive nerve endings in esophageal mucosa to produce the pain of heartburn.

Gaviscon Coats
The Gaviscon foam coating clings to esophageal mucosa for pinpoint neutralization of gastric contents which might reflux from the stomach.

Gaviscon Floats
In the cardia and fundus of the stomach, GAVISCON® FOAMTAB® tablets form a soft, viscous layer of floating antacid foam that precedes gastric contents refluxing into the esophagus.

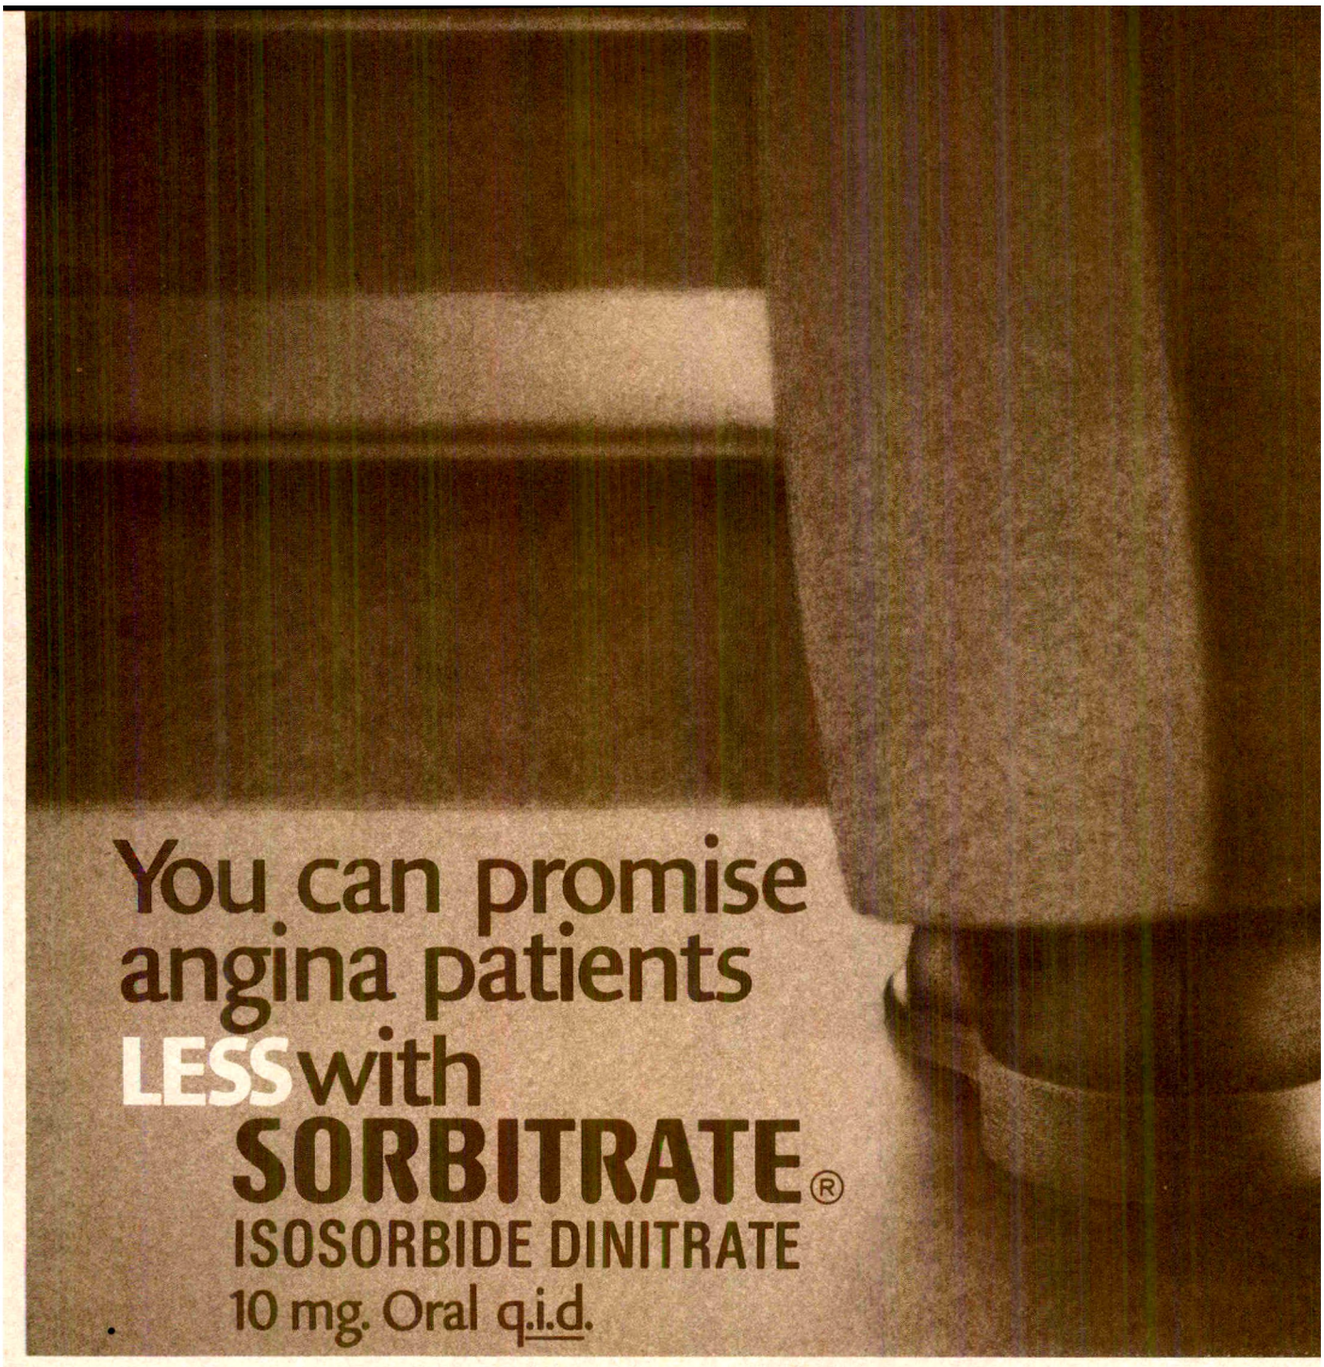


GAVISCON®

FOAMTAB®

(Alginic acid, 200 mg; aluminum hydroxide dried gel, 80 mg; magnesium trisilicate, 20 mg; sodium bicarbonate, 70 mg)
CHEWABLE ANTACID TABLETS for relief of heartburn accompanying hiatal hernia, gastroesophageal reflux, and esophagitis.

Another patient benefit product from MARION PHARMACEUTICAL DIVISION MARION LABORATORIES, INC. KANSAS CITY, MISSOURI 64137



LESS frequency and severity of anginal attacks.*

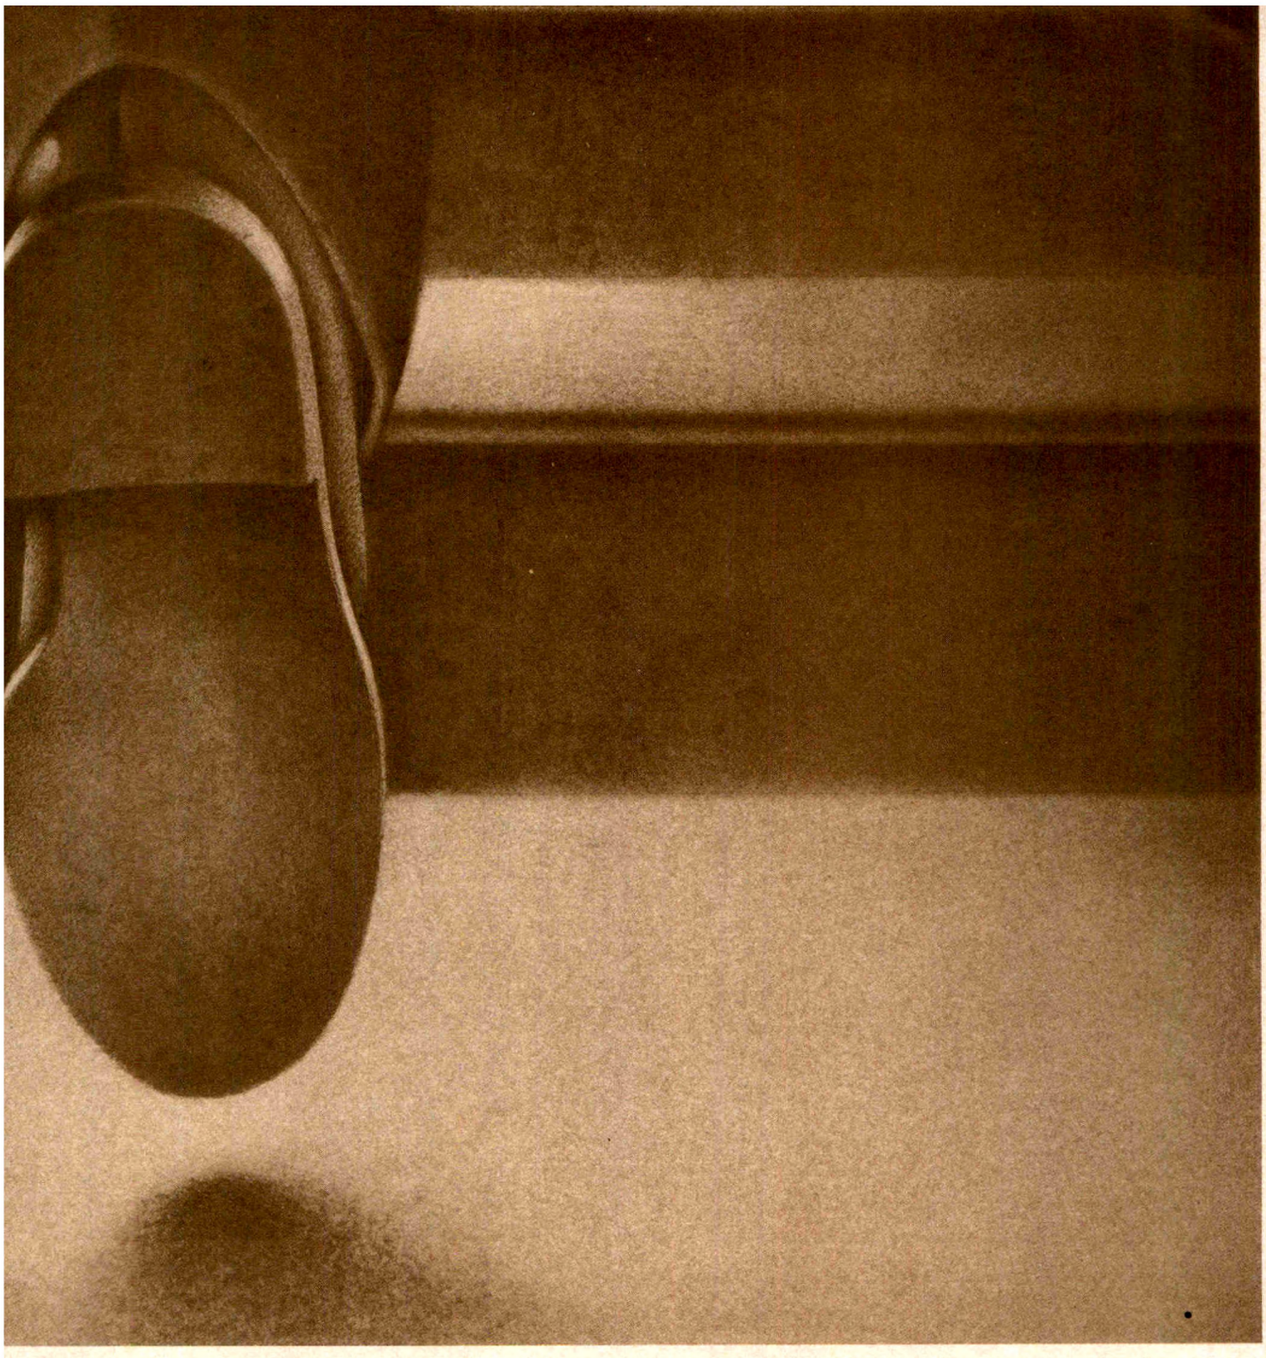
LESS need for nitroglycerin p.r.n.

And probably

LESS anxiety and apprehension over imminent attacks.

Duration:
4-6 hours for prolonged protection
Onset of action:
within 15-30 minutes
And when indicated:
Sorbitrate® (isosorbide dinitrate) 5 mg. oral tablets

*Oral dosage forms of this drug have been evaluated as possibly effective. See Brief Summary.



MARY OF PRESCRIBING INFORMATION

lications: Based on a review of this drug by the National Academy Sciences—National Research Council and/or other information, A has classified the indication as follows:
"Possibly" effective: For the treatment of angina pectoris.
Final classification of the less-than-effective indications require ther investigation.

raindications: A history of sensitivity to the drug.
nings: Data supporting the use of nitrates during the early days of acute phase of myocardial infarction are insufficient to establish y.
autions: Should be used with caution in patients who have glaucoma. ance and crosstolerance to other nitrates may occur.
erse Reactions: Headache which may be severe and persistent. ering the dose and using analgesics will help control the headaches h usually diminish or disappear as therapy is continued.
dverse reactions seen occasionally: Cutaneous vasodilation with ning; transient dizziness and weakness as well as other signs of bral ischemia associated with postural hypotension; individual marked sensitivity to the hypotensive effects of nitrates wherein severe responses can occur even with the usual therapeutic dose (alcohol may enhance this effect); drug rash and/or exfoliative dermatitis.

This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine and other agents.

Dosage and Administration: Oral tablets.

Individual Dose: Smallest effective dose should be employed. Five to 10 mg. is the range commonly used although doses of up to 30 mg. have frequently been employed.

Dosage Schedule: Smallest effective dose necessary for the prevention and treatment of pain of an anginal attack. Oral SORBITRATE may be taken 3 to 4 times daily. Although the onset and duration of effect of coronary nitrates may vary, following are the generally reported ranges of these values for SORBITRATE:

Onset of Effect: Oral: 15 to 30 minutes.

Duration of Effect: Oral: Estimated to be 4 to 6 hours.

It is recommended that the oral dosage be taken on an empty stomach.

hypertension puzzle

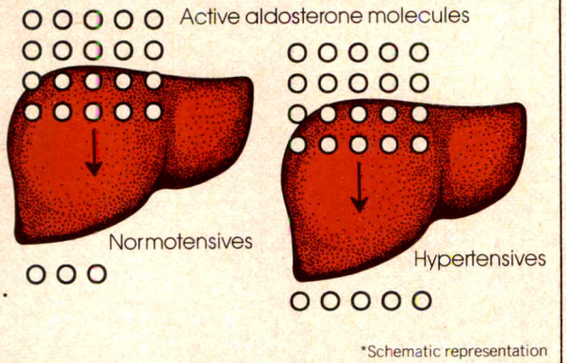
The liver metabolizes significantly less aldosterone in hypertensives than in normotensives.[1,2]

A significantly decreased hepatic MCR (metabolic clearance rate) of aldosterone, without significantly decreased SR (secretion rate), was demonstrated in approximately 90 percent of a group of 56 patients with benign essential hypertension.[1]

Thus "Failure of the aldosterone SR to fully adapt to the decrease in MCR may be responsible for a relative state of hyperaldosteronism in many patients with BEH [benign essential hypertension], even when the secretion and excretion rates are within normal range.

"It is conceivable that it is the mineralocorticoid [aldosterone] excess that is leading to an increase of sodium content in the arteriolar wall and the hypertensive process itself, in many patients with BEH."[2]

Metabolic clearance of aldosterone in hypertensives and in normotensives*



*Schematic representation

To help control the aldosterone factor in essential hypertension

Aldactazide®

(spironolactone 25 mg./hydrochlorothiazide 25 mg.)

- Spironolactone blocks the pressor effect of aldosterone at the arteriole,[3-5] and exerts natriuretic action in the distal renal tubule.
- Hydrochlorothiazide exerts additive antihypertensive effect through its action at a different renal site.
- Aldactazide helps maintain potassium balance—without the need for potassium supplements—because the potassium-sparing action of spironolactone offsets the potassium-losing effect of hydrochlorothiazide.

See following page for brief summary.

To help control the aldosterone factor in essential hypertension

Aldactazide®

(spironolactone 25 mg./hydrochlorothiazide 25 mg.)

Indications—Hypertension; edema or ascites of congestive heart failure, cirrhosis of the liver and the nephrotic syndrome; idiopathic edema. Some patients with malignant effusion may benefit from Aldactazide therapy.

Contraindications—Acute renal insufficiency, rapidly progressing impairment of the renal function. Anuria; sensitivity to thiazides or other sulfonamide-derived drugs. Probably contraindicated in acute or severe hepatic failure.

Warnings—Fixed-dose combination drugs are not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual patient. If the fixed combination represents the dosage so determined, its use may be more convenient in patient management. The treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

Potassium supplementation is recommended only in exceptional instances, but may be considered when a glucocorticoid is also given. Utilize normal dietary sources of potassium if possible when potassium supplementation is necessary. If enteric-coated potassium is used be alert to the possible development of hemorrhagic, stenotic, ulcerated or perforated small-bowel lesions; deaths have occurred. The possibility of exacerbation or activation of systemic lupus erythematosus by sulfonamide derivatives, including thiazides, has been reported.

Administer thiazides with caution to pregnant or lactating patients. Adverse reactions which may occur in the adult (hyperbilirubinemia, thrombocytopenia, altered carbohydrate metabolism, etc.) may possibly occur in the newborn, since thiazides cross the placental barrier and may also appear in breast milk.

Precautions—Consider the possibility of fluid and electrolyte imbalance. Serum and urine electrolyte determinations are particularly important in patients with excessive vomiting or in those receiving fluids parenterally. Medications such as digitalis may also influence serum electrolytes. Warning signs of possible fluid and electrolyte imbalance are: dryness of the mouth, thirst, weakness, lethargy, drowsiness, restlessness, muscle pains, cramps or fatigue, hypotension, oliguria, tachycardia, gastrointestinal symptoms. Hypokalemia may develop with brisk diuresis in severe cirrhosis or during the concomitant use of glucocorticoids or ACTH. Inadequate oral electrolyte intake contributes to hypokalemia. Hypokalemia may cause signs of digitalis intoxication with previously tolerated doses of digitalis.

Give Aldactazide cautiously to patients with severe liver disease since thiazides can precipitate hepatic coma; discontinue if mental confusion increases. Consider also other factors that may precipitate hepatic coma, including blood in the gastrointestinal tract or preexistent potassium depletion. Reversible elevation of NPN and BUN may occur in some patients receiving Aldactazide. The most common electrolyte disturbance is dilutional hyponatremia which requires appropriate corrective measures. A true low-salt syndrome is rare; discontinue Aldactazide and administer sodium for this condition.

Although rare, the most potentially serious electrolyte disturbance is hyperkalemia; if this occurs discontinue Aldactazide and restrict potassium intake. Rarely, fatality due to hyperkalemia has been reported. Hyperkalemia is more likely to occur in severely ill patients with relatively small urine output or in patients receiving supplemental potassium; determine serum electrolytes frequently in such patients. Consider the possibility of hyperuricemia or a decrease in tolerance to glucose.

Patients with severely resistant edema may have an increased diuretic response following the addition of a potent glucocorticoid, such as 15 to 20 mg. of prednisone daily, to Aldactazide therapy. Supplemental potassium will usually be necessary in such patients and the usual precautions with glucocorticoids are necessary. Use caution if regional or general anesthesia is necessary since Aldactazide reduces vascular responsiveness to norepinephrine in such patients. Thiazides may increase responsiveness to tubocurarine. The antihypertensive effects of hydrochlorothiazide may be enhanced in patients who have undergone sympathectomy.

Pathologic changes in the parathyroid glands, with hypercalcemia and hypophosphatemia, have been observed in a few patients on prolonged thiazide therapy.

Thiazides may increase serum PBI levels without signs of thyroid disturbance.

Adverse Reactions reported with *spironolactone* use: Drowsiness and lethargy, mental confusion, diarrhea and other gastrointestinal symptoms, mild androgenic manifestations (including hirsutism, menstrual irregularity, deepening of the voice), gynecomastia, inability to achieve or to maintain erection, headache, maculopapular or erythematous cutaneous eruptions, urticaria, drug fever, ataxia.

Adverse reactions reported with *thiazide* use: purpura, thrombocytopenia, leukopenia, agranulocytosis, gastrointestinal disorders (anorexia, nausea, vomiting, diarrhea, abdominal cramps), rash, pruritus, paresthesia, acute pancreatitis, jaundice, dizziness, vertigo, headache, xanthopsia, photosensitivity, urticaria, necrotizing angiitis, aplastic anemia, orthostatic hypotension, muscle spasm, weakness, restlessness. Reduce dosage or withdraw drug whenever adverse reactions are moderate or severe.

Dosage and Administration—Dosage should be determined by individual titration. *For essential hypertension* the daily *adult* dosage is two to four tablets in divided doses; continue treatment for two weeks or longer. Adjust the dosage according to the response of the patient. Reduce the dosage of other antihypertensive agents, particularly ganglionic blocking agents, by 50 percent since Aldactazide potentiates the action of such drugs. *For edema, ascites or effusion in adults* the average dosage is one tablet 4 times daily; dosage may range from 1 to 8 tablets daily in divided doses. The daily dosage of Aldactazide *in children* should provide 0.75 to 1.5 mg. of Aldactone® (spironolactone) per pound of body weight.

Computerized System for Noninvasive Techniques

I. Its Value for Systolic Time Intervals

SAMUEL ZONERAICH, MD, FACC
OLGA ZONERAICH, MD
JOHN RODENRYS, MS

Jamaica, Queens, and Stony Brook, New York

A total computerized system for the study of the noninvasive techniques and especially for external systolic time intervals is presented. Heart rate, left ventricular ejection time index (LVETI), Q–S_2 I (electromechanical index), preejection period (PEP), PEP/LVET ratio, isovolumic contraction time corrected for pulse transmission (ICTc), electromechanical interval (EMI), mechanical systole (S_1–S_2), DA/DT (quantitative apex cardiogram) and heart sounds were calculated from simultaneous recordings of electrocardiogram, carotid pulse and apex cardiogram by a multichannel, multifilter Cambridge MCIV phonocardiograph and by a CVA/94 unit MDS computer program.

A parallel study of these variables in 100 healthy persons by conventional manual calculations made from the Cambridge recordings and by the CVA/94 MDS computer system revealed identical results. The computerized system could more rapidly and accurately calculate many variables for systolic time intervals, thus offering the possibility for better evaluation of left ventricular function. Regression equations in relation to heart rate were found only for Q–S_2 = 520.4 − 1.79 heart rate; LVET = 417.5 − 1.59 heart rate; and S_1–S_2 = 435.7 − 1.58 heart rate. ICTc and EMI differences were negatively correlated at the $P = 0.001$ level. LVETI and Q–S_2 correlated positively at the $P = 0.01$ level. DA/DT reflecting quantitative apex cardiography could be calculated only by computer.

An extensive search for the potential usefulness of noninvasive methods in cardiology has been made in this laboratory[1–5] and others during the last few years. Data have been accumulated on the duration of various phases of cardiac systole by using simultaneous external polycardiographic techniques. The durations of these phases, when studied by noninvasive methods, were found to be altered in many abnormal cardiac states.

The use of systolic time intervals has been criticized because the regression equation in relation to heart rate varies widely in normal control subjects as studied by various groups and because there are problems of methodology and experimental design.[6] A review of normal values for systolic time intervals compiled from 14 original papers[7–20] indicates the wide range of these variables in normal subjects (Table I).

The purpose of this study was (1) to determine the usefulness of a rapid computer analysis for the measurement of systolic time intervals; (2) to eliminate human error in a parallel study by comparing the data obtained from conventional high fidelity equipment and manual measurements, with those obtained by a computerized system; (3) to calculate, through a computerized system, a large number of known variables, for a better and broader evaluation of left ventricular function; and (4) to compute new variables, not obtainable by conventional means.

Because of different characteristics of phonocardiographic machines, several groups established their own normal values. Other groups used formulas established by one or two investigators. EMI = electromechanical interval; HR = heart rate; ICT = isovolumic contraction time; LVET = left ventricular ejection time; NC = no correlation with heart rate; PEP = preejection period; PTT = pulse transmission time; Q–S_2 = electromechanical systole; S_1–S_2 = mechanical systole.

Material and Methods

One hundred ambulatory, nonhospitalized persons, ranging in age from 17 to 62 years (mean 36.6), with no history of heart disease were included in this study. The number of men and women was almost equal.

All subjects had a normal history, normal cardiovascular system on clinical examination, normal electrocardiogram, a systolic pressure of 140 mm Hg or less and a diastolic pressure of 90 or less. They were receiving no medication. The studies were performed at approximately the same time (early in the morning).

The subjects were placed in the left lateral decubitus. During held expiration a 10 second recording was made of simultaneous apex cardiogram, carotid pulse tracing, phonocardiogram and lead II electrocardiogram with a Cambridge multichannel MCIV recorder and immediately after with the Medical Data Systems (MDS) CVA/94 unit (Medical Data Systems, Inc., San Diego, Calif.) (Fig. 1). 1-665 Cambridge pulse transducers with a time constant of 3.5 seconds were used to record the apex cardiogram and carotid pulse (funnel shape pick-up). A Cambridge 2100-4 microphone was used to record the phonocardiogram. The paper speed was 100 mm/sec. A Cambridge 1-206, five lead cable was used to record lead II of the electrocardiogram.

The MDS system utilized a Hewlett-Packard 21050 to record the carotid pulse and a single direct contact microphone 21050 A to record the apex cardiogram and phonocardiogram. A Hewlett-Packard 14056-B, three lead electrocardiographic cable was used to record lead II. After verification of proper signal placement, using the oscilloscope monitor on the CVA/94 cart, a simultaneous 10 second recording was made on the CVA/94 strip chart and on the magnetic tape using a frequency modulation (FM) recording technique.

Intervals

The following variables were computed with the CVA/94 computer program and, conventionally, by MCIV Cambridge recording:

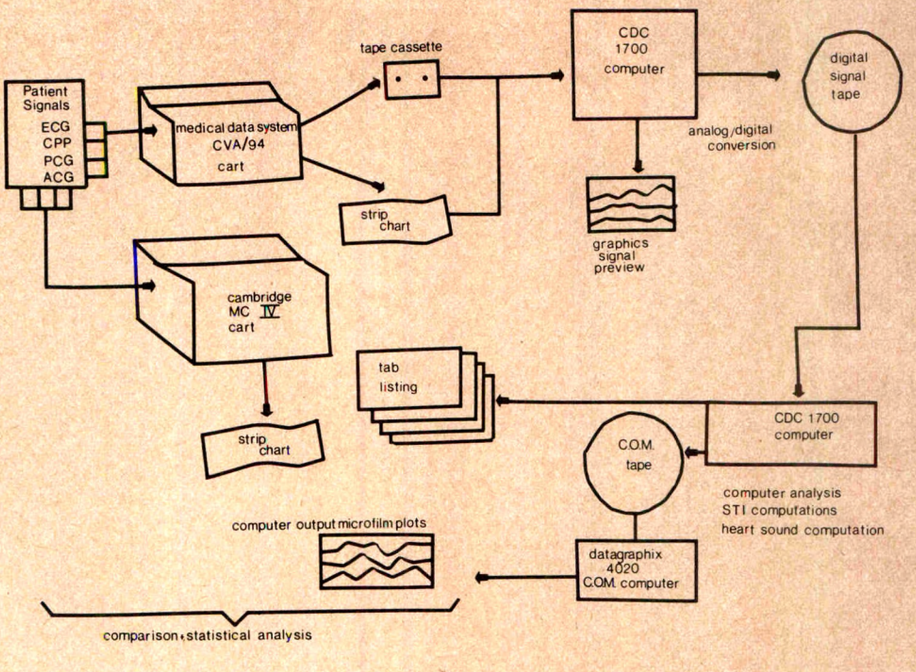

FIGURE 1. Schematic drawing of flow of patient signals during study using recordings and data processing performed by the Cambridge recorder and conventional calculation and by the CVA/94 unit MDS computer system. ACG = apex cardiogram, CPP = carotid pulse; ECG = electrocardiogram; PCG = phonocardiogram.

Heart rate: R–R interval (beats/min).

Left ventricular ejection time index (LVETI): carotid upstroke to trough of carotid incisura, corrected for heart rate.

Electromechanical systole index (Q–S_2 I): Q wave of the electrocardiogram to the aortic component of the second heart sound, corrected for heart rate.

Preejection period (PEP): Q wave to leg of upstroke of the carotid pulse, corrected for pulse transmission time.

Electromechanical interval (EMI): Q wave to upstroke of apex cardiogram.

Isovolumic contraction time, corrected for pulse transmission time (ICTc): (a) leg of upstroke of apex cardiogram to leg of upstroke of carotid pulse, corrected for pulse transmission time; (b) (leg of apex cardiogram to second heart sound) minus left ventricular ejection time.

PEP/LVET: ratio of preejection period to left ventricular ejection time.

Quantitative apex cardiogram (DA/DT) (calculated only by computer): ratio of the relative excursion of the apex cardiogram from leg of upstroke to the point of maximal slope (rate of change of apex cardiogram) divided by the interval between the Q wave of the electrocardiogram and the time of maximal slope.

Manual Analysis

Manual calculations of the systolic time intervals obtained with the Cambridge MCIV recording were read to the nearest 5 msec for 10 consecutive cycles. The rate-dependent raw values were corrected for heart rate and then averaged to obtain a representative value. Raw values that were not rate-dependent were directly averaged to obtain a representative value.

Computer Processing

The recordings made on the magnetic tape were processed by computer in two stages: (1) analog to digital conversion, and (2) CVA/94 computer program analysis.

The analog to digital conversion was performed on a CDC 1700 computer. The analog tape cassettes were played back into the CDC 1700 computer through an analog tape recorder and the signals digitized at the rate of 1,000 times/sec for 10 seconds. After analog to digital conversion, an interactive graphics monitor was used to display the digital signals. A check was made at this time for artifactual or missing signals. After verification of satisfactory signals, the patient's signals were written on digital magnetic tape.

The CVA/94 computer program analysis was performed on a CDC 1700 computer using the digital magnetic tape that was previously written. During the processing, 10 consecutive cardiac cycles were analyzed. The computer performed two basic functions; detection of heart sounds and computation of systolic time intervals. During the computer analysis, all rate-dependent intervals were converted into their respective indexes. At the completion of processing, a 45 line printer and a computer output microfilm (C.O.M.) tape were generated. In addition, 700 items of information on each patient were printed on the line printer for the basic reference file.

The C.O.M. tape was taken to a Datagraphic X4020 C.O.M. computer which produced graphs of the original signals of the patients (Fig. 2 and 3) with computer-generated annotations. These plots are for physician review of configuration and computer accuracy. The graphs are stored on microfilm and 11 by 11 bond paper. Normal values for the interval are printed by the computer for comparison.

The computer program also provides data on the time of occurrence of the following heart sounds: systolic clicks, aortic component of the second heart sound (A_2), opening snap, third (S_3) and fourth (S_4) heart sounds and the mitral component of the first heart sound (S_1).

Comparison and Statistical Analysis

During the statistical comparison, the data from the Cambridge tracings and the Medical Data Systems computer program were assumed to be from two different populations. A Student t test for the differences between the means of two variables was performed. A correlation study,

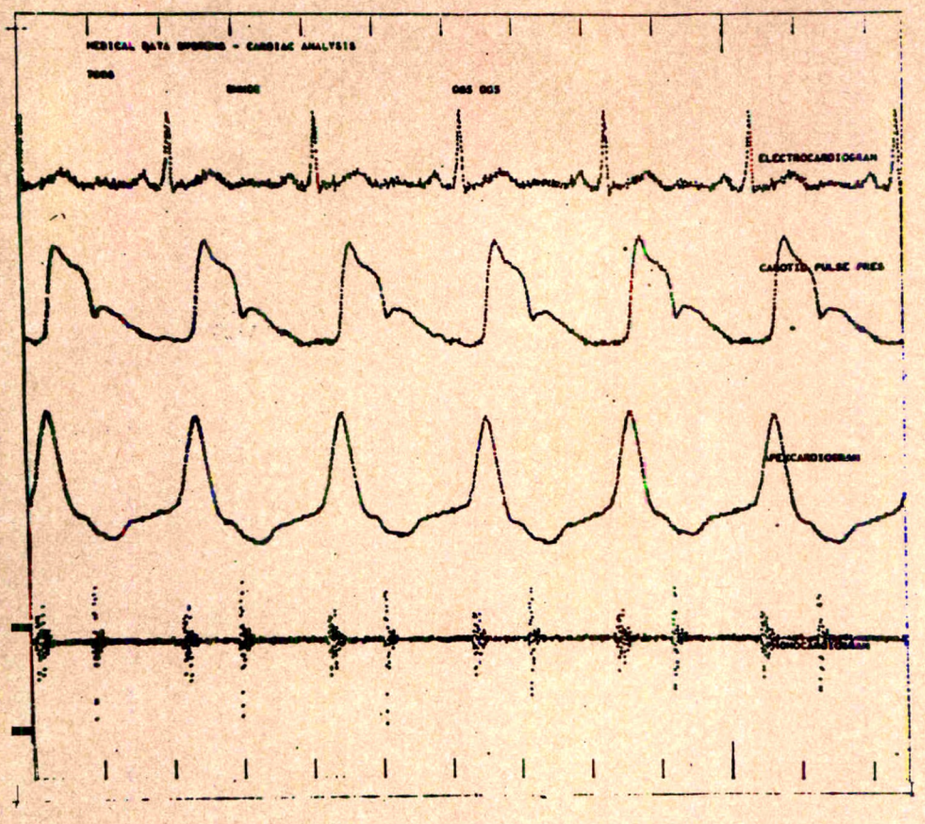

FIGURE 2. Computer graphs of the original patient signals. **From top to bottom:** electrocardiogram, carotid pulse tracing, apex cardiogram and phonocardiogram. Numbers at top identify patient's code number, hospital code number and tape file index.

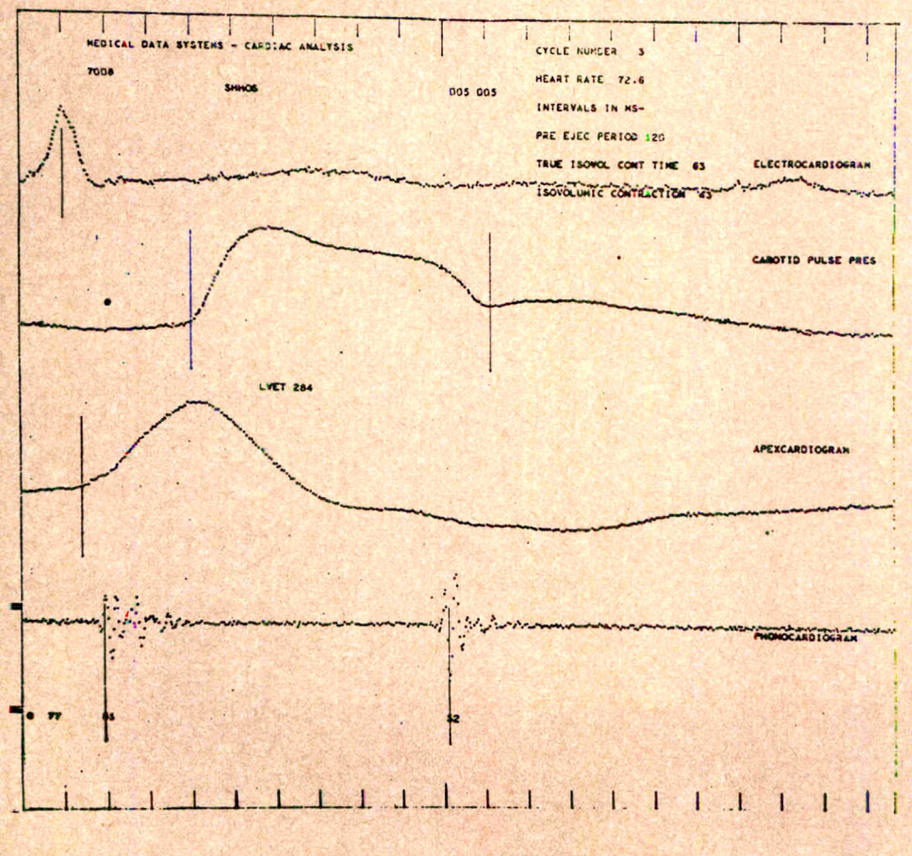

FIGURE 3. Computer analysis of one cardiac cycle. The figures are registered on the chart. **From top to bottom:** electrocardiogram, carotid pulse tracing, apex cardiogram and phonocardiogram. The patient's code number, hospital code number, tape file index and both the first and second heart sounds are indicated. Values are shown for cycle number, heart rate, preejection period, true isovolumic contraction time, isovolumic contraction time and left ventricular ejection time (LVET).

using the null hypothesis, was also performed to determine the relation between the differences of the variables.

Results

As shown in Table II, none of the differences between the manual and the computer results were significant (6 values were at the $P = 0.50$ level and 1 was at the $P = 0.30$ level), indicating that the computer system was almost duplicating the results obtained by manual, conventional calculation of the Cambridge recorded signals.

The results indicate only two significant relations among the differences. Differences for isovolumic contraction time, corrected for pulse transmission time (ICTc), correlated negatively with each other at the $P = 0.001$ level. This is an expected finding, since a prolonged ICTc interval will shorten the electromechanical interval and vice versa. Left ventricular ejection time index and Q–S_2 were positively correlated at the $P = 0.01$ level. This correlation probably results from a subjective bias of selecting the component of the second sound that is closest to the incisura in reading the charts manually.

There was no relation between preejection period and heart rate. Therefore no linear regression formula was calculated for the former variable.

ICTc was calculated for comparison by two methods: (1) from leg of the upstroke of the apex cardiogram to leg of the upstroke of the carotid pulse corrected for pulse transmission time, and (2) (leg of the apex cardiogram to S_2) minus left ventricular ejection time. The results indicated that the first method showed less scatter and a lower standard deviation. Thereafter, the first method was used routinely.

Discussion

Our study clearly demonstrates that many of the disadvantages of using systolic time intervals could be avoided by using better techniques of recording and calculating these intervals. Our approach for recording multiple variables is based on theoretical and practical considerations indicating that no single measure has proved to be of unchallenged superiority in evaluating left ventricular function and that the interpretation of results obtained by any method must be qualified by recognition of the limitations of the technique.

It is important to realize that the early vibrations of the first heart sound[21,22] are occasionally difficult to identify for calculation of isovolumic contraction time, that the latter may increase the value of preejection period as a measure of left ventricular performance and, finally, that newer variables such as electromechanical interval and DA/DT may reflect significant events in the cardiac cycle.

Use of the apex cardiogram for the calculation of isovolumic contraction time diminishes the wide variability encountered in the normal population when measurements for this variable are based on the identification of a high vibration in the first heart sound. Recording of the apex cardiogram requires minimal experience. Poor or unobtainable tracings due to obesity, chronic lung disease or other causes occur in less than 10 percent of recordings in our experience. Minimal arterial distortion resulting from filtering and information gain are occasionally encountered in obese subjects when the arterial pulse is recorded.[23]

Our data indicate that the preejection period could not be corrected for heart rate, since heart rate has a

TABLE II

Comparison of Manual Results with Results Obtained with Computer System (msec)

Variable*	Regression Equation	Manual Results	Computer Results	Difference	*t* Value	Probability
QS_2I	520.4 − 1.79(HR) (no. = 93; $r = -0.68$)	520.0 ± 20.8	518.7 ± 16.6	±1.3	0.43	$P > 0.50$

PEP/LVET	Not significant (no. = 93; $r = -0.16$)	0.291 ± .064	0.287 ± 0.55	+0.004	0.42	$P > 0.50$
DA/DT	Not significant (no. = 93; $r = -0.09$)	.....	26.1 ± 13.1	...	...	...

*Mean pulse transmission time was 28.5 msec.

DA/DT = quantitative apex cardiogram; EMI = electromechanical interval; ICTc = isovolumic contraction time corrected for pulse transmission; LVETI = left ventricular ejection time index; PEP = preejection period; PEP/LVET = ratio of preejection Period to left ventricular ejection time; QS_2I = electromechanical systole index; S_1–S_2 = mechanical systole.

minimal effect on its duration.[24] The same is true for isovolumic contraction time. The linear regression equation for left ventricular ejection time obtained by us is similar to that found by Weissler et al.[7]

Isovolumic contraction time calculated from the leg of the upstroke of the apex cardiogram to the leg of the carotid upstroke is easily identifiable from simultaneous recordings of the apex cardiogram and carotid pulse. The beginning of the ejection period could not be calculated from the apex cardiogram alone by conventional methods of calculation, since it is difficult to identify the beginning of the ejection period that occurs before the E point of the apex cardiogram.[8] Instead, the real beginning of the ejection period calculated from the upstroke of the apex cardiogram alone was obtained only by computer.

DA/DT identified a fraction of the preejection period, corresponding to the upstroke of the first derivative of the apex cardiogram and considered to be similar to the first derivative of the left ventricular pressure.[25] The magnitude of the first derivative of the apex cardiogram has been considered to be proportional to the velocity of motion of the left ventricular wall and related to the functional status of the myocardium.[26]

The interval between the onset of ventricular depolarization and the preejection peak of the first derivative of left ventricular pressure, suggested by Mason et al.[27] as an index of left ventricular function, has been correlated by Vetter et al.[28] with the interval between the onset of ventricular depolarization and the preejection peak of the first derivative of the apex cardiogram. Statistically significant correlations were obtained with ejection fraction, left ventricular end-diastolic pressure and left ventricular end-diastolic volume. The data obtained by this group support the use of quantitative apex cardiography for screening of serial clinical studies of left ventricular function.

Advantages of Computerized System

Computing systems have been used for noninvasive techniques in the past by Freis and Kyle,[29] who recorded the carotid and brachial pulses on magnetic tape, plotted the curves with a computer and then manually identified the time intervals. Eddleman[30] analyzed the precordial pulsations by normalized plots of kinetocardiograms. Golde and Burstin[31] manually calculated systolic time intervals in normal children, stored the obtained data on magnetic tape and used an IBM 360-50 computer for statistical analysis. Our computerized system for the first time eliminates any manual identification for calculations of variables of systolic time intervals.

The advantages of fast and accurate calculations are evident. Evaluation of left ventricular performance, which requires the use of many variables and is difficult to measure manually, can easily be calculated by the computing system. DA/DT as an expression of quantitative apex cardiography, for evaluation of left ventricular function, could be identified by the computer from the apex cardiogram alone.

Graphic computer output at a ratio of more than 1,000 msec permits analysis of individual heart sound components and timing relations. Printed computer output provides computation for up to 10 cardiac cycles and performs automatic correction for rate-dependent variables.

Reliable data obtained by conventional high fidelity phonocardiographic equipment are almost identical to those obtained by the computing system (Table II) and confirms the validity of ratios and variables conventionally obtained by external measurements of systolic time intervals. The hemodynamic factors involved in determining the systolic time intervals are now better recognized. Simultaneous measurements of intracardiac dynamics have demonstrated close parallelism between direct and indirect measurements[32] of systolic time intervals. Externally recorded systolic time intervals are used on a large scale for the evaluation of left ventricular performance in man in acute and chronic cardiovascular disease.

The use of the computerized system offers several distinct advantages over the present conventional recording system. By following precisely defined algorithms and computing first derivatives, the computer eliminates subjective variability in the identification of events in the cardiac cycle. This is particularly important in the identification of muffled heart sounds and slurred pulse wave upstrokes. The significant increase in accuracy (1 msec compared to 5 msec with conventional recordings) obtainable with the computer system should reduce the present variances and overlapping results obtained from the calculation of systolic time intervals calculated by different observers.

Individual position assessment of the morphologic aspects of the tracing is facilitated by the high graphic output speed used in the display of the tracings and by the printed computation covering 10 heart cycles. The greatest potential advantage of the computerized system lies in its ability to calculate quickly more sophisticated variables related to contractility from externally measured tracings. The use of these variables, difficult to measure manually, could lead to a better evaluation of left ventricular performance.

Quantification of Serum Creatine Phosphokinase Isoenzyme Activity

ROBERT ROBERTS, MD
PHILIP D. HENRY, MD
SAKE A. G. J. WITTEEVEEN, MD
BURTON E. SOBEL, MD, FACC

La Jolla, California
St. Louis, Missouri

Three serum creatine phosphokinase (CPK) isoenzymes (MM, MB and BB) have been recognized. Myocardium is richly endowed with MB CPK. Accordingly, increased serum MB CPK activity reflects myocardial injury. Although recent advances have facilitated detection of activity of CPK isoenzymes, available techniques have unavoidable quantitative limitations. Accordingly, we used a new procedure to quantify CPK isoenzymes in serum samples with normal or increased total CPK activity. Samples were diluted or concentrated so that total CPK activity was 0.100 to 1.200 IU/ml and then subjected to electrophoresis on cellulose acetate. Regions of the strips encompassing each isoenzyme were cut out, immersed in 0.5 to 3 ml of assay medium in which the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH) was generated as a function of isoenzyme activity. NADPH was detected by serial determinations of fluorescence in the medium. The assay was linear with respect to time and isoenzyme activity (0.010 to 1.2 IU/ml, no. = 100) and recovery averaged 83 ± 1.8 percent (standard deviation). Reproducibility was within 2 percent. Accuracy of the method was validated with selected mixtures of BB and MM isoenzymes. Serum MB CPK activity averaged only 0.002 ± 0.001 IU/ml in normal persons (no. = 27), compared to 0.064 ± 0.043 IU/ml in 30 patients with myocardial infarction. Serum MB CPK activity was not increased in 23 patients after intramuscular injections or abdominal surgery. The procedure described permits quantitative determination of activity of individual CPK isoenzymes in serum samples with or without increased total CPK activity and thus is of potential value in the quantitative assessment of myocardial infarction by serum enzyme analysis.

Serum creatine phosphokinase (CPK) determinations are becoming increasingly important in the diagnosis[1] and quantification[2–4] of acute myocardial infarction. Three serum CPK isoenzymes, each a dimer (MM, MB, and BB), have been recognized. Extracts of human myocardium contain both MB and MM in contrast to extracts of skeletal muscle, which contain primarily MM. Thus, ischemic myocardial injury is reflected by increased serum MB activity.[5–7] Recent improvements in procedures for assay of CPK isoenzyme activity involve separation of isoenzymes by electrophoresis and scanning of the electrophoretic medium to detect fluorescence of the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH).[5,8] However, quantitative results obtained with all methods dependent upon scanning tend to be inaccurate for several reasons[9,10]: (1) Isoenzymes may be distributed asymmetrically in the electrophoretic supporting medium so that selection of the position used for scanning may influence results. (2) Activity of individual isoenzymes may be underestimated because of limited diffusion of substrate into the supporting medium or loss of NADPH or dye from the medium. (3) Apparent activity of specific isoenzymes may deviate from linearity with respect to time or

actual activity because of disparate activities of one or more isoenzymes in a mixture. Accordingly, we developed and evaluated a procedure for quantitative analysis of CPK isoenzymes designed to eliminate these difficulties and used it to measure activity of CPK isoenzymes in serum from hospitalized subjects with and without acute myocardial infarction.

Methods

Blood samples were collected in 0.010 molar neutralized EGTA, and serum was separated by centrifugation. Supernatant fractions of 16,000 g were prepared from human papillary muscles obtained freshly during the course of mitral valve replacement, and from brain obtained at autopsy.[3] Total CPK activity was measured spectrophotometrically after samples were diluted with 0.01 molar Tris, pH 7.4 containing 0.2 percent bovine serum albumin (Tris-BSA), so that CPK activity was approximately 0.1 IU/ml and thus within the limits of linearity of the assay.[11] CPK isoenzymes were separated by cellulose acetate electrophoresis.[7,12] Samples were diluted with Tris-BSA or concentrated with Aquaside II (Calbiochem) to produce total CPK activity values of 0.100 to 1.200 IU/ml. Control experiments were performed by omitting creatine phosphate as substrate.

In preliminary experiments (see Results) we found that detection of electrophoretically separated isoenzymes by fluorescence scanning[5,8] was inadequate for quantification. *Accordingly, the following approach was employed:*

1. CPK isoenzymes were separated by cellulose acetate electrophoresis.

2. After electrophoresis, sections of the cellulose acetate strips containing each isoenzyme were cut out, immersed in 0.5 to 3 ml of the CPK assay medium in a disposable cuvette, and incubated at 25° C with constant shaking. Incubation time and volume were chosen to provide linear reaction rates and sufficient fluorescence from NADPH generated by isoenzymes on each selected portion of the strip. Analysis of 100 samples each of sections containing the three isoenzymes indicated that the enzymes were contained within the following regions: MM, 4 mm cathodal to 12 mm anodal; MB, 12 mm anodal to 37 mm anodal; BB, 37 mm anodal to 47 mm anodal.

3. NADPH generated was detected by serial measurement of fluorescence in the aqueous medium in which the selected portions of the cellulose acetate strips were being incubated.

To determine whether NADPH was eluted quantitatively under these conditions we applied 10 μl aliquots of samples containing known quantities of NADPH to moist cellulose acetate membranes, allowed the samples to dry for 15 minutes, eluted the NADPH from the strips under the same conditions as those used in the isoenzyme assay procedure and determined fluorescence in the aqueous medium with use of spectrophotometry.

To determine whether the isoenzyme assay was linear with respect to time and enzyme activity, aliquots of rabbit skeletal muscle CPK were applied to cellulose acetate strips but not separated by electrophoresis. Selected regions of the strip were cut out and incubated in CPK reaction medium. Fluorescence in the aqueous medium was determined serially with an Aminco-Bowman fluorometer while the cellulose acetate strip was removed transiently from the solution.

To assess recovery of isoenzyme activity from cellulose acetate strips, fluorescence detected with aliquots added to the medium itself was compared with fluorescence detected when corresponding aliquots were assayed in cellulose acetate strips immersed in incubation medium.

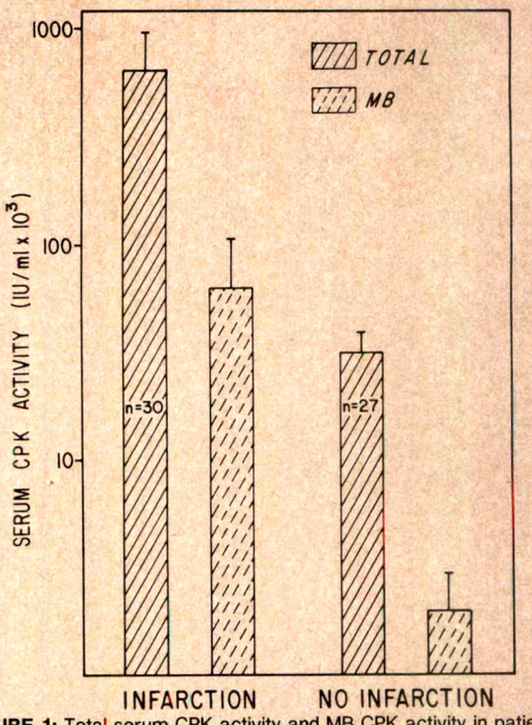

FIGURE 1: Total serum CPK activity and MB CPK activity in patients with myocardial infarction and in hospitalized patients without infarction. CPK activity and MB CPK activity were assayed in samples obtained from patients with myocardial infarction and selected on the basis of peak CPK activity for each patient. Results expressed represent means plus 1 standard deviation indicated by the vertical bars. Serum MB CPK activity in patients with infarction averaged 0.064 IU/ml, compared with 0.002 IU/ml in samples from hospitalized patients without infarction.

To determine whether electrophoresis altered recovery of CPK activity, aliquots of rabbit skeletal muscle CPK were subjected to electrophoresis before fluorometric assay of CPK activity in appropriate regions of the cellulose acetate membrane. Percent recovery was calculated by comparison with activity observed when corresponding aliquots were assayed in solution. Recovery of MM and MB isoenzymes in serum samples was determined in the original sample and in serial dilutions.

Reliability of the assay was examined with human myocardial supernatant fractions containing MM and MB CPK. Activities of each were determined 10 times from aliquots of the initial sample and 10 times each from aliquots of the sample diluted to contain 0.2 and 0.1 IU/ml.

Accuracy of the method was assessed with solutions formulated with selected quantities of BB and MM isoenzymes.

Case material: Isoenzymes were assayed quantitatively in serum samples containing MM and MB isoenzymes and increased total CPK activity from 30 patients with acute myocardial infarction, 27 patients without infarction and normal total CPK activity, 23 patients with elevated total CPK activity after intramuscular injections (16 patients) and abdominal surgery (7 patients). Isoenzymes were assayed also in 16 skeletal muscle extracts obtained at operation or at autopsy.

TABLE I

Total CPK and CPK Isoenzyme Activity in Serum Samples and Skeletal Muscle Extracts (means ± 1 standard deviation)

Category and no.	Total CPK	MM CPK	MB CPK
	A. Serum Samples (IU/ml)*		
Hospitalized control subjects (27)	0.036 ± 0.013	0.033 ± 0.012	0.002 ± 0.001
Patients with acute myocardial infarction (30)	0.860 ± 0.120	0.797 ± 0.112	0.063 ± 0.043
Patients receiving intramuscular injections (deltoid)			
Diazepam (5)	0.454 ± 0.051	0.451 ± 0.052	0.003 ± 0.001
Morphine sulfate (7)	0.347 ± 0.089	0.345 ± 0.089	0.003 ± 0.002
Ampicillin (4)	0.595 ± 0.121	0.593 ± 0.121	0.002 ± 0.001
Patients undergoing abdominal surgery (7)	1.024 ± 0.232	1.022 ± 0.232	0.003 ± 0.002
	B. Skeletal Muscle Extracts (IU/g)†		
Obtained at autopsy (10)	2.630 ± 0.260	2.630 ± 0.260	0
Obtained at operation (6)	1.430 ± 0.080	1.430 ± 0.000	0

* Serum samples analyzed were those exhibiting peak total CPK in patients who had serial samples obtained at 3 hour intervals.

† Extracts of skeletal muscle were prepared as 1:25 homogenates in 0.25 M sucrose, 1 mM EGTA and 10 mM potassium phosphate buffer, pH 7.4. Total CPK and CPK isoenzymes were assayed in 16,000 g supernatant fractions. Tissue samples were obtained from the rectus abdominis muscle in patients undergoing abdominal surgery and from the deltoid, pectoralis major and psoas muscles in patients who had died 4 to 6 hours before the study.

In studies designed to determine the effects of storage media on preservation of isoenzyme activity, papillary muscle extracts were diluted with human serum, divided into aliquots and protected with 0.005 mercaptoethanol, neutralized 0.010 molar sodium ethyleneglycol tetraacetic acid (EGTA) or 2.5 molar sucrose or a combination of the three. Samples were frozen on dry ice and ethanol, stored at −20° C and assayed serially after fast thawing.

Results

MB and MM activity in serum samples: MM and MB activities in serum samples with peak total CPK activity from 30 patients with acute myocardial infarction and in serum samples from 27 patients without increased total serum CPK are shown in Figure 1. Both total CPK and MB CPK activity were increased in samples from patients with acute myocardial infarction. Furthermore, the average absolute activity of MB CPK was more than 20 times greater in samples from patients with infarction. Increased MB CPK activity after infarction has been identified in previous studies.[5,6,8,9] However, the sensitivity of the present method permits detection of some MB CPK in serum from patients without acute myocardial infarction who have normal total serum CPK activity.

Total serum CPK activity may increase after intramuscular injections or surgery, presumably because of release of CPK from skeletal muscle, and frequently the diagnosis of acute myocardial infarction must be considered in patients in this setting. Accordingly, we assayed CPK isoenzymes in samples with increased total CPK activity from hospitalized patients without myocardial infarction who had received intramuscular injections of diazepam, morphine sulfate or ampicillin. Total CPK, MB CPK and MM CPK activity in these samples are tabulated in Table I and compared with results in samples from patients who had recently had abdominal surgery or myocardial infarction. MB CPK activity was not appreciably increased in samples from patients after intramuscular injections or surgery even when total serum CPK values were as high as those in patients with acute myocardial infarction.

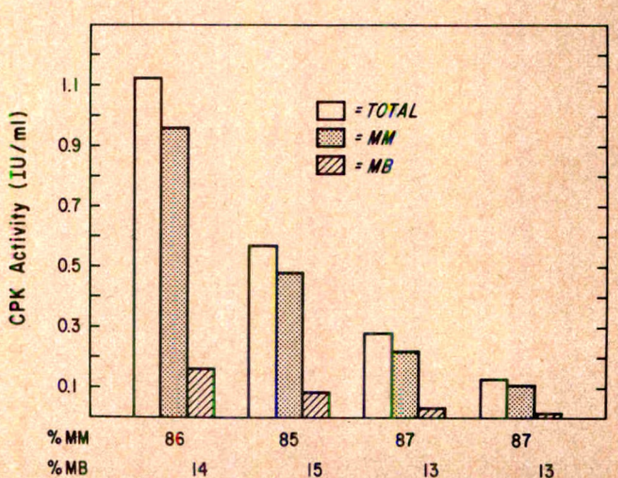

FIGURE 2. Activity of total serum CPK, MM CPK and MB CPK in aliquots from serial dilutions of the same initial serum sample. The proportion of MM and MB isoenzymes remained constant in aliquots from serial dilutions of the initial sample with total CPK activity levels ranging from 1.120 to 0.120 IU/ml. Results are averages of duplicate determinations with each dilution.

Both total CPK and activity of each isoenzyme (BB, MM, and MB) remained constant for at least 2 weeks when samples were stored with EGTA, mercaptoethanol or sucrose as described under Methods.

Evaluation of the quantitative method: Recovery of NADPH from cellulose acetate membranes ranged from 97.5 to 99.5 percent (no. = 10). Fluorescence increased linearly with time for at least 5 minutes in each case when CPK in rabbit skeletal muscle samples (0.010 to 1.2 IU/ml) was assayed after electrophoresis (no. = 100).

Average recovery was 97 ± 2.5 percent (standard deviation) (no. = 100) when rabbit skeletal muscle samples were applied to cellulose acetate but not separated by electrophoresis. After electrophoresis recovery was virtually constant, averaging 83 ± 1.8 percent (no. = 100). Determinations of MM activity after electrophoresis varied by ±3 percent (no. = 100 samples with activity of 0.010 to 1.2 IU/ml). Results with serial dilutions of serum samples containing more than one isoenzyme (Fig. 2) indicated consistent proportions of MB and MM CPK in aliquots with total CPK activity values ranging from 1.120 to 0.120 IU/ml.

When each of three papillary muscle extracts (MB CPK activity = 0.018, 0.037 and 0.256 IU/ml) was assayed 10 times, apparent activity of each isoenzyme varied by only ±1.5 percent (range). When selected mixtures of BB from human brain and MM CPK from rabbit skeletal muscle were assayed, the observed and expected values for each isoenzyme agreed within ±3 percent (three mixtures with respective total CPK activity levels of 0.2, 0.5 and 1.0 IU/ml).

Difficulties encountered with conventional scanning procedures: Although fluorescence scanning is a sensitive technique,[8,13] in our hands it had serious quantitative limitations. For example, when the fluorometer was used to scan five different positions on the same strip, the apparent MB CPK isoenzyme activity ranged from 12 to 38 mIU/ml. When aliquots of the same sample were applied to 10 different strips and each strip was subsequently scanned, the apparent activity of MB CPK in the sample ranged from 11 to 39 mIU/ml. When selected mixtures of BB and MM CPK were applied to eight different strips and fluorometric scanning was performed, the apparent ratio of BB to MM activity differed from that expected by 20 to 80 percent (no. = 8) despite vigorous efforts to apply the samples uniformly. In preliminary experiments (data not shown) in which electrophoresis was performed on agarose[5,8] rather than on cellulose acetate, we encountered similar difficulties. Thus, despite the sensitivity exhibited by fluorescence scanning, we found quantitative limitations that were minimized or avoided by the procedure used in this study.

Discussion

Increased total serum CPK activity is a hallmark of acute myocardial infarction. However, total CPK activity increases after intramuscular injections, trauma and in association with many disorders. Release of CPK from organs other than the heart could influence estimation of infarct size based on serum CPK analysis. Thus, quantification of serum CPK isoenzymes is of particular importance in delineating the source of CPK in serum.

Although fluorescence scanning has been useful for detecting CPK isoenzymes,[8] several factors may limit its value as a quantitative tool including (1) asymmetric distribution of isoenzymes along the axis of scanning,[9,10,13–15] (2) loss of NADPH from the electrophoretic medium,[16] (3) limitation of penetration of substrate into the supporting medium,[9,16] and (4) deviation of the reaction from linearity with respect to one or more isoenzymes in a mixture because of disparate activities of each.[9,16]

Advantages of method: The method described was designed to avoid these difficulties and to facilitate accurate quantitative determinations of the activity of each individual isoenzyme in samples containing a mixture. Since isoenzymes are assayed separately, reaction conditions can be adjusted to achieve linearity with respect to time and activity of each isoenzyme. All NADPH generated contributes to fluorescence since it is eluted into the aqueous reaction medium. Availability of substrate to each isoenzyme in the supporting medium is faciliated by constant shaking and immersion of the supporting medium into the reaction solution. The problem of nonuniform distribution of the sample is eliminated since the entire region of the supporting medium encompassing each isoenzyme is utilized. Reactions are performed kinetically. The method detects individual isoenzymes with an activity level of less than 0.002 IU/ml, and hence is capable of quantifying isoenzymes even when total serum CPK activity is not increased. Results appear to be reproducible.

Clinical application: The precision, accuracy and sensitivity of this method make it a potentially useful adjunct in delineating the source of CPK contributing to total serum CPK activity in patients and in quantifying myocardial injury by analysis of serial changes in activity of serum enzymes.[4] The technique should prove particularly useful in detecting and quantifying myocardial injury in patients with concomitant injury to skeletal muscle, such as those undergoing coronary bypass grafting and other surgical procedures.
